Methods: An assay was established to analyze the role of genes of interest in *Drosophila* nephrocytes. In the experimental strain, the secreted protein Atrial Natriuretic Protein (ANP)-GFP-GFP was ectopically expressed by the *ubiquitin* promoter (*ubi::ANP-GFP-GFP*). This line also contained a *sns-Gal4* transgene. Nephrocytes filter and then take up proteins of defined size, here ANP-GFP-GFP. This allows testing the impact of genes of interest on nephrocyte filter function by crossing in respective *UAS-dsRNA* strains. Standard immunofluorescence and co-immunoprecipitation assays were employed to establish a novel protein interaction.

Results: Immunohistochemistry indicates that Nephrin and the Rap GEF C3G co-localized in human podocytes. The interaction of the two proteins was confirmed by co-immunoprecipitating Nephrin and C3G in HEK cell lysates. To test the functional relevance of these proteins we used the *Drosophila* system where cell type specific gene silencing experiments can be performed. Nephrocyte specific knockdown of the Nephrin orthologue *sns* as well as *C3G* compromised filtration and protein uptake as shown by defective ANP-GFP-GFP uptake. We demonstrated that the C3G effector Rap1 was necessary for *Drosophila* nephrocyte function.

Discussion and conclusion: *Drosophila melanogaster* is a powerful model system to study nephrocyte function and Nephrin signaling. C3G interacts with Nephrin and is required for nephrocyte function.

D1050B Piragua, a ZAD and zinc finger transcription factor, genetically interacts with the membrane protein Flower in the embryo. *Juan Riesgo-Escovar*. Instituto de Neurobiologia, UNAM, Queretaro, Queretaro, MX.

The *piragua* (*prg*) locus encodes a protein with an amino terminal ZAD (zinc associated domain) and nine C2H2 zinc fingers. It is expressed throughout the life cycle, and is required for embryogenesis and early larval life. A fraction of mutant embryos die during embryogenesis, either with an early phenotype (no cuticle formed), or at the end of embryogenesis with defective cuticles (dorsal closure and head involution defects). Surviving embryos die as first instar larvae. I also found that *flower*, that codes for a membrane protein, is required for embryogenesis. Two mutants *flower* alleles examined display late embryonic developmental cuticular phenotypes, of which most are head involution defects. Surviving embryos die as first instar larvae, as do surviving *piragua* embryos. In a published gain-of-function screen in wing imaginal discs, both genes were isolated by virtue of expression in dying, outcompeted cells, and for both being required for cell death in these cells (Rhiner, et al, 2010). We wondered whether the two loci might genetically interact in the embryo. Genetic experiments show that indeed the two loci interact, as homozygous mutants for one allele while heterozygous for the other show a significant augmentation of embryonic phenotypes. In contrast, mutant eye phenotypes for *piragua* are at variance from those of mutant *flower* alleles. *piragua* mutant eye clones show extensive cellular disarray, picnotic figures, lack of eye bristles, and aberrant cone morphology. This compares to a much less dramatic phenotype of lack of supernumerary cell culling at the eye borders during eye formation, a process that requires *flower* (Merino, et al 2013). This implies that *piragua* and *flower* might have both common and distinct functions.

D1051C Identification and characterization of Sugar-free frosting/SAD kinase substrates that regulate neural glycosylation in the *Drosophila* embryo. *Sarah Baas Robinson*, Varshika Kotu, Peng Zhao, Debora Witkoski, Lance Wells, Michael Tiemeyer. University of Georgia, Athens, GA.

Spatio-temporal regulation of protein glycosylation is critical for normal development and is altered in various human pathologies. However, the signaling pathways that confer tissue and cell specific glycan expression patterns are largely unknown. We previously characterized a *Drosophila* mutation which we named *sugar-free frosting* (*sff*), that impacts the expression of a subset of N-linked glycans known as HRP-epitopes in the embryonic nervous system. The gene affected in the *sff* mutant is the *Drosophila* homologue of the *C.elegans* and mammalian SAD kinases. In *Drosophila*, we demonstrated that the *sff* mutation affects glycan processing through reorganization of Golgi compartments. However, the downstream effectors through which Sff kinase acts to bring about these changes are currently unknown. To identify the molecular targets of Sff kinase, we undertook differential phosphoproteomic analysis of wildtype and *sff* mutant embryos collected at the developmental stages at which HRP epitopes first appear. Using immunohistochemistry, genetic analysis, and confocal microscopy, Bifocal (Bif), Rasputin (Rin), and Liprin-alpha (Lip-α) were identified as downstream effectors of Sff signaling in the regulation of glycan processing. In combination with *bif* or *liprin-α* mutations, *sff* double mutants exhibit altered overlap between the trans-Golgi network and cis-Golgi compartment. We also detected Rasputin co-localization with Golgi compartmental markers and this association was altered in *sff* mutant embryos. Taken together, Bif as a putative cytoskeletal regulator, Lip- α as a coiled coil protein, and Rin as the ortholog of RasGAP SH3 binding protein, highlight downstream pathways through which Sff kinase activity fine tunes protein glycosylation in response to external stimuli.

D1052A The UPR Pathway Activates the TOR Signaling through Atf6. *J. Seo*, D. Allen, S. Petty. Rogers State University, Claremore, OK.

Multiple cellular signaling pathways are interconnected to maintain homeostasis in a cell. The target of rapamycin (TOR) signaling pathway is an essential regulator of cell growth and survival; the unfolded protein response (UPR) pathway is a central mechanism to counteract endoplasmic reticulum (ER) stress instigated by the accumulation of misfolded proteins in ER. Although the two pathways regulate similar cellular processes, they have been until recently studied independently. Here, we show that the UPR pathway activates the TOR signaling pathway through activating transcription factor 6 (Atf6).

Atf6 is a transmembrane protein resides in the ER membrane. Upon ER stress, cytoplasmic domain of Atf6 is processed, is translocated to the nucleus, and activates its target genes to abate the stress. We demonstrated that knocking-down of Atf6 has decreased the TOR activity in S2R+ *Drosophila* cells by assessing the phosphorylation state of ribosomal protein S6 kinase (S6K), a well-characterized TOR target. Conversely, overexpression of Atf6 has increased the TOR activity. Supporting the notion, knocking-down of enzymes processing Atf6 has reduced the TOR activity. Taken together, our data demonstrate that Atf6 is a key molecule to connect the two signaling pathways.

D1053B Characterizing the role of the Fat cadherin family in the mitochondria using CRISPR. *N. Yau*[1,2], A. Sing[1], Y. Tsatskis[1], Y. Qu[1], H. McNeill[1,2]. 1) Lunenfeld-Tanenbaum Research Institute, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada.

Proper development of multicellular organisms requires a coordination of conserved developmental pathways involved in proper tissue growth and patterning. Genetic analyses have identified Fat (Ft), an atypical cadherin that functions to regulate planar cell polarity (PCP) tissue organization and the Hippo pathway. Mutations of Ft cadherins have been implicated in polarity defects, tissue overgrowth, and spindle orientation defects.

The intracellular domain (ICD) of Ft has been previously dissected using structure-function analyses, and distinct regions affecting Ft's function in PCP and Hippo signaling have been identified. We recently have identified a novel signaling role for Ft in regulating mitochondrial function that maps to previously identified regions in the ICD. We showed that Ft is processed intracellularly to generate Ft^{mito}, and is required for regulating the stability and/or ability of Complexes I and/or V. Our analysis of the ICD of Ft identified two predicted mitochondrial targeting sequences (MTS), and a highly conserved region that is necessary for Ndufv2 binding. Subsequent experiments will help understand the mechanism of how Ft regulates mitochondrial function. We are currently conducting CRISPR mutagenesis and genetic analyses to ablate the two MTS sites as well as other conserved regions in the ICD to understand how their loss affects mitochondrial function. I am also deleting a conserved potential cleavage site in the ICD to examine if the intracellular processing of Ft is lost and whether the mitochondrial localization of Ft is affected. I will conduct tissue-specific RNAi knockdown of Ft to determine whether the mitochondrial activity of Ft is ubiquitous throughout the *Drosophila* larvae. These experiments will allow us to examine the role of Ft in the mitochondria endogenously, and can be applied to understand how endogenous deletions within the ICD affect Ft's other functions in PCP and Hippo signaling.

D1054C Transcriptome analysis to identify genes responding to mechanical force in developing *Drosophila* embryos. *T. Ishibashi*[1], K. Yamaguchi[2], S. Shigenobu[2], K. Matsuno[1]. 1) Osaka University, Toyonaka, Osaka, JP; 2) National Institute for Basic Biology, Okazaki, Aichi, JP.

Various types of mechanical force are involved in biological processes. Especially during development, cells are subjected to dynamic mechanical force. Cells growing in limited area push and pull their neighboring cells, which may change the shape of the tissues encompassing or surrounding these cells. Recently, it has been reported that mechanical force also modulates cell behaviors, such as polarization, cell migration, cell growth, and differentiation. However, most of these studies rely on cultured cells. Therefore, it is largely unknown what molecules are involved in generation and reception of mechanical force, and how they work in developmental events.

In order to reveal these issues, we planed to perform RNA-seq transcriptome analysis to identify genes induced by mechanical force in *D. melanogaster* embryos. First, we constructed the mechanical force application system. We confirmed that the compression during the whole embryogenesis perturbed development, however the compression for 30 minutes did not affect the hatching rate. Next, we checked the global stress response to the compression. We confirmed that ER-stress response was not affected by the compression for 30 minutes.
Here, we will describe our experimental system and discuss our future directions.

D1055A Functional characterization of *creld* in *Drosophila melanogaster*. *M. Paradis*, B. Stümpges, M. Hoch, R. Bauer. University of Bonn, Limes Insitute, Bonn, DE.

cysteine-rich with EGF-like Domains (creld) genes encode evolutionary conserved proteins. Two paralogues are identified in mammals: *Creld1* was shown to act as a regulator of the calcineurin/NFATc signaling pathway, whereas c*reld2* is involved in ER stress response.
The Drosophila genome encodes only one *creld* gene yielding two splice variant proteins (46% similarty to mammalian CRELD1 and 49% similarty to CRELD2). In order to elucidate the function of *Drosophila* Creld proteins, we generated a *Drosophila* null mutant for c*reld* and analyzed the ensuing phenotypes.
As the mammalian orthologues, Creld is localized to the ER membrane. However, we could not confirm an upregulation of gene expression under ER stress of either Creld isoforms, neither in wild type flies nor Schneider cells. Addtionally, c*reld* mutants are able to survive under ER stress (induced by feeding tunicamycin and thapsigargin), indicating that the knock out of Creld is not provoking ER stress sensitivity.
Creld mutant flies suffer from extensive neurodegeneration, accompagnied by severe locomotor and flight defects and reduced viability, but fertile. q-RT-PCR analysis of adult flies could identify a decreased relative mitochondrial DNA content in *creld* mutants compared to wild type flies, suggesting problems with mitochondrial biogenesis or quality control. Additonally, a decreased number of mitochondria was confirmed in larval tissue using immunofluorescent techniques. The observed phenotypes could significantly be rescued by complementing the food with mitochondrial activity inducing drugs. We performed climbing assays with mutant flies fed with these drugs and were able to see significantly increased climbing capabilites of those flies compared to mutants fed with normal yeast food without any addtives. But no indication of oxidative stress or increased ROS production was observable in *creld* mutant flies.
We hypothesize that the observed neurodegeneration is at least partly induced by energy deprivation that goes along with reduced mitochondrial mass, and which was evident by increased AMPK phosphorylation.
We conclude from our data that Creld might be involved in mitochondrial biogenesis and/or quality control. Due to its localization to the ER membrane, it might pose a link between the ER compartment and mitochondria, which are closely connectet in order to regulate Ca^{2+} signaling, regulating intracellular trafficking and controlling mitochondrial biogenesis. Future research will adress the function of Creld in this context.

D1056B The Tumor Microenvironment And Mechanisms Governing Ras Tumor Overgrowth. *Chiswili Yves Chabu*[1,2], Tian Xu[1,2]. 1) Yale University School Of Medicine, New Haven, CT; 2) Howard Hughes Medical Institute.

We have been using *Drosophila* genetics to dissect the regulation of growth and metastasis, and have discovered conserved cell intrinsic and cell-cell signaling mechanisms within the tumor microenvironment. Here, I will discuss our recent findings of tumor-host and tumor-tumor signaling mechanisms promoting oncogenic Ras-mediated tumor overgrowth. First, we found that oncogenic Ras cells elevate the exocytosis of TNF to the surrounding wild-type cells, which consequently activate JNK signaling. This causes surrounding wild-type cells to secrete JAK-STAT ligands to activate JAK/STAT signaling in tumor cells and result in tumor overgrowth. Second, we discovered that oncogenic Ras signaling triggers the secretion of EGFR ligands. In turn, EGFR stimulates tumor overgrowth independent of the canonical Sos/Ras signaling pathway, but via ARF6. EGFR promotes ARF6 to control Hedgehog cellular transport in order to activate Hh signaling, which cooperates with oncogenic Ras to drive overgrowth. Consistent with these studies, blocking secretion or ARF6 function inhibits the growth of oncogenic Ras-driven tumors in mammals. Collectively, these data highlight important cell-cell interactions within the tumor microenvironment and also explain both, the puzzling requirement of EGFR in some Ras cancers and the oncogenic cooperation between EGFR and Hh signaling.

D1057C The "gatekeeper" function of *Drosophila* Seven-IN-Absentia (SINA) E3 ligase and its human homologs, SIAH1 and SIAH2, is highly conserved for proper RAS signal transduction in *Drosophila* eye development. *Robert E. Van Sciver*[1], Yajun Cao[1], Atique U. Ahmed[2], Amy H. Tang[1,2]. 1) Eastern Virginia Medical School, Norfolk, VA; 2) Mayo Clinic, Rochester, MN 55905.

Seven-IN-Absentia (SINA) is an evolutionarily conserved E3 ubiquitin ligase that is the most downstream signaling module identified in the RAS pathway. Underscoring the importance of SINA is its high evolutionary conservation with over 83% amino acid identity shared between *Drosophila* SINA and human SINA homologs (SIAHs). As a major signaling "gatekeeper" in the RAS pathway, we have shown that SIAH is required for oncogenic K-RAS-driven tumorigenesis and metastasis in human pancreatic, lung and breast cancer. Since SIAHs appear to be the ideal drug target to inhibit "undruggable" K-RAS activation, it is important to delineate the activity, regulation, and substrate targeting mechanism(s) of this highly conserved family of SINA/SIAH E3 ligases by deploying this elegant and well-established *Drosophila* photoreceptor development system to study RAS activation. In the developing eye, photoreceptor cells are recruited sequentially and acquire their distinctive cell fates through a series of local inductive events. The 800x cell arrays allowed us to dissect the role of SINA/SIAH downstream of RAS activation in photoreceptor cell development. To delineate SINA function, we have isolated multiple EMS-induced *sina* point mutant alleles that have shown much stronger mutant phenotypes than those of the previously published *sina*^{2} and *sina*^{3} alleles, suggesting that the *sina*^{2} and *sina*^{3} alleles are hypomorphic alleles. Here, we have an opportunity to characterize the null and stronger *sina*^{mutant} alleles by sequencing the EMS-induced *sina* mutant collection. To define SINA/SIAH functional conservation, we have generated a complete panel of transgenic fly models that express either wild-type (WT) or proteolysis-deficient (PD) SINA/SIAH. The corresponding *UAS-sina/siah*$^{GOF/LOF}$ phenotypes have

been characterized using *sev*-, *GMR*-, *dpp*- and *salivary gland*-GAL4 drivers to elucidate the PNS developmental outcome of altered SINA/SIAH expression upon RAS activation. Ectopic expression of $sina^{WT/PD}$/$siah^{WT/PD}$ in neurons resulted in dramatic changes in neuronal cell fate in the developing eye, and PNS neurodegenerative phenotypes. Our results show that the biological functions of fly SINA and human SIAH1/SIAH2 are evolutionarily conserved and functionally interchangeable. Mechanistic insights and regulatory principles learned from *D. melanogaster* can be directly applied to cancer biology to develop and validate next-generation anti-SIAH-based anti-K-RAS and anticancer therapy in the future.

D1058A Calcium dynamics can be used to reveal mechanisms of epithelial wound detection. *Erica Shannon*, Monica E. Lacy, M. Shane Hutson, Andrea Page-McCaw. Vanderbilt University, Nashville, TN.

When an epithelial tissue is wounded, the cells undergo a set of coordinated behaviors to close the wound and repair the tissue. Cells across the epithelium participate in this response, not just the cells bordering the wounds. We want to know how cells, including those away from the wound site, get information that a wound has occurred. The earliest observed wound response is a calcium wave, previously reported to originate in cells on the wound margin and expand outward several cells in diameter. This calcium wave is highly conserved and is important for wound healing. Normally, calcium concentrations inside cells are maintained at low levels by pumping calcium out of the cell or into the ER. When the cytoplasmic concentrations rise, calcium can act as a second messenger and can affect multiple signaling pathways. However, the mechanism of wave initiation remains unknown. Based on the calcium wave kinetics we have observed, we hypothesize that the calcium wave upon wounding is a result of changes in tissue mechanics.

We have analyzed the kinetics of the calcium wave using *in vivo* live imaging of the *Drosophila* pupae notum, an epithelial monolayer of diploid cells that expresses the GFP-based GCaMP calcium reporter. Our data reveals two distinct stages of calcium dynamics upon wounding; an initial release and stochastic flares. During the initial release, calcium flows simultaneously into multiple cells (at varying distances from the wound margin), only milliseconds after wounding. The second stage of calcium release occurs ~30-60 seconds after wounding and is characterized by random flashes of calcium that propagate around the wound for up to 30 minutes. These flashes are consistent with calcium induced calcium release.

The spread of the initial release from cells proximal to the wound toward cells distal to the wound is on the order of 1-10 μm/ms. Preliminary analysis suggests that diffusion cannot account for such a rate of spread. Thus we are testing the role of mechanotransduction in wound detection. We will use genetic tools to manipulate tissue mechanics and then assess how the calcium wave is affected by the mechanical perturbations.

D1059B Involvement of the histone demethylase KDM5 in the control of apoptosis. *C. Drelon*, X. Liu, J. Secombe. Albert Einstein College of Medicine, Bronx, NY.

KDM5 proteins are highly conserved histone demethylases with several conserved domains. In addition of well-described JmJC domain, the catalytic domain, KDM5 proteins contain a JmJN domain, an ARID DNA binding domain, a C5HC2 zinc finger of unknown function and two or three histone binding PHD motifs. Whereas mammalian cells encode four KDM5 paralogs KDM5A, KDM5B, KDM5C and KDM5D, Drosophila has a single KDM5 ortholog, making of flies a good model to study the biology of KDM5 family proteins. KDM5 proteins are involved in the control of gene transcription, acting as an activator or a repressor in a context-dependent manner. Because knockout of mouse KDM5B and Drosophila kdm5 result in lethality, KDM5 proteins play an essential role in transcriptional regulation. Moreover alterations of KDM5 expression have been described in several human cancers. For example overexpression of KDM5A or KDM5B are implicated in prostate, breast and gastric cancers. However the roles of KDM5 proteins in physiological contexts and in tumor development remain poorly understood.

In order to study the biology of KDM5, our lab carried out RNA sequencing experiments of *kdm5* hypomorphic mutant adult flies that have 70% less KDM5 protein than wildtype. These analyses highlighted alterations in genes required for apoptosis. Additionally anti-KDM5 ChIP sequencing experiments conducted by our lab shown that KDM5 is bound to the promoter region of several of cell death genes. Our qPCR analyses confirmed the down-regulation of many pro-apoptotic genes in *kdm5* mutant flies. Moreover to verify the ChIP-seq data, we conducted ChIP qPCR experiments and confirmed the binding of KDM5 to the promoter of the *Dark* gene. Dark is required for the activation of Dronc initiator caspase and is essential for most of cell death. We therefore propose that kdm5 could directly participate at the induction of apoptosis.

We continue to investigate the role of KDM5 in apoptosis and to define the precise mechanism by which KDM5 controls the expression of apoptosis genes. Because KDM5 interacts with several transcription factors involved in stimulating cell death such as Myc and Foxo, these are good candidates for recruiting KDM5 to its targets. In parallel we are identifying which domains of KDM5 are required for this function. Although KDM5 is most well known for its histone demethylase activity, previous work from our lab and others have demonstrated critical KDM5 functions are independent of its well-described enzymatic activity.

D1060C A Role for Histone Deacetylases in Regulating Sensitivity to Apoptotic Stimuli in *Drosophila melanogaster*. *K. Marischuk*, Y. Kang, A. Bashirullah. University of Wisconsin-Madison, Madison, WI.

A cell's sensitivity to apoptotic stimuli is highly variable, making it possible for the same stimuli to trigger a death response in one tissue and not in another. Previous research in our lab has shown that differences in sensitivity to apoptotic stimuli during Drosophila development are established by regulating levels of pro-apoptotic proteins—cells with lower levels being less sensitive to apoptotic stimuli. We hypothesized that histone deacetylases (HDACs) could play a major role in repressing transcription of pro-apoptotic genes in tissues with low sensitivity. By using HDAC inhibitory drugs, we showed that reducing the activity of Class I HDACs is sufficient to increase expression of pro-apoptotic genes and thereby elevate apoptotic sensitivity. We then used knockdown of individual HDACs to identify Rpd3 as the HDAC most responsible for

these changes in responsiveness to apoptotic stimuli in whole animals as well as in specific tissues. HDAC inhibitors are used widely in drug cocktails to treat cancer patients, but the mechanism by which they act is not wholly clarified. Our results suggest that these drugs may act, at least in part, by priming both normal and malignant cells for a death response.

D1061A Argonaute-1 regulates developmental apoptotic process through JNK signaling pathway in *Drosophila*. *T. Mondal*[1], U. Bhadra[2], M. Pal Bhadra[1]. 1) CSIR-Indian Institute of Chemical Technology, Hyderabad, TS, INDIA; 2) CSIR-Centre for Cellular & Molecular Biology, Hyderabad, TS, INDIA.

Argonaute family proteins are not only conserved in higher organisms but also found in archaea and bacteria (*Aquifex aeolicus*). The name Argonaute (Ago) came from the phenotypic resemblance of *Arabidopsis thaliana* mutants with mollusk 'Argonaut'. PAZ and PIWI domain containing argonaute family proteins are well known for their role in RISC complex of RNAi pathway. Role of Ago-1 in micro RNA biogenesis has been thoroughly studied, but its role in mitotic cell cycle progression is not studied much. In our earlier observation we have established the role of Ago-1 in cell cycle control in association with G2/M cyclin. We have further extended our study in understanding the relationship of Ago-1 in the regulation of apoptosis during *Drosophila* development. Apoptotic cell death plays a very critical role during development of multi cellular organism. Apoptotic process is controlled by multiple regulatory pathways. In this study we have used *Drosophila* eye as the phenotypic marker in producing overexpression of Ago-1 by employing the unique UAS-GAL4 system under the expression of eye specific promoter. Overexpression of Ago-1 in the eye resulted in smooth-eye phenotype with reduced number of ommatidia along with fused ones and loss of bristles in eye area. By combining a single copy of the dominant negative *basket* (*Drosophila* homolog of JNK) gene mutation, we found a drastic reversal to the normal phenotype indicating an active involvement of the basket with Ago-1 induced developmental apoptotic process. Pro-apoptotic genes hid, grim & rpr and *Drosophila* caspase genes, dronc, ice & Dcp-1 are also involved in this machinery. Thus Ago-1 regulated developmental apoptotic process in *Drosophila* development is JNK dependent.

D1062B Signaling mechanisms between apoptotic cells and non-professional phagocytes. *Sandy Serizier*[1], Iker Etchegaray[2], Kim McCall[1]. 1) Boston University, Boston, MA; 2) University of California San Francisco, San Francisco, CA.

Cells death is a key process that is necessary for the maintenance of tissues, and the removal of dangerous or unwanted cells. Apoptosis is one of the best-characterized types of programmed cell death. Membrane blebbing, caspase activation, chromatin condensation, and DNA fragmentation are all hallmarks of apoptosis. The Drosophila ovary is a powerful system to study programmed cell death because this system uses both apoptotic and non-apoptotic mechanisms. During mid-oogenesis, starvation cues reproducibly induce an apoptotic program and in late oogenesis, non-apoptotic programmed cell death occurs developmentally. Upon apoptotic cell death, follicle cells act as non-professional phagocytes to clear the debris. The molecular mechanisms that govern the communication between apoptotic cells and non-professional phagocytes in this system, however, are understudied. We have found that Draper, an engulfment receptor, is required for engulfment by follicle cells in the ovary. Interestingly, when Draper is overexpressed in follicle cells, the germline undergoes programmed cell death. In an effort to understand the underpinnings of engulfment receptor-induced cell death, we sought to characterize the type of cell death and signaling pathways involved in Draper-mediated germline cell death in the Drosophila ovary. Because Draper loss of function mutants elicit defects during cell death in late oogenesis, some of the key regulators of engulfment receptor mediated cell death may function normally during non-apoptotic cell death.

D1063C Drosophila Wnt and STAT Define Apoptosis-Resistant Epithelial Cells for Tissue Regeneration after Irradiation. *S. Verghese*, T. T. Su. University of Colorado, Boulder, CO.

Drosophila larvae irradiated with doses of ionizing radiation (IR) that kill about half of the cells in larval imaginal discs still develop into viable adults. How surviving cells compensate for IR-induced cell death to produce organs of normal size and appearance remains an active area of investigation. We have identified a subpopulation of cells within the continuous epithelium of *Drosophila* larval wing discs that shows intrinsic resistance to ionizing radiation (IR)- and drug-induced apoptosis. These cells reside in domains of high Wingless (Wg, Drosophila Wnt-1) and STAT92E (sole *Drosophila* STAT homolog) activity, and would normally form the hinge in the adult fly. Resistance to IR-induced apoptosis requires STAT and Wg, and is mediated by transcriptional repression of pro-apoptotic gene *reaper*. Lineage tracing experiments show that, following irradiation, apoptosis-resistant cells lose their identity and translocate to areas of the wing disc that suffered abundant cell death where they assume appropriate new identities. Our findings provide a new paradigm for regeneration in which it is unnecessary to invoke special damage-resistant cell types such as stem cells. Instead, differences in gene expression within a population of genetically identical epithelial cells can create a subpopulation with greater resistance, which, following damage, survive, alter their fate, and help regenerate the tissue.

D1064A BAF phosphorylation regulates necrotic pyknosis. *L. Hou*[1,2], K. Liu[1], Y. Li[2], X. Ji[2], L. Liu[2]. 1) State Key Laboratory of Membrane Biology, School of Life Sciences, Peking University, Beijing, 100871, China; 2) Aging and Disease Lab of Xuanwu Hospital and Center of Stroke, Beijing Institute for Brain Disorders, Capital Medical University, Youanmen, Beijing, 100069, China.

Necrotic cell death (necrosis) widely occurs in human pathologies, however, the therapeutic strategies to suppress it are still lacking due to our inadequate knowledge on its molecular mechanisms. One of the morphological markers of necrosis is nuclear condensation (pyknosis), which has been used widely to distinct from apoptosis. However, the molecular mechanism of necrotic pyknosis and its functional role in necrosis propagation are still unclear. To address these questions, we generated a genetic model in *Drosophila* to temporally follow the progression of necrotic pyknosis. Surprisingly, we observed an intermediate state of chromatin detachment from the nuclear envelope (NE),

followed with the NE completely collapsed onto chromatin. This phenomenon leads us to discover that phosphorylation of barrier-to-autointegration factor (BAF) mediates this initial separation of NE from chromatin. Functionally, inhibition of BAF phosphorylation suppressed the necrosis in both *Drosophila* and human cells. This suggests that necrotic pyknosis is an essential and evolutionally conserved step for the propagation of necrosis. Therefore, BAF phosphorylation may represent a biochemical marker of necrosis and potentially serve as a therapeutic target for necrosis-related diseases.

D1065B Signaling and mechanisms regulating Germ Cell Death (GCD), an alternative cell death pathway in *drosophila*. *K. Yacobi-Sharon*, E. Arama. Weizmann Institute, Rehovot, IL.

Apoptosis is the most abundant form of programmed cell death (PCD) in metazoans, but some cells seem to utilize different cell death pathways independent of caspases, the executioners of the apoptotic program. To date, very little is known about the signaling and molecules underlying such alternative cell death pathways. In a previous work (Yacobi-Sharon et al., *Dev Cell*, 2013), we discovered and delineated a cell death pathway which is utilized to normally and constantly eliminate about one quarter of the emerging (premeiotic) spermatogonial cells in the adult *Drosophila* testis. This new cell death pathway, also termed Germ Cell Death (GCD), displays distinct morphological features reminiscent of both apoptosis and necrosis, requires lysosomal and mitochondrial proteases, and is independent of the main apoptotic effector caspases. Whereas this study uncovered some of the GCD executioners, nothing is known about the signaling pathway which triggers this cell death pathway.

Similar to the male germ cells in mammals, which require constant contact with their somatic supporting (Sertoli) cells for proper development, the *Drosophila* male germ cells are enveloped by a pair of somatic supporting (cyst) cells throughout maturation. Interestingly, we found that following GCD, the cyst cells activate caspases and undergo apoptosis, thus suggesting that GCD may be regulated extrinsically by signals originating in these somatic supporting. Indeed, by knocking down different signaling pathways in the cyst cells we identified the Hippo/Warts pathway as an important regulator of GCD. The Hippo/Warts signaling pathway is known to limit organ/cell growth and promote apoptosis by inhibiting the anti-apoptotic and pro-proliferative activity of the transcriptional coactivator Yorkie. Cyst cell-specific knockdown of either the main kinase in this pathway, Warts, or its coactivator, Mats, significantly attenuated GCD levels, whereas knockdown of Yorkie resulted in the enhancement of GCD levels. Further genetic and electron microscopy experiments support a model in which Hippo/Warts signaling in the supporting cells triggers the alternative cell death of the germ cells, which is followed by apoptosis of the supporting cells. These results demonstrate a role of the Hippo/Warts pathway in a non- autonomous regulation of a cell death program.

D1066C Survival of proliferative, radio-resistant polyploid cells in *Drosophila* requires FANCD2. *Heidi Bretscher*, Don Fox. Duke University Medical Center, Durham, NC.

Crucial checkpoints detect DNA damage and arrest the cell cycle, allowing cells to repair DNA or undergo apoptosis. These responses maintain a stable genome. DNA damage checkpoints are also exploited therapeutically to kill proliferative tumor cells. However, many tumors eventually become resistant to death by DNA damage. Resistance is associated with mutations in DNA checkpoint responders, and/or inactivity of canonical checkpoint regulators. How such resistant cells can proliferate and survive DNA damage is poorly understood.

Cells lacking elements of the DNA damage response are not limited to pathological conditions. The endocycle, a conserved cell cycle in which cells alternate between S and G phases, increasing in ploidy without increasing in cell number, is known to silence elements of the DNA damage response. However, many endocycled cells do not divide. In the *Drosophila* rectum, we previously found endocycled papillar cells re-enter mitosis as polyploid cells.

Here, we show that papillar cells also acquire radiation-resistance during the endocycle, allowing us to study the effects of a silenced DNA damage response on subsequent mitosis. We find papillar cells accumulate DNA breaks and acentric DNA fragments during endocycles. Rather than undergo high fidelity DNA repair prior to mitosis, papillar cells divide with broken DNA. Amazingly, papillar cells employ an active mechanism to properly segregate acentric DNA fragments during anaphase, enabling cell survival and proper organogenesis. We find that this response requires the Fanconi Anemia FANCD2/FANCI heterodimer and frequent partner Bloom helicase. Lack of FANCD2 results in failure to incorporate acentric DNA into daughter nuclei, leading to micronuclei. This causes papillar cell death and formation of a non-functional organ. Interestingly, this response is independent of canonical DNA damage response proteins. Our work sheds light on a non-canonical chromosome patching mechanism used to accurately segregate broken acentric DNA during mitosis. We speculate that this response may be shared by other cells lacking an intact DNA damage response, such as radiation-resistant tumor cells.

D1067A Tousled-like kinase regulates G2/M transition through Tak1 to activate p38a MAPK. *G. Liaw*. Natl Yang-Ming Univ, Taipei, TW.

To maintain genome integrity, cell-cycle checkpoints are monitoring DNA damages and abnormal chromosome segregation caused by environmental stresses. Numerous studies have demonstrated that *Tousled-like kinase* (*Tlk*) activity is required for the faithful segregation of chromosomes and the DNA repair. Previous studies show that *tlk* overexpression delays G2/M transition. The delay is relieved by reduced *p38a* activity, consistent with both *Tlk* and *p38a* activities required for stalling G2/M transition under heat shock. Phosphorylation of p38 is significantly increased by overexpressed kinase-dead Tlk (Tlk^{KD}), suggesting that Tlk is a cofactor of a kinase that activates p38a. To find the kinase, proteins in Tlk co-immunoprecipitated complexes are identified by mass spectrometry. Using the esyN program, I find four identified proteins, Rm62, MEP-1, Hsc70-5 and EF1a48D that directly or indirectly link to Tak1. The Tlk^{KD}-facilitated p38 phosphorylation is abolished by removing *Tak1* activity, consistent with both *Tlk* and *Tak1* activities required for stalling G2/M transition under heat shock. Similarly, responding to heat shock, G2/M transition is unstoppable in eye discs with reduced two gene activities among *EF1a48D*, *Hsc70-5*, *Tak1* and *Tlk*.

Taken together, Tlk acts as a positive mediator of Tak1 that activates p38a to delay G2/M transition induced by either *Tlk* overexpression or heat shock. *Tlk* activity likely coordinate G2/M checkpoint and responses to environmental insults to maintain genome integrity.

D1068B Rescue from Ring Chromosome Dominant Lethality by Mutations in *lok* (Chk2) and *p53*. *H. LIN*. UNIVERSITY OF UTAH, SALT LAKE CITY, UT.

Ring chromosomes are known for a number of unique properties, including mitotic and meiotic instability, and dominant lethality. There is substantial cytological support for an underlying mechanism of chromatin bridging as the cause of these phenomena. Sister chromatid exchange and sister chromatid union have been proposed as mechanisms to produce chromatin bridges that may lead either to chromosome loss or lethality.

We constructed new ring *XY* chromosomes that produce strong dominant embryonic lethality. These ring chromosomes produce very few gynandromorphs, suggesting that the mechanism that causes dominant lethality is different than the mechanism that produces gynandromorphs. To determine the nature of the lethal mechanism, we investigated whether the canonical DNA damage response is responsible for embryonic death of zygotes with a ring chromosome. By crossing ring *XY* males to *lok* (encoding Chk2) or *p53* homozygous females we found that both maternal genotypes are able to strongly rescue viability of progeny that inherit the ring chromosome.

Rescue by *lok* or by *p53* differs significantly in that *lok* mutant mothers produce gynandromorph offspring, while *p53* mothers do not. This further suggests that the ring chromosome loss and ring chromosome dominant lethality have distinct causes, and that Chk2 and P53 respond to distinct chromosome abnormalities. Chk2 may normally detect aberrant behavior that would otherwise lead to chromosome loss, while P53 may detect chromosome breakage events. In wildtype embryos, both events would evoke checkpoints that result in lethality, but in mutants, distinct outcomes can be detected. We are continuing to investigate the nature of *lok* and *p53* rescue.

D1069C DNA replication proteins: two mutations better than one? *Chris I. Knuckles*, Wayne A. Rummings, Lucas T. Hopkins, Tim W. Christensen. East Carolina University, Greenville, NC.

Essential to the survival of cellular life is proper replication and maintenance of the genome. Replication proteins Mcm10 and RecQ4 have well-characterized essential roles in assembly, initiation, and proper functioning of the eukaryotic replication machinery. Specifically, Mcm10 aids in the recruitment of Pol-α/primase as well as tethering the ssDNA stabilizing replication protein A (RPA) to the CMG complex, and RecQ4 delivers the GINS complex to the replication fork, which is essential for replication initiation. Past evidence suggests that Mcm10 is not required for RecQ4 chromatin localization or association with the CMG complex, conflicting with previous reports that Mcm10 mediates the interaction between RecQ4 and Mcm2-7 in an S-CDK dependent manner. A recent study demonstrated that truncating residues from the N-terminus (Sld2-like) domain of RecQ4 eliminated the Mcm10 interaction surface. We have found that a homozygous mutation of RecQ4 is lethal in fruit flies that do not also possess a C-terminal domain (CTD) truncation allele of Mcm10, suggesting that Mcm10's RecQ4 interaction surface lies in the CTD of Mcm10. Additionally, we have used the Yeast Two-Hybrid System to demonstrate the interaction between Mcm10's CTD and RecQ4. Specifically, our results indicate that the Mcm10-RecQ4 interaction is essential for high-stress replication states – like embryogenesis and endoreplication in larval salivary glands – but not for normal cell cycles. The Mcm10 CTD truncation rescue of lethal RecQ4 phenotypes can reveal much about how the cooperative roles of these proteins affect DNA replication, but this requires further investigation. Our research aims to explore the nature of the Mcm10-RecQ4 interaction by conducting genetic studies, protein interaction assays, stem cell proliferation analysis in the Drosophila ovary, and the generation of null Mcm10 and RecQ4 alleles using the CRISPR/Cas9 system. We propose that the Sld2-like domain of RecQ4 interacts with the CTD of Mcm10, mediating its associations with the replication fork and other replication factors like RPA and Ctf4.

D1070A A Y chromosome variant mediates sex ratio of surviving *Blm* null embryos. *Abbie Olson*[1], Mallory McDermott[1], Lindsey Riggs[1], Leigh Latta[1], Mia Levine[2,3], Eric Stoffregen[1,3]. 1) Lewis-Clark State College, Lewiston, ID; 2) University of Pennsylvania, Philadelphia, PA; 3) Co-senior authors.

Repetitive DNA poses distinct challenges to the DNA replication machinery, particularly during the rapid syncytial cell cycles of early *Drosophila* embryo development. The maternally deposited Blm DNA helicase mediates such challenges that arise during this unique stage of development. Surviving progeny from *Blm* mutant mothers show a female sex bias, which has been attributed to the absence of the highly repetitive Y chromosome DNA sequences in the developing embryo. If survival to adulthood is dependent on total repetitive DNA content, then Y chromosomes that harbor variable amounts of heterochromatin (a proxy for repetitive DNA content) may show variation in male survivorship. To investigate this possibility, we crossed Y chromosomes isolated from a worldwide sample of *Drosophila melanogaster* populations into a common genetic background and quantified bulk heterochromatin using a classic position effect variegation assay ("PEV"). After classifying these Y chromosomes as strong or weak suppressors of PEV, we crossed them to *Blm* homozygous females. Contrary to our prediction, the strongest suppressor of PEV (i.e., the line presumed to have the most bulk heterochromatin, and thus the most Y-linked repetitive DNA) did not exacerbate the female-biased sex ratio among survivors. Indeed, PEV suppression was a poor predictor of progeny sex ratio. However, we discovered one Y chromosome that consistently altered the ratio of female:male survivors compared to all other Y chromosomes tested. Our data implicate the existence of particular Y chromosome features that pose distinct, Blm-dependent challenges to DNA replication. Currently, we are exploring both the identity of these repetitive features and the molecular mechanism underlying Y-dependent replication challenges that arise during syncytial embryonic cycling.

D1071B Aging impairs double-strand break repair by homologous recombination in Drosophila. *H. A. Ertl*[1], L. Delabaere[2], D. Massey[1], F. Sohail[1], E. J. Beinenstock[1], H. Sebastian[2], I. Chiolo[2], J. R. LaRocque[1]. 1) Georgetown University Medical Center, Washington DC; 2) University of Southern California, Los Angeles, California.

Aging is characterized by genome instability, which contributes to cancer formation and cell lethality leading to organismal decline. The high levels of DNA double-strand breaks (DSBs) observed in old cells and premature aging syndromes are likely a primary source of genome instability, but the underlying cause of their formation is still unclear. DSBs might result from higher levels of damage or repair defects emerging with advancing age, but repair pathways in old organisms are still poorly understood. Here we show that pre-meiotic germline cells of young and old flies have distinct differences in their ability to repair DSBs by the error-free pathway homologous recombination (HR). Repair of DSBs induced by either ionizing radiation (IR) or the endonuclease I-SceI is markedly defective in old flies. This correlates with a remarkable reduction in HR repair measured with the DR-*white* DSB repair reporter assay. Strikingly, most of this repair defect is already present at 7 days of age. Finally, HR defects correlate with increased amount of Rad51 expression and recruitment to damage in old organisms, suggesting that HR in older flies is defective after Rad51 recruitment. These data reveal that DSB repair defects arise early as the organism ages, and, contrary to previous conclusions, suggest HR defects as a leading cause of genome instability in older animals.

D1072C Determining the role of a novel protein, Ankle1, in a resolvase complex of *Drosophila melanogaster*. *M. Hartmann*, J. Sekelsky. University of North Carolina at Chapel Hill, Chapel Hill, NC.

DNA double strand breaks are repaired through homologous recombination in mitotically dividing cells and germ line cells undergoing meiosis. Intermediates formed through homologous recombination are processed by structure-specific resolvases resulting in crossovers and noncrossovers. There are several known eukaryotic resolvases with a number of functions, but there are many aspects of the complexes yet to be uncovered. Specifically, I aim to elucidate the multiple complexes that function as resolvases and in what contexts they operate. Three main resolvases being studied include GEN1/Yen1, and the complexes MUS81-EME1 and SLX1-SLX4. In *Drosophila*, we believe MEI-9- ERCC1 in conjunction with MUS312 (SLX4) is the major meiotic resolvase. However, there are residual crossovers present in a *mus312* mutant and MUS312 may interact with other proteins in a mitotic context. Therefore, I hypothesize SLX4 assembles multiple complexes and that there are other proteins yet to be discovered forming resolvase complexes. MEI-9 and MUS81 are both nucleases that belong to the ERCC4 nuclease family of proteins, and both MEI-9 and MUS81 have binding partners that contain inactive nuclease domains. It is suspected that MUS81-EME1 work in concert with SLX1-SLX4 to resolve junctions, so due to the similarities between MUS81 and MEI-9, I hypothesize that there is another protein similar to SLX1 working in concert with the MUS312-MEI9-ERCC1 resolvase complex. We have identified a candidate gene, *Ankle1* that may act in a complex through interactions with the scaffolding protein MUS312 in concert with MEI-9 – ERCC1. *Ankle1* is a GIY-YIG nuclease domain protein, similar to SLX1. In humans, Ankle1 has been shown to possess endonuclease activities both in vitro and in vivo. I am interested in determining if the *Drosophila* Ankle1 protein has the same endonuclease properties. My goal is to study the *in vitro* activities of Ankle1 and correlate these data with genetics studies. Components of the enzyme complexes will be determined by direct protein-protein interactions and proteomic studies. Preliminary protein-protein interaction studies using the yeast two-hybrid assay have shown an interaction of Ankle1 with MUS312 and MEI-9. I have used the CRISPR/Cas9 gene editing tool to create a mutant of *Ankle1* in *Drosophila*, and I plan to use this mutant for further genetic characterization. Mitotic and meiotic repair assays will be done with single and multiple mutants in *Drosophila melanogaster* to deduce functions and epistatic relationships. Through this research, I will elucidate the interactions of Ankle1, while uncovering the roles of resolvases in recombination.

D1073A Does remodeling of the Myb-MuvB transcriptome promote the switch from mitotic cycles to endocycles? *M. Rotelli*, B. Calvi. Indiana University, Bloomington, IN.

The endocycle is a cell cycle variant that is composed of alternating G and S phases without mitosis. Repeated endocycles result in polyploidy and large cell size. Cells switch from mitotic cycles to endocycles (M-E switch) during the normal development of numerous organisms, including protozoa, insects, plants, and mammals. It is known that the endocycle oscillator is regulated by alternating activity of Cyclin E / CDK2 and APC/C^{cdh1}. Yet, the molecular mechanisms that remodel the mitotic cycle into the endocycle are mostly not understood. We previously analyzed the transcriptome of endocycling cells in the *Drosophila* larval salivary gland and fat body. This study revealed that endocycling cells have dampened expression of genes that are regulated by the E2F1 / Dp and Myb-MuvB (MMB a.k.a. dREAM) transcription factor complexes. It is well established that the MMB can act as either a transcriptional activator or repressor to regulate mitotic cell cycle progression in a variety of organisms, including humans. Many of the MMB-regulated genes that are required for mitotic entry / progression and cytokinesis were expressed at lower levels during fly endocycles. We are currently exploring whether remodeling of the MMB from a transcriptional activator to repressor promotes the M-E switch.

Genetic ablation of mitosis can create induced endocycling cells (iECs). For example, RNAi knockdown of Cyclin A or overexpression of the APC/C activating subunit Fzr (CDH1) both block mitosis and switch cells to an endocycle oscillator. These iECs represent an opportunity to investigate mechanisms of the M-E switch independent of developmental inputs. Our current results suggest that these iECs also have dampened expression of MMB-regulated genes. These results suggest that MMB activity is integrated with the master cell cycle control system, the mechanisms of which we are defining further. It has been shown that polyploid cells in several tissues of the mouse have a transcriptome signature similar to that which we described for fly endocycles. The insights into endocycle regulation revealed by our study, therefore, will likely be conserved across organisms including humans. Moreover, evidence suggests that some cancer cells inappropriately switch to endocycles, which may lead to genome instability and cancer progression. Therefore, this study also has broader impact for understanding the molecular circuitry of these cancer iECs.

D1074B Hippo signaling regulates tissue regeneration from a quiescent cell population. *J. H. Meserve*, R. J. Duronio. UNC-Chapel Hill, Chapel Hill, NC.

Following tissue damage, stem or precursor cells often undergo proliferation to replace lost cells. This proliferation is tightly regulated as inappropriate cell cycle re-entry can lead to tumor growth and cancer. It is unclear how proliferation, often of cells that are normally quiescent, is controlled following tissue damage. I have investigated the mechanism driving regeneration in a quiescent tissue using the *Drosophila melanogaster* eye imaginal disc as a model. The eye disc contains a population of quiescent, undifferentiated cells that re-enter the cell cycle and undergo compensatory proliferation following damage driven by *GMR-hid*. To identify genes involved in this process, I performed an RNAi screen of ~400 transcription factors. Knockdown of the transcription factor *scalloped* completely blocked compensatory proliferation. Knockdown of Scalloped's transcriptional co-activator Yorkie also disrupts compensatory proliferation. Furthermore, in *GMR-hid* discs, both Scalloped and Yorkie are required to drive accumulation of Cyclin E, a previously characterized transcriptional target that is essential for entry into S-phase. Yorkie is a transcriptional effector of the Hippo pathway, which has been implicated in regeneration in *Drosophila* and vertebrates. Our genetic data suggests that activation of Yorkie is likely driven by inhibition of Hippo pathway components by the LIM domain containing-protein Ajuba. Based on previous work in other labs and our own data manipulating cytoskeletal activity, we propose a model where changes in cellular tension induced by massive tissue extrusion drives activation of Ajuba and, ultimately, compensatory proliferation. In addition to the mechanism driving compensatory proliferation in the developing eye, we are also interested in the eventual fate of these compensatory proliferating cells, as it is currently unclear whether these cells can faithfully replace all cells lost following tissue damage. One possibility is cells that re-enter the cell cycle and proliferate are able to adopt all retinal cell type fates, including neuronal photoreceptors which differentiate before compensatory proliferation occurs; alternatively, the fate of these cells may be limited to lineages that have not yet differentiated at the time compensatory proliferation occurs. To investigate this question, I am performing lineage tracing experiments to determine the fate of these compensatory proliferating cells. These results will be important for understanding how cell fate might be affected following tissue damage and whether the mechanisms driving cell cycle changes, from quiescent to proliferating, also drive changes in cell fate that contribute to productive regeneration.

D1075C miRNA regulation of *dacapo* expression in the *Drosophila* embryo. *J. Petley*, C. Swanson. Arcadia University, Glenside, PA.

Cyclin-dependent kinase inhibitors (CKIs) play important roles in embryonic development by directly inhibiting the cell cycle machinery to promote cell cycle exit and limit tissue growth. The *Drosophila* CKI Dacapo (Dap) contributes to normal cell cycle exit in multiple developmental contexts, including the embryonic epidermis, nervous system, and eye. Because of its function as a potent cell cycle inhibitor, altered Dap expression can significantly disrupt normal development. For example, in the embryonic epidermis, premature Dap expression can induce early cell cycle exit, while the absence of Dap expression leads to delayed cell cycle exit and inappropriate cell division. Thus Dap expression must be carefully controlled to ensure normal tissue growth and differentiation. Indeed, multiple mechanisms have been shown to contribute to the regulation of Dap expression, including transcriptional regulation via a complex cis-regulatory region, miRNA-mediated translational inhibition, and regulated proteolysis via interaction with the $CRL4^{Cdt2}$ ubiquitin ligase. We have further examined the role of miRNA-mediated regulation of Dap expression in the embryonic epidermis. We have found that a *dap* transgene expressed under the control of the endogenous cis-regulatory region but lacking the endogenous 3'UTR is expressed prematurely in the embryonic epidermis. In addition, miRNA "sensor" transgenes that include the *dap* 3'UTR are repressed in comparison with controls. Finally, embryos lacking expression of a miRNA known to bind the *dap* 3'UTR, *miR-7*, exhibit premature *dap* expression. Future experiments will continue to explore the functional significance of miRNA-mediated repression of Dap expression in the embryonic epidermis.

D1076A Modulation of $CRL4^{Cdt2}$ activity in the syncytial embryo. *J. Speciale*[1], B. Duronio[2], C. Swanson[1]. 1) Arcadia University, Glenside, PA; 2) University of North Carolina, Chapel Hill,.

$CRL4^{Cdt2}$-mediated protein destruction is a developmentally critical phenomenon required for proper progression of both canonical and non-canonical cell cycles. $CRL4^{Cdt2}$ induces replication-coupled destruction of its substrates, which include the Drosophila proteins Double-parked (Dup), E2f1, and Dacapo (Dap). Despite its critical role in overseeing S phase progression and maintaining genome stability, we have observed modulation of $CRL4^{Cdt2}$ function in several developmental contexts. For example, our preliminary data suggest that $CRL4^{Cdt2}$ activity may be modified in the rapid, non-canonical cell cycles of the syncytial embryo. More specifically, we have observed differential stability of substrates in this context: Dup appears to be targeted for destruction during S phase as normal, while E2f1 and Dap are stable. These data suggest that $CRL4^{Cdt2}$ is active, but that at least two of its substrates are protected during these early cell cycles. We have identified sequences within the E2f1 protein that are required for protection in the early embryo. Continuing experiments seek to elucidate the mechanism, and ultimately the developmental function, of differential $CRL4^{Cdt2}$ substrate stabilization during early embryonic development. Our findings suggest that $CRL4^{Cdt2}$ activity may be modulated to accommodate unique cell cycle programs such as the rapid cycles of the syncytial embryo.

D1077B Identifying regulators of meiotic entry in male *Drosophila melanogaster*. *J. E. Tomkiel*[1], G. K. Yasuda[2], B. T. Wakimoto[3], B. Giri[1]. 1) Univ North Carolina, Greensboro, NC; 2) Seattle University, Seattle, WA; 3) University of Washington, Seattle, WA; 4) Univ. North Carolina, Greensboro, NC.

Many aspects of meiotic entry in male Drosophila are controlled by the activity of the meiotic specific *cdc25* homologue *twine, a* protein tyrosine phosphatase that activates p34cdc2. Mutations in *twine* and its translational regulators *boule* and *off-schedule* prevent meiotic entry. A second G2-M translational regulatory step occurs after *twine* expression, and is controlled by the Cytoplasmic Polyadenylation Element Binding (CPEB) protein orb2. Similarly, mutations in *orb2* result in a prolonged G2-M arrest. To identify other genes responsible for

regulating the G2-M transition, we have identified male sterile mutations that cause a similar meiotic phenotype. Seven chromosome 2 and eight chromosome 3 mutations were identified from a collection of previously identified male sterile mutations (Wakimoto BT, Lindsley DL and Herrera C., 2004). These represent thirteen complementation groups: twelve unique genes and one complementation group consisting of three mutations that fail to complement the amorphic *twineHB5* allele. We have taken a bioinformatics approach to confirm the 3 new twine alleles and identify the mutated genes in the 12 remaining lines. We created strains bearing four mutations each (i. e. transheterozygous for mutations on both chromosome 2 and 3), and performed whole genome sequencing at 11x coverage to identify the causative mutations. We identified new missense mutations in *twine* for each of the three non-complementing mutations. Towards identify the unknown genes, we have filtered variants in the genome sequence data by chromosome and eliminated variants shared between lines. We are presently completing recombination mapping with respect to dominant mutations to further delimit variants to candidate genes.

D1078C Epithelial tricellular junctions act as interphase cell shape sensors to orient mitosis. *F. Bosveld*[1], O. Markova[1], B. Guirao[1], C. Martin[1], Z. Wang[1], A. Pierre[2], M. Balakireva[1], I. Gaugue[1], N. Christophorou[1], D. K. Lubensky[3], N. Minc[2], Y. Bellaïche[1]. 1) Institut Curie, Paris, FR; 2) Institut Jacques Monod, Paris, FR; 3) University of Michigan, Ann Arbor, USA.

The orientation of cell division along the long axis of the interphase cell -the century -old Hertwig's rule- has profound roles in tissue proliferation, morphogenesis, architecture and mechanics. In epithelial tissues, the shape of the interphase cell is influenced by cell adhesion, mechanical stress, neighbour topology, and planar polarity pathways. At mitosis, epithelial cells usually adopt a round shape to ensure faithful chromosome segregation and to promote morphogenesis. The mechanisms underlying interphase cell shape sensing in tissues are therefore unknown. Here we show that in ***Drosophila*** epithelia, tricellular junctions (TCJs) localize microtubule force generators, orienting cell division via the Dynein-associated protein Mud independently of the classical Pins/Gα_i pathway. Moreover, as cells round up during mitosis, TCJs serve as spatial landmarks, encoding information about interphase cell shape anisotropy to orient division in the rounded mitotic cell. Finally, experimental and simulation data show that shape and mechanical strain sensing by the TCJs emerge from a general geometric property of TCJ distributions in epithelial tissues. Thus, in addition to their function as epithelial barrier structures, TCJs serve as polarity cues promoting geometry and mechanical sensing in epithelial tissues.

D1079A A new toolbox for the fly *Sciara* - a new/old model system that disobeys the rules for chromosome movement on spindles. *S. A. Gerbi*, Y. Yamamoto, J. Urban, J. Bliss. Brown Univ BioMed Division, Providence, RI, USA.

The fly *Sciara* has long been recognized as an outstanding model system to elucidate questions of chromosome mechanics. *Sciara* offers many unique biological features, several of which impact chromosome movement on spindles:

(a) chromosome imprinting; **(b)** a monopolar spindle in male meiosis I; **(c)** non-disjunction of the X chromosome in male meiosis II; **(d)** chromosome elimination in early embryogenesis; **(e)** sex determination; **(f)** evolution towards parthenogenesis; **(g)** germ line limited (L) chromosomes; **(h)** DNA amplification in salivary gland polytene chromosomes; **(i)** high resistance to radiation.

We have now developed a toolbox to enable *Sciara* research, and we welcome new investigators [http://brown.edu/go/sciara-stocks]. We are completing the *Sciara* genome with cutting edge approaches for assembly using long reads from the PacBio RSII and Oxford Nanopore MinION sequencing platforms, using Illumina reads for polishing, and using BioNano Irys optical maps for scaffolding. Genome annotation used RNA-seq data from the *Sciara* transcriptome interrogating both sexes at multiple stages. We have used the genomic data to identify sequences of "DNA puffs" that represent sites of DNA amplification in salivary gland polytene chromosomes regulated by ecdysone.

We have developed methods for transformation of *Sciara* to manipulate its genome. DNA has been introduced into ectopic sites in the *Sciara* genome using piggyBac. We present here a new method for site-specific integration of large DNA into the *Sciara* genome. Previously, others have accomplished this by homologous recombination (HR). However, HR is inefficient; instead, the preferred pathway in most cells is non-homologous end-joining (NHEJ), but its primary previous application has been to create small indels. We have coupled NHEJ with obligate ligation-gated recombination (ObLiGaRe) for high efficiency precise insertion of large DNA into a unique double-strand break. This approach is easily applicable to a broad range of organisms, including those where a transformation system has not been available.

With the new toolbox of the genome assembly and transformation methodology, the time is now ripe to elucidate many canonical processes using the unique biological features of *Sciara*.

D1080B Cell size regulation in Drosophila sensory organ precursor asymmetric cell divisions. *Nitya Ramkumar*[1], Nelio Rodrigues[2], Buzz Baum[1]. 1) University College London, London, GB; 2) The Francis Crick Institute Lincoln's Inn Fields Laboratory Room 605 44 Lincoln's Inn Fields London WC2A 3LY.

Asymmetric cell division is the unequal segregation of cell fate determinants into daughter cells following mitosis. In addition, some asymmetric divisions lead to daughter cells of unequal sizes. The regulation and functional significance of the unequal daughter cells size are unknown. To investigate this, we are using the bristle pattern in the adult fruit fly, which arises in the notum (dorsal thorax) during pupariation. The sensory organ precursor (SOP) cells undergo a series of asymmetric divisions to give rise to the cells of the mecahnosensory organ. During the first division, cell fate determinants, Numb and Partner of Numb localize to the anterior cortex, while Bazooka localizes to the posterior and each segregates into the anterior and posterior daughter cells respectively. In addition, the resulting daughter cells are of unequal sizes, a larger posterior cell and a smaller anterior cell. Chromosome passenger complex (CPC) are a complex of proteins, that localize early in mitosis to the kinetochores. During anaphase, they move from the kinectochores to the spindle midzone, and specify the position of the future cleavage furrow. Owing to their dynamic localization pattern during mitosis, we are investigating their role in the asymmetric SOP divisions.

Additionally, using genetic tools, we aim to perturb the daughter cell size and the relative size of the cells to determine the significance of cells size during lineage specification.

D1081C Characterizing the Role of Rough Deal (Rod) Protein in *Drosophila* Male Meiosis. *Qiutao He*, Bruce McKee. Department of Biochemistry and Cellular and Molecular Biology, The University of Tennessee, Knoxville, TN.

Meiosis is a specialized cell division in sexual reproduction which produces the haploid gametes from diploid precursor cells. Two separated stages are involved in this process – meiosis I and meiosis II. Meiosis I is considered as a reductional division since the homologous chromosomes segregate to opposite spindle poles while equational sister chromatids separation takes place in meiosis II. Accurate chromosome segregation enable the genetic fidelity and prevent the generation of aneuploidies. Spindle assembly checkpoint (SAC) is a surveillance mechanism to ensure completion of bipolar alignment before chromosome segregation and the role of SAC in meiosis has not been fully characterized. Rough Deal is a protein involved in SAC and responsible for the recruitment of other SAC-related proteins onto kinetochores during cell division. In mitosis, mutations in *rod* lead to stretched chromatid arms, anaphase lagging chromatids and chromosome mis-segregation while null mutations are lethal. In present study, we took advantage of a fully viable meiosis-specific *rod* allele to assess the role of *rod* in male meiosis. Genetic cross experiments exhibited high rates of sex chromosome nondisjunction in both stages of meiosis. Although chromosome morphology, conjunction and cohesion were normal throughout prophase I, the loss of centromere cohesion on autosomes appeared at metaphase I and later stages based on anti-CID immunostaining and FISH analysis. Cytological data in anaphase I revealed additional abnormalities, such as uneven chromosome segregation and lagging chromosome, and equational sex chromosome segregation was also observed at this stage. Future studies will concentrate on how *rod* mutation affect centromere cohesion and chromosome segregation in *Drosophila* meiosis. .

D1082A Cohesion without cohesin in *Drosophila* meiosis. *A. Mukherjee*, B. McKee. University of Tennessee, Knoxville, TN.

Meiosis is essential for sexual reproduction and therefore occurs in all eukaryotes, including single celled organisms that reproduce sexually. The proper segregation of homologous chromosomes and sister chromatids in meiosis requires multiple functions of a multi-subunit protein complex known as cohesin. Cohesin forms a ring around duplicated sister chromatids and prevents them from separating prematurely. In Drosophila, mitotic cohesin is composed of four subunits: the long coiled-coil proteins SMC1 and SMC3 and two non-SMC subunits SCC1/RAD21 and SCC3/SA and all four subunits are required for mitotic cohesion. However, RAD21 is dispensable for meiotic cohesion and although SMC1 and SMC3 are present on meiotic centromeres and on synapsed chromosome arms, as expected, their functions in meiosis remain poorly characterized. Moreover, unlike in other eukaryotes in which screens for meiotic cohesion genes have revealed meiosis-specific cohesin paralogs such as the conserved RAD21 paralog REC8, similar screens in Drosophila identified three novel genes that encode meiosis-specific centromere proteins (SOLO, ORD and SUNN (SOS)) with no apparent similarity to cohesins. Loss-of-function mutations in all three genes disrupt centromere cohesion and SMC1/3 centromere localization, and cause random chromatid segregation. We are investigating the role of cohesins in *Drosophila* male and female meiosis by using germ-line specific RNAi (RNA interference) to deplete one of the core cohesins - SMC3. When we knockdown SMC3 in the male germline we observe premature loss of cohesion between the sister centromeres of some (but not all) chromosomes during prophase I, and numerical mis-segregation of major autosomes (2^{nd} and 3^{rd}). Surprisingly, however, cohesion and segregation of the sex chromosomes is nearly unaffected by depletion of SMC3. Even more remarkably, SMC3 knockdown in the female germline has no apparent effect on centromere cohesion. This result is probably not due to incomplete depletion of SMC3 as synaptonemal complexes (which require SMC1 and SMC3 as components of the lateral elements) are completely eliminated in the SMC3-depleted oocytes. We show that despite the absence of cohesin proteins from centromeres, SOLO localizes normally to the centromeres in SMC3 knockdown in both male and female germlines. These results suggest the hypothesis that SOLO along with SUNN and ORD can provide cohesion to centromeres in the absence of the cohesins. This is the first clear evidence for a non-cohesin-based cohesion mechanism in any eukaryote.

D1083B The role of the endoplasmic reticulum during asymmetric cell division in *Drosophila melanogaster*. *S. A. Beyeler*. San Francisco State University, San Francisco , CA.

A crucial step for multicellular organism success is proper asymmetric cell division. Little is known about how organelles like the endoplasmic reticulum (ER) are partitioned during asymmetric cell division. While we know the ER will divide asymmetrically during asymmetric cell divisions, we don't know what is regulation this movement. Drosophila melanogaster offers a great model for asymmetric cell division, in their larval neural stem cell divisions. Our lab has shown the intermembrane ER protein, jaugunal, will partition to only one daughter cell during asymmetric cell division in embryonic neural stem cells. As jagunal null mutant flies die in 2^{nd} instar we want to investigate if this death is due in part to improper asymmetric cell division in larval neural stem cells. This lead to the hypothesis that jagunal is part of a regulation pathway partitioning the ER during asymmetric cell division in larval neural stem cells. To test this, we used fluorescent immunostaining with confocal microscopy to visualize known cell polarity markers, aPKC (localizes apically) and prospero (localizes basally), to see if they were affected during cell division by a lack of jagunal. We found that both aPKC and prospero localize properly in the absence of a functional jagunal. This could mean that jagunal and the ER is acting upstream of cell polarity to affect daughter cell fate. Future studies will investigate jagunal's role in notch/delta signaling in the larval brain to find a regulation mechanism for ER asymmetry.

D1084C To get more for less: Thermodynamic versus active mechanisms of the nucleolus assembly. *H. Falahati*, E. Wieschaus. Princeton University, Princeton, NJ.

Cells are unique in their ability to avert thermodynamic equilibrium by spending energy, and yet to exploit the laws of thermodynamic to minimize their energetic costs. Although biochemical assays can determine whether a single reaction is active or thermodynamically driven, addressing this question becomes particularly challenging for complex in vivo phenomena such as the formation of multicomponent membrane-less organelles. There is growing evidence supporting the possibility that such organelles form as a new phase, separating from the cytoplasm or nucleoplasm. Any in vivo assessment of this hypothesis, however, requires a robust and unambiguous manipulation of the factors affecting phase transition processes. To tackle this problem we have developed an in vivo approach for unambiguous disentanglement of a thermodynamically driven phase separation from an active process. This approach is based on the different predictions of each of the two models in response to changes in temperature. To employ this approach we used a microfluidics device for accurate temperature control during confocal imaging, and quantitative image analysis to study the mechanism by which six different nucleolar proteins localize to the nucleolus in *D. melanogaster* embryos. Our results indicate that the nucleolus assembly in vivo is an interplay between thermodynamically driven phase separations and active assembly processes, with the localization of the individual proteins following one of these two distinct mechanisms.

D1085A SIRS is a spindle-independent mechanism of chromosome separation in mitotic polytene tissues. *B. Stormo*, D. Fox. Duke University, Durham, NC.

The canonical cell cycle alternates rounds of chromosome replication with chromosome segregation. This process ensures that at metaphase each chromosome is composed of a single pair of chromatids that can be bi-oriented by the spindle and segregated evenly. However, many cells undergo an alternate cell cycle termed the endocycle in which multiple rounds of DNA replication take place without intervening segregation. Endocycled tissues are traditionally thought of as being terminally differentiated. However, as we previously showed in the Drosophila rectum, as well as following treatment with many common mitosis blocking drugs, endocycled cells return to the mitotic cell cycle. How cells respond to the challenge of segregating reduplicated chromosomes is not well understood.

The Drosophila rectum provides a developmentally accessible model to answer this question., During rectal development, cells undergo two rounds of the endocycle and then undergo two rounds of mitosis. We find that despite re-entering mitosis with re-duplicated chromosomes, papillar cell division is relatively error free. Using a combination of live-imaging, pharmacology, genetics, and classical cytology we have defined a process that we call Separation Into Recent Sisters (SIRS). SIRS is a spindle- independent process that separates the developmentally programmed polytene chromosomes in the Drosophila rectum into individual pairs of sister chromatids prior to anaphase.

In contrast to the perfectly executed polytene separation during SIRS, mitosis after aberrant (non-programmed) endocycles is highly error prone and results in aneuploidy and cell death. SIRS is lacking in such cells, and as a result polytenes form conjoined chromosomes at anaphase. Further, we have found that while conjoined chromosomes following induced endocycles activate the mad1/mad2 dependent spindle checkpoint, SIRS instead relies on a checkpoint-independent function of mad2 to regulate the length of mitosis. Together, these data give important insights into how endocycled cells respond when they return to mitosis. These findings have relevance to both developing polyploid tissues as well as the many pathological conditions in which polyploidy plays a role.

D1086B ER-associated membrane contribution to cellularization furrows in *D. melanogaster* embryo morphogenesis. *E. Holt*, B. Riggs. San Francisco State University, San Francisco, CA.

Cellular blastoderm formation in the early *Drosophila melanogaster* embryo occurs as a synchronous compartmentalization of thousands of cortical nuclei during a specialized cytokinetic event known as Cellularization. This process is characterized by the formation of cellularization furrows invaginating between adjacent nuclei. This invagination has been shown to require the reorganization of intracellular membrane stores through endocytic pathways and most recently has been associated with morphological changes to microvillar membrane reservoirs. Currently it is not known if there are additional intracellular components involved in proper furrow formation and as such we are interested in the role of the endoplasmic reticulum and its capacity to act as an intracellular source of membrane. In preliminary investigations we find the ER-associated small GTPase Rab10, known to mark areas of ER-tubule growth, localizes to the ingressing cellularization furrow. We hypothesize that ER-tubule growth constitutes a novel source of membrane contribution during cellularization furrow formation. Here we investigate the role of Rab10 during morphogenesis of the early *D. melanogaster* embryo. Using time-lapse confocal microscopy we find that cellularization furrow formation kinetics are negatively affected in Rab10-deficient embryos using Rab10.RNAi under GAL4/UAS control. This data suggest a possible role for ER-associated membrane addition during growth phases of furrow ingression. A more detailed functional analysis is necessary to identify the role of ER growth during cellularization.

D1087C A cell cycle-regulated ArfGAP-Arf1 pathway for Golgi organization and cleavage furrow biosynthesis. *F. Rodrigues*, W. Shao, T. Harris. University of Toronto, Toronto, Ontario, CA.

Biosynthetic traffic drives plasma membrane growth. For early cleavage of the *Drosophila* embryo, this growth is rapid, but regulated, for repeated cycles of furrow ingression and regression. We report that furrow ingression requires Asap, a conserved Arf GTPase activating protein (GAP). Although Asap has several known effects, our genetic analyses argued that furrow loss with *asap* RNAi was linked predominantly to reduced Arf1 function at the Golgi. Moreover, Arf1 levels at the Golgi displayed a direct relationship with total cellular levels of Asap. Although Asap lacks Golgi enrichment, a conserved residue for Arf1 regulation by Asap was required for Golgi organization and output. We propose that

Asap maintains Arf1 activity at the Golgi by recycling Arf1 from post-Golgi compartments. This role appears essential for cell division, and is thus unlike the roles of characterized Golgi Arf GAPs which act redundantly for cell viability. Strikingly, Asap re-localized to the nuclear region at metaphase, a shift that coincided with transient Golgi re-organization preceding cleavage furrow regression. Thus, we further propose that Asap sequestration underlies periods of Golgi attenuation and furrow regression during the cell cycle.

D1088A Anillin and Citron Kinase, Sticky, collaborate during the contractile ring-to-midbody ring transition. *D. Wernike*, N. El Amine, A. Kechad, G. Hickson. Sainte-Justine Hospital Research Center, Montreal, Quebec, CA.

Cytokinesis, the final phase of cell division, physically separates one cell into two daughter cells. Its spatiotemporal control is crucial for metazoan development, and failures in the cytokinetic machinery often are associated with the formation of cancer. During cytokinesis, an actomyosin contractile ring (CR) constricts and transitions into the midbody ring (MR), a structure that forms around the midbody as it matures from the midzone microtubules (MTs) that become compacted during CR closure. In *Drosophila* S2 cells, we recently showed that the conserved scaffold protein Anillin promotes the transition from CR to MR. During this maturation process, the Citron kinase Sticky retains Anillin's N-terminus for incorporation into the MR, while the septin Peanut acts on the C-terminus of Anillin to remove excess Anillin and membrane via shedding. We found that Anillin-depleted S2 cells not only fail to form a proper MR, but also are deficient in forming a constricted zone of MTs at the midbody. Interestingly, Sticky-depleted cells, which also fail MR formation and cytokinesis, exhibit no earlier MT defects at the midbody. Hence, MR formation (Sticky-dependent) and midbody maturation (Sticky-independent) are two separable Anillin-dependent events, which we aim to further dissect in this study. Using a diverse panel of Sticky and Anillin truncations combined with live imaging and RNAi of endogenous proteins, we are currently defining the contributions of specific domains of Sticky and Anillin required for their normal CR localization and retention at the MR. Because shedding depends on Anillin, and not on Sticky, removal of Sticky likely occurs via its association with Anillin. Surprisingly, we found that Sticky-ΔRBD-FP is shed, but fails to retain Anillin at the MR, suggesting that Sticky's association with Anillin and its ability to form a stable MR may be separate events. Also, our preliminary data from immunoblotting suggest that the very N-terminus of Anillin is sufficient to pull-down Sticky from S2 cell lysate. Taken together, this work will strengthen our understanding about how the cell cortex is organized and re-organized in a mechanistic way to ensure the robustness of cytokinesis.

D1089B Mechanotransduction mechanisms in compensatory cellular hypertrophy. *K. Morimoto*[1,2], E. Suzuki[2], W. Deng[3], Y. Tamori[2]. 1) Keio University, Fujisawa, JP; 2) National Institute of Genetics, Mishima, JP; 3) Florida State University, Tallahassee, FL.

In multicellular organisms, tissue integrity and organ size are maintained through removal of aberrant or damaged cells and compensatory proliferation. The sensing and removal of aberrant cells by their neighbors involve cell competition, a remarkable homeostatic process at the cellular level. In proliferating tissues, cell division is the primary strategy winner cells use to compensate for the loss of loser cells during cell competition. In post-mitotic *Drosophila* follicular epithelia, however, we have shown that the loss of local tissue volume resulting from loser-cells elimination triggers sporadic cellular hypertrophy to repair the tissue. This ''compensatory cellular hypertrophy'' (CCH) is implemented by polyploidization through the endocycle, a variant cell cycle composed of DNA synthesis and gap phases without mitosis, dependent on activation of the insulin/IGF-like signaling (IIS) pathway. Furthermore, several lines of evidence in our study suggest that the IIS-dependent CCH is triggered by tensile forces resulting from the elimination of loser cells. Using stretched follicle cells as a model system, we found that a transient receptor potential (TRP) channel is involved in the process of mechanotransduction. Given the fact that similar hypertrophic cellular growth can be observed in different contexts such as *Drosophila* epidermis, mammalian hepatocytes or corneal endothelial cells, the tension-induced compensatory cellular hypertrophy is likely a conserved strategy for postmitotic tissue homeostasis.

D1090C A screen using FijiWings reveals the E3 Ubiquitin Ligase Neuralized as a novel Tribbles target. *A. Shipman*, L. Dobens. Sch Biological Sci, UMKC, Kansas City, MO.

The Drosophila wing is an ideal tissue to examine how cell proliferation is coordinated with cell growth to pattern proper tissue size. We have developed FijiWings, a set of macros that automate plug-ins in the ImageJ/Fiji software, to accomplish morphophometric analysis of wing features. FijiWings uses pattern recognition to outline wing veins and calculate tissue size and image processing to identify individual trichomes and calculate cell size. Using a misexpression approach, we have shown previously that FijiWings can effectively detect changes in both tissue and cell size resulting from manipulations of the insulin signaling pathway. We have used FijiWings to reveal that misexpression of the Tribbles pseudokinase, which binds and blocks the activity of key regulatory molecules that mediate insulin-regulated cell growth and cdc25-triggered cell proliferation, decreases overall wing tissue size but increases the size of individual cells. Using Fijiwings, we screened the Basler collection of growth regulatory genes for modifiers of the Tribbles wing misexpression phenotype and identified several potential Trbl interactors, including multiple E3 ubiquitin ligases. One of these E3 ubiquitin ligases is Neuralized, a component of the Notch signaling pathway, and here we present data from several approaches designed to validate the interaction between Tribbles and Neuralized to better understand a general mechanism for Tribbles regulation of RING-finger E3 ubiquitin ligases.

D1091A Crosstalk between mitochondrial fusion and the Hippo pathway in controlling cell proliferation during *Drosophila* development. *Q. Deng*[1,2], T. Guo[1,2], X. Zhou[2,3], Y. Xi[1,2], X. Yang[1,2], W. Ge[1,2]. 1) Institute of Genetics, Zhejiang University School of Medicine, Hangzhou,China 310058; 2) College of Life Sciences, Zhejiang University, Hangzhou, China 310058; 3) Skate Key Laboratory of Biotherapy and Cancer Center, West China Hospital,Sichuan University, Chengdu, China.

Cell proliferation and tissue growth depend on the coordinated regulation of multiple signaling molecules and pathways during animal development. Previous studies have linked mitochondrial function and the Hippo signaling pathway in growth control. However, the underlying

molecular mechanisms are not fully understood. Here we identify a Drosophila mitochondrial inner membrane protein ChChd3 as a novel regulator for tissue growth. Loss of ChChd3 leads to tissue undergrowth and cell proliferation defects. ChChd3 is required for mitochondrial fusion and removal of ChChd3 increases mitochondrial fragmentation. ChChd3 is another mitochondrial target of the Hippo pathway, although it is only partially required for Hippo pathway mediated overgrowth. Interestingly, lacking of ChChd3 leads to inactivation of Hippo activity under normal development, which is also dependent on the transcriptional co-activator Yorkie (Yki). In addition, depletion of two other mitochondrial fusion compoents, Opa1 and Marf, inactivates the Hippo pathway as well. Taken together, we propose that there is a crosstalk between mitochondrial fusion and the Hippo pathway which is essential in controlling cell proliferation and tissue homeostasis in Drosophila.

D1092B Yorkie activates transcription by recruiting the histone deacetylase HDAC1 and promoting histone deacetylation. *W. Ge*[1,2,4], F. Wang[1,2], Z. Nan[1,2], Z. Wang[1,2], J. Zhang[3], P. Guo[1,2], J. Lv[1,2], X. Xu[1,2], L. Wu[1,2], T. Guo[1,2], Q. Deng[1,2], Q. Zhou[3], X. Yang[1,2,4], Y. Xi[1,2,4]. 1) Institute of Genetics, Zhejiang University School of Medicine, Zhejiang University, Hangzhou, China 310058; 2) College of Life Sciences, Zhejiang University, Hangzhou, China 310058; 3) Life Sciences Institute, Zhejiang University, Hangzhou, China 310058; 4) Department of Genetics, Zhejiang University School of Medicine, Zhejiang University, Hangzhou, China 310058.

Control of organ size is a fundamental aspect in biology and plays important roles in development. The Hippo pathway is a conserved signaling cascade that controls tissue and organ size through the regulation of cell proliferation and apoptosis. Here, we report on the roles of *Drosophila* histone deacetylase HDAC1 in regulating the Hippo signaling pathway. Loss of HDAC1 function causes tissue undergrowth and the downregulation of Hippo target gene expression. Furthermore, Hippo pathway-mediated overgrowth and target gene expression are dependent on HDAC1. Mechanistically, we show that HDAC1 associates with the transcriptional coactivator Yorkie (Yki), and they co-occupy sites on chromatin at Hippo target gene loci. Finally, we provide evidence that Yki recruits HDAC1 to promote histone H3 lysine 27 (H3K27) deacetylation at Hippo target genes. Taken together, our findings suggest that recruiting of the histone deacetylase HDAC1 to Hippo target genes by Yki is required to activate gene expression, and highlight a positive role for HDAC1 in controlling specific gene expression program.

D1093C Role of Tctp interaction with a septate junction protein Coracle in imaginal disc development. *S. Lee*. KAIST, Daejeon, KR.

Translationally controlled tumour protein (TCTP) is a highly conserved protein in eukaryotes and has been implicated in multiple events, including growth control. To find new roles of TCTP *in vivo*, we performed biochemical and genetic screens for TCTP-interacting genes. From this screen, we identified Coracle (Cora) as a new binding partner of TCTP. Cora is a septate junction protein of the protein 4.1 family required for maintaining the transepithelial barrier and the apical basal epithelial polarity together with Yurt, Neurexin Ⅳ and Na^+/K^+ ATPase. We show that *cora* mutations enhance the phenotypes of TCTP knockdown by RNAi expression, resulting in synthetic lethality or headless flies depending on the affected tissues. Biochemical analyses indicate that Cora forms a complex with TCTP by direct binding. Loss of Cora causes decreased levels of TCTP protein and affects Arm expression. Loss of TCTP also shows reduction of Cora and Arm expression. Further, TCTP and Cora show overlapping localization in epithelial tissues. We also identified additional biochemical and genetic interaction of TCTP with other septate junction genes. Taken together, this study suggests a novel linkage between TCTP and the septate junction proteins implicated in growth regulation.

D1094A A matter of growth and death: An unexpected output of the Hippo Network in the *D. melanogaster* trachea. *S. S. McSharry*, C. Feng, G. J. Beitel. Northwestern University, Evanston, IL.

The infamous and highly conserved Hippo Network, well known for controlling cell and tissue size, also regulates the size of the tube-shaped tracheal system of the developing fruit fly, but in an unexpected way. Mutations in HN genes cause tracheal size phenotypes that are the opposite of the same mutations in other tissues. For example, a loss-of-function mutation in Yorkie (Yki), the transcription factor regulated by the Hippo Network, yields reduced eye or wing size, due in part to increased apoptosis. However, as we have previously reported, the same Yki mutation causes tracheal overgrowth without affecting cell number. This phenotype is ultimately due to loss of Yki-dependent over-activation of Ice, the fly homologue of the mammalian executioner caspase-3, a protein that is both necessary and sufficient to execute cell death in most cells. Here, we report that activated (cleaved) caspase is enriched at the apical surface of tracheal cells in both wild-type and Yki mutant embryos. This result suggests that the non-apoptotic target(s) of Ice that regulate tube size may also be localized to the apical surface. Moreover, compartmentalization of Ice at the apical surface may allow activation of non-apoptotic targets without cleavage of apoptotic targets. Increased staining of activated Ice is observed in some tracheal tube-size control mutants, and we are presently using this assay to investigate which tracheal genes may regulate tracheal tube size by modulating Ice activity. We also present results from epistasis experiments that explore the complex relationships between and among members of the HN such as Yki and Ice, and known regulators of tracheal size, including components of the septate junction.

D1095B Kibra and Merlin orchestrates activation of Hippo pathway core kinases cassette independent of Expanded *in vivo*. *T. Su*, M. Ludwig, R. Fehon. The University of Chicago, Chicago, IL.

Kibra, Merlin and Expanded function as upstream components of the Hippo pathway to regulate the activity of the core kinase complex, consisting of Hippo, Salvador and Warts. Previous biochemical studies indicated that Kibra, Merlin and Expanded form a complex and function together to activate the downstream kinases, but genetic experiments have suggested that Merlin and Kibra function in parallel to Expanded. To better understand the functional relationships between upstream components in relation to the core kinases, we have examined their functions in living tissues using fluorescently-tagged, endogenously expressed pathway components. Interestingly, while a recent study has shown that Expanded organizes pathway components in the apical junctional region of imaginal epithelial cells, we find that Merlin and Kibra

organize a distinct signaling complex at the apical cortex that is medially rather than junctionally localized. Gain- and loss-of-function experiments indicate that Kibra plays a key role in organizing this apical medial signaling center by recruiting both Salvador and Hippo. Merlin functions to promote Kibra-mediated recruitment of Salvador. Furthermore, we have found that Crumbs, which is localized junctionally, functions to negatively regulate the activity of this signaling complex by tethering Kibra at the junctions, despite the fact that loss of function Crumbs mutants have a modest overgrowth phenotype. Together, our studies reveal the complexity with which Hippo pathway activity is regulated, and suggest new mechanisms for pathway control in developing epithelia.

D1096C Characterization of *rio* (*CG11340*) as a regulator of tissue-specific growth in the larval trachea of *Drosophila*. *Robert Ward*, Kayla Wilson, Erin Suderman. Univ Kansas, Lawrence, KS.

During post-embryonic development in animals, organs and tissues grow at different rates relative to each other, which is likely tied to the unique requirements of each organ's function during development. Tissue-specific growth mechanisms can generate allometric differences that vary between individuals within a species and play critical roles in interspecific divergence. The fact that organs grow at different rates suggests that there must be tissue-specific mechanisms to control their differential post-embryonic growth trajectories, although surprisingly we know little about them. To gain a better understanding of these tissue specific growth mechanisms, we have been characterizing mutations that specifically alter the growth of the larval trachea in *Drosophila melanogaster*. Larval trachea growth is well suited for these studies since the trachea shows allometric growth during the larval stages, the trachea can be imaged and measured in living animals, gene expression can be specifically altered in the trachea using *breathless-GAL4*, and genes have been identified that appear to regulate tissue-specific growth in the larval trachea. Specifically, animals with mutations in *uninflatable (uif)* and *Matrix metalloproteinase 1 (Mmp1)* have larval tracheae that are roughly half the relative size of those in wild type animals. Through a screen of EMS-induced larval lethal mutations, we identified three allelic mutations that show substantially increased trachea to body length proportions in late third instar larvae. We named this gene *rio* based upon its long and winding tracheal phenotype. Whole genome sequencing followed by deficiency and specific mutation complementation tests revealed that *rio* mutations map to *CG11340*, which encodes a glycine gated chloride channel. Characterizing of *rio* mutants indicated that the enhanced tracheal growth occurs primarily in late 3rd instar, and in an extended late larval period (beyond when their heterozygous siblings pupariate). Enhanced tracheal size is not associated with increased cell number per metamere. In addition, the taenidia in *rio* mutant trachea appear normal. Interestingly, Uif expression appears to be generally higher in *rio* mutant trachea, with small numbers of individual cells showing a stochastic strong upregulation of Uif expression. *RNAi* of *CG11340* in trachea using *breathless-GAL4* recapitulates these tracheal phenotypes, whereas *RNAi* of *CG11340* in various imaginal discs have no obvious effect on growth or differentiation of these tissues.

D1097A Genetic manipulations of EGF ligands in motor neurons affect myoblast proliferation and muscle patterning in Drosophila. *Darren Wong*, Kole Sedlack, Erin Enright, Katie Lincoln, Arya Chalke, Kumar Vishal, Fernandes Joyce. Miami University, Oxford, OH.

Two phases of myogenesis occur in *Drosophila*- the embryonic period during which larval muscles develop, and the pupal period during which adult muscles develop. Adult myogenesis is dependent on innervation and embryonic is not (Fernandes and Keshishian, 1999). This allows us to explore how the nerve may signal to myoblasts or organizer cells. This is important, because vertebrate skeletal muscles also depend on innervation for their development. We use the indirect flight muscles of the fly as a model system- these ar esome of the largest muscles in the fruifly. Based on previous studies [Fernandes and Keshishian, 2005], the influence of motor neurons on myoblast proliferation was proposed to be brought about through the founder cell. This has been confirmed by 2 sets of preliminary data (1) Ablation of founder cells causes a 30% reduction in BrDU positive myoblasts, which is similar to what is seen during denervation (2) Blocking EGF signal reception in myoblasts causes 20% reductions in proliferation and causes patterning defects in 95% of animals. To test if the motor neuron was the source of signals, we have used two approaches- Blocking the synthesis of EGF ligands and overexpressing the signals. The number of adult nuclei in sections of adult muscles can be used as an indicator of the extent of myoblast proliferation. Our results thus far show that spitz and vein are predominant EGF ligands that mediate the neuronal influence on organizer cells to influence myoblast proliferation. Blocking synthesis with RNAi caused decreased number of nuclei in adult muscles, and conversely overexpression caused an increase in the number of nuclei. Our results indicate that the EGF signaling pathway operates during the motor neuron mediated proliferation of myoblasts during myogenesis.

D1098B Investigating the role of epithelial curvature in growth control. *Lina ZHANG*[1,2], Tiantian JI[1,2], Xianwei CHEN[1,2], Hongkai LIU[1,2], Yan YAN[1,2]. 1) HKUST, Division of Life Science, Hong Kong, China; 2) HKUST, Center for Systems Biology and Human Health, Hong Kong, China.

Epithelial cells are highly polarized cells with distinct apical and basolateral domains defined by specific protein complexes. The conserved Scribble module localizes at the basolateral region. It consists of three scaffold proteins, namely Scribble (Scrib), Discs large (Dlg) and Lethal giant larvae (Lgl). The Scribble module was originally identified in *Drosophila* as a group of "neoplastic tumor suppressor genes" (nTSGs). *Drosophila* imaginal disc cells homozygous mutant for the Scribble module genes grow into tumors that are disorganized, undifferentiated, lethal and transplantable. In mammals, loss of the Scribble module function is also linked with epithelial tumor progression.

We noticed that the cells deficient for the Scribble module show location-dependent growth phenotypes. Specifically, the Scrib and Dlg deficient cells can only grow into tumor-like masses in the highly curved epithelial regions including the hinge region of wing imaginal discs and the polar region of the follicular epithelia. We found that the ectopic activation of myosin II activity induces folding in the flat wing pouch region and rescues the Scrib and Dlg deficient cells from cell competition-induced elimination. The folded wing hinge region exhibits higher Yki activity. Moreover, MDCK and MCF10A cells cultured on curved surfaces display differential YAP/TAZ activity correlating with the substrate

curvature. These data indicate that the curvature might play a role in modulating the epithelial baseline Yki activity and thus influence the growth outcome of the nTSG mutant cells.

D1099C Elucidating the role of various signaling pathways in *lgl* derived tumors in *Drosophila* egg chambers. *Deeptiman Chatterjee*, Wu-min Deng. Florida State University, Tallahassee, FL.

Major signaling pathways have been conserved between *Drosophila* and humans, making the former a good model organism for cancer research. Loss of polarity and tissue organization being one of the prominent characteristics of epithelial-derived cancers, it has been widely studied in *Drosophila*. Some of the first apical-basal polarity genes that regulate tissue organization have been studied in *Drosophila* egg chambers, the spatiotemporal development of which is quite well characterized. Many of these genes act as tumor suppressors in the epithelial follicle cells as they maintain the polarity and prevent defective overgrowth in the epithelia. One such tumor suppressor is the *lethal Giant Larvae* or *lgl*, a polarity-determining gene that works in consort with others such as *dlg* and *scrib* to characterize the basolateral region of the epithelial cell. Loss of *lgl* function results in rampant loss in polarity and an overgrowth phenotype. The spatiotemporal dynamism of follicular epithelia provides a unique opportunity to elucidate how various signaling pathways, namely the *JAK-STAT, JNK, Hippo* and *Notch*, act with each other to promote overgrowth and metastasis in *lgl*-derived tumors. Using various cell signaling reporters, antibody staining and tissue-specific Gal4 drivers to knockdown gene expression, we have found growth-promoting roles of JAK-STAT and JNK pathways in *lgl* tumors. We have also found that while the Hippo pathway is important in promoting Notch signaling in the regulation of cell differentiation and growth, its disruption causes a loss of polarity in the epithelia. We have also investigated the role of the *Hippo* and *Notch* pathways in causing overgrowth phenotype in *Drosophila*..

D1100A Pointed/ETS acts as a novel tumor suppressor that regulates Ras-mediated cellular senescence. *T. Ito*[1], M. Enomoto[1], T. Igaki[1,2]. 1) Laboratory of Genetics, Graduate School of Biostudies, Kyoto University, Kyoto, Japan; 2) PRESTO, Japan Science and Technology Agency (JST), Saitama, Japan.

Oncogenic activation of Ras is often not sufficient for driving malignant progression, because it can cause premature senescence. This suggests that mutations in the regulators of cellular senescence could cooperate with oncogenic Ras to drive tumor progression. Here, we performed a genetic screen in *Drosophila* eye imaginal discs to identify dominant mutations that cause tumor progression in conjunction with oncogenic Ras (Ras^{V12}). Using the MARCM technique, we induced mosaic expression of Ras^{V12} in the eye discs and simultaneously introduced a series of heterozygous chromosomal deficiencies. As a result, we identified a mutation in the ETS transcriptional activator Pointed (Pnt) as a strong dominant-enhancer of Ras^{V12}-induced tumorigenesis. In addition, overexpression of Pnt dramatically inhibited Ras^{V12}-induced tumor overgrowth. Interestingly, we found that loss of Pnt abrogated Ras^{V12}-induced cellular senescence. Our data show that Pnt acts as a novel tumor-suppressor that regulates Ras-mediated cellular senescence in *Drosophila*.

D1101B Myc regulates cytoophidium formation. *J. L. Liu*, G. Aughey, S. Grice. Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford OX1 3PT, United Kingdom.

The coordination of metabolism with cell growth is critical for regulation of organismal development. Therefore there is significant interplay between metabolic enzymes and key developmental regulators such as transcription factors. The enzyme CTP synthase (CTPsyn) is essential for metabolic homeostasis as well as growth and development, due to its role in synthesising precursors for many fundamental cellular macromolecules such as RNA and lipids. However, the mechanisms by which CTPsyn is regulated during development are little understood. Here we have shown that Myc, an oncogene and a key development regulator, is necessary and sufficient for the assembly of CTPsyn-containing macrostructures termed cytoophidia. We show that the presence of CTPsyn is required for Myc to mediate its effect on cell growth during *Drosophila* development. Roles for CTPsyn and Myc in tumourigenesis have been well established and both proteins have been considered promising therapeutic targets. By better understanding the relationship between these two proteins, we can gain important insights, not only into tumour pathology and aetiology, but also metazoan developmental processes.

D1102C A distinct tumor suppressor role of Snr1 from the SWI/SNF complex in *Drosophila* imaginal tissues. *Gengqiang Xie*, Wu-Min Deng. Florida State University, Tallahassee, FL.

Components of the SWI/SNF chromatin-remodeling complex are among the most frequently mutated genes in various human cancers, yet only SNF5, a core member of the SWI/SNF chromatin-remodeling complex, is found mutated in malignant rhabdoid tumors (MRTs), which are primarily found in young children. How SNF5 functions differently from other members of the SWI/SNF complex remains unclear. Here we use *Drosophila* imaginal epithelial tissues to demonstrate that Snr1, the conserved homolog of human SNF5 (hSNF5), prevents tumorigenesis by ensuring normal endosomal-trafficking-mediated signaling cascades. We show that disruption of *snr1* causes massive apoptosis in the wing pouch area and obvious overgrowth in the notum region of imaginal discs. Blocking apoptosis by coexpression of the anti-apoptotic protein p35 in *snr1*-knockdown cells results in neoplastic tumorigenic overgrowth in imaginal epithelial tissues, whereas depletion of any other members of the SWI/SNF complex does not induce similar phenotypes. The *snr1*-knockdown-induced tumors show multiple hallmarks of cancer, including sustained proliferation, altered metabolism, and dedifferentiation. Unlike other components of the SWI/SNF complex which are only detected in the nucleus, Snr1 is observed in both the nucleus and the cytoplasm. The cytoplasmic function of Snr1 is probably necessary for endosomal trafficking, because components of the trafficking signaling pathway are enriched in *snr1*-depleted cells and transmembrane proteins are accumulated in the cell surface. Further experiments demonstrate that aberrant regulation of multiple signaling pathways, including Notch, JNK, and JAK/STAT is responsible for *snr1*-loss-of-function-mediated tumor progression. RNA profiling of *snr1*-

depleted tumors by RNA-Seq analysis confirms that, indeed, several signaling targets are transcriptionally degregulated. Our data provide an alternative way to understand the mechanism of how hSNF5 suppresses MRTs during early childhood. The detailed results will be presented in the 57th Annual *Drosophila* Research Conference @TAGC.

D1103A Oncogenic properties of Troponin-I. *S. Casas-Tinto*, A. Ferrús. Cajal Institute, Madrid, Madrid, ES.

Human tumors of various tissue origins show an intriguing overexpression of genes not considered oncogenes, such as that encoding Troponin-I (TnI), a well-known muscle protein. Out of the three TnI genes known in humans, the slow form, *TNNI1*, is affected the most. *Drosophila* has only one gene that encodes all forms of TnI, *wupA*. Here, we carried out a study on excess- and loss-of function conditions for *wupA* in *Drosophila*, and assayed *TNNI1* down regulation in human tumors growing in mice. *Drosophila* TnI excess-of-function causes tissue overgrowth and potentiates the phenotypes due to oncogenic mutations in Ras, Notch and Lgl genes. By contrast, TnI loss-of-function reduces proliferation and antagonizes the overgrowth due to these oncogenic mutations. The conserved Hippo signaling pathway requires the up-regulation of TnI for tumor overgrowth. Troponin-I defective cells exhibit aberrant number of centrosomes, multiple double strand DNA breaks and undergo Flower-dependent cell competition in the wing disc. Human tumor cell lines treated with a human Troponin-I peptide arrest in $G_{0.}$ In addition, the proliferation of non-small-cell lung carcinoma xenografts in mice is restrained by down-regulation of the *TNNI1* gene. Thus, Troponin-I reveals as a novel oncogene that links abnormal cell signaling, proliferation, genome integrity and tumor growth, and may open the possibility for a novel therapeutic target/marker.

D1104B A shared loser molecular signature identifies stress signaling pathways common to loser cells, which play distinct roles in cell competition. *M. P. Dinan*, I. Kucinski, E. Piddini. Gurdon Institute, University of Cambridge, Cambridge, UK.

Cell competition is a process by which a population of fitter cells (winners) outcompetes neighbouring weaker cells (losers), inducing their elimination by cell death or differentiation. This mechanism has been proposed to a play role in tissue health and turnover and in disease states such as cancer. There are many known mutations, which can induce a loser status, however despite its discovery four decades ago, the molecular properties of cells that earmark them as losers have not been identified.

To identify molecular differences between winner and loser cells we generated and analysed RNAseq data from control (wild-type) cells and from a subset of loser mutations, from *Drosophila* wing imaginal discs in the absence of cell competition. We focused on two mutations, which are seemingly functionally unrelated, yet share the loser phenotype: *Minute* (ribosomal) heterozygous mutations and a mutation in *mahj* (involved in cell polarity and protein degradation). To enrich for genes involved in the loser cell status we focused on the intersection of genes that were differentially expressed in both of these mutants compared to the wild type. This intersection includes genes indicative of a constitutively activated stress response, encompassing JNK, JAK/STAT, p53/DNA damage and oxidative stress response pathways. We then assessed the functions of these pathways in loser cells. While some pathways have an autonomous pro-survival role, we found that others can specifically modulate cell competition. In particular the JAK/STAT signaling pathway, activated by constitutive production of Unpaired ligands from loser cells, is important not only for loser cell proliferation, but also for cell competition, as it is responsible for the overgrowth of winner cells. Thus, winner cell overgrowth does not require winner-loser recognition, but stems directly from excessive availability of proliferative signals.

In summary, loser cells carrying *Minute* and *mahj* mutations exhibit a common molecular signature, which involves activation of stress and pro-survival pathways. JAK/STAT signaling autonomously promotes proliferation while, at the same time non-autonomously boosts growth of the competing winner population.

D1105C Dissecting a common principle underlying cell competition and wound healing. *C. Iida*, S. Ohsawa, M. Yamamoto, T. Igaki. Kyoto university graduate school of biostudies, Kyoto, Kyoto, JP.

Cell competition is a form of cell-cell interaction that can eliminate oncogenic mutant cells from the epithelia tissue. For instance, clones of oncogenic cells mutant for apico-basal polarity genes such as *scrib* or *dlg* are actively eliminated from the tissue when surrounded by wild-type cells. We have recently identified the Sas-PTP10D system as a ligand-receptor system required for this tumor-suppressive cell competition. To investigate the physiological role of the Sas-PTP10D system, we focused on the process of wound healing, as it is crucial for epithelial homeostasis and has been considered to share a common principle with cancer, namely cancer as an overhealing wound. After cutting the *Drosophila* wing imaginal disc, the wound is usually healed during development and it generates a normal wing in the adult. We found that defects in the Sas-PTP10D system significantly inhibited the wound healing. Our data also indicated that the Sas-PTP10D system regulates wound healing by modulating the Hippo pathway through EGFR and JNK signaling. The mechanism by which the Sas-PTP10D system regulates wound healing will be discussed.

D1106A Functional analysis of the Ribosome protein mutant in cell competition. *Zhejun Ji*, Abhijit Kale, Marianthi Kiparaki, Nicholas Baker. Albert Einstein College of Medicine, Bronx, NY.

Cell competition can occur between distinct genotypes within multicellular organs. We mapped a recessive mutation that prevents competition of RpL36+/- cells to the gene encoding Ribosomal Protein S12. Null alleles of RpS12 are recessive lethal, and we have generated several transgenic fly lines and showed that null alleles can be rescued by genomic constructs lacking the major introns and their encoded snoRNAs, confirming that it is the protein coding region that is essential. We have also produced RpS12 specific antibodies and demonstrated their specificity by immunoprecipitation and immunostaining assays. We have described the localization of the RpS12 protein in wild type and Minute genotypes, and in the suppressor allele for cell competition. Immunostaining of Drosophila salivary glands and wing imaginal discs

showed that RpS12 is mainly distributed in the cytoplasm. A substantial amount of RpS12 is also detected around the nucleolus. There is no clear difference for the cellular localization among these three genotypes. Future work will be focused on mapping the region of RpS12 protein that is important in cell competition and its mechanism of action.

D1107B RpS12 role in cell competition. *Marianthi Kiparaki*, Zhejun Ji, Abhijit Kale, Nicholas Baker. Albert Einstein College of Medicine, Bronx, NY, NY.

Cell competition is a homeostatic mechanism, which non-autonomously determines the fate of the cells- to die (lose) or to thrive (win). This phenomenon was originally described 40 years ago to occur between wild type cells (winners) and cells that are haploinsufficient for ribosomal proteins (which are called Minute cells-losers). Since then, cellular differences in a handful of genes have been described to trigger cell competition. Previous members in our lab conducted an EMS unbiased genetic screen to identify mutations that permit the survival of Minute cells during cell competition. Interestingly, one of these mutations was mapped in the ribosomal protein gene RpS12. RpS12 homozygous mutant flies are viable, fertile, with no obviously identifiable phenotype. We are currently in the process of investigating the role of RpS12 in cell competition. By sucrose density gradient analysis, we have shown that the mutant form of RpS12 is able to assemble into the ribosomes in vitro (S2 cells) and in vivo (fly tissues). Our polysome analysis also showed that RpS12 exists in extra-ribosomal fractions. Our efforts are now being directed towards the characterization of the potential extra-ribosomal role of RpS12 by purification of RpS12 complexes. It is tempting to think RpS12 as an internal ribosome-quality control factor that helps to identify the less ribosome-efficient cells in the tissue and eliminate/restrict them for the flourishing of the organism.

D1108C Epithelial Slit-Robo signaling regulates tumor-suppressive cell competition. *J. Vaughen*[1], T. Igaki[1,2]. 1) Laboratory of Genetics, Graduate School of Biostudies, Kyoto University; 2) PRESTO, Japan Science and Technology Agency (JST).

Dynamic cellular interactions occur between heterogeneous cell populations during both development and tumorigenesis. Intricate cellular communication also underpins 'cell competition', a conserved tumor-suppression mechanism whereby aberrant "loser" cells are actively eliminated by neighboring "winner" cells. For example, while *Drosophila* tissue mutant for conserved apicobasal-polarity gene *scribble* (*scrib*) forms lethal neoplasms, mosaic clones of *scrib* cells are eliminated by neighboring wild-type cells. While cell competition is conserved in vertebrates and can similarly function as a tumor-suppressor, the mechanisms underlying how cell competition enforces homeostasis remain incompletely understood.

To gain insight into cell competition, we conducted a genetic deficiency screen in *Drosophila* eye epithelia mosaic for *scrib* and wild-type cells. We identified the axon-guidance signaling system, Slit-Roundabout (Robo), as essential for proper *scrib* cell elimination. Heterozygosity for the secreted ligand *slit* or the transmembrane receptors *robo1* or *robo2,* but not *robo3*, caused aberrant *scrib* clone overgrowth. Moreover, Slit-Robo antibodies accumulated around specific populations of apically extruding *scrib* cells. Through genetic perturbation of Slit-Robo within or around *scrib* clones, we demonstrate that Slit acts locally on Robos inside *scrib* cells to extrude the aberrant loser cells away from the main epithelium. One source of the Slit ligand required for *scrib* cell competition is *scrib* loser cells, suggesting that Slit-Robo signaling is autocrine in the context of *scrib* competition.

Surprisingly, while Robo-overexpression in *scrib* cells drastically enhanced apical extrusion of *scrib* clones, it also unexpectedly blocked *scrib* cell elimination. Instead, excessive extrusion merged *scrib* clones in the apical lumen and prevented proper cell competition. Thus, balanced Slit-Robo signaling and extrusion are essential for *scrib* cell competition and homeostasis. Notably, either loss or gain of Slit-Robo signaling is associated with various human epithelial cancers. Because cell competition also eliminates human cell lines mutant for *scrib*, epithelial Slit-Robo signaling could broadly enforce tumor-suppression and epithelial homeostasis through the removal of aberrant, precancerous loser cells.

D1109A The ligand Sas and its receptor PTP10D drive tumor-suppressive cell competition. *M. Yamamoto*, S. Ohsawa, K. Kunimasa, T. Igaki. Kyoto University, Kyoto, Japan.

Normal epithelial cells often exert anti-tumor effects against neighboring oncogenic cells. In *Drosophila* imaginal epithelium, clones of oncogenic cells mutant for apico-basal polarity genes such as *scrib* or *dlg* are actively eliminated from the tissue by cell competition when surrounded by wild-type cells. We and other groups have previously shown that JNK signaling is required for this cell elimination. However, the initial event occurring at the interface between normal cells and polarity-deficient cells remained unknown. To address this, we performed an EMS-based genetic screen in *Drosophila* eye imaginal disc and identified the ligand Sas and the receptor-type tyrosine phosphatase PTP10D as the cell-surface ligand-receptor system that drives tumor-suppressive cell competition. At the interface between wild-type "winner" and polarity-deficient "loser" cell clones, winner cells relocalize Sas to the lateral cell surface while loser cells relocalize PTP10D to the lateral cell surface. This leads to trans-activation of Sas-PTP10D signaling in loser cells that restrains EGFR signaling, thereby enabling elevated JNK signaling in loser cells to cause cell elimination. In the absence of Sas-PTP10D, elevated EGFR signaling in loser cells switches JNK's role from pro-apoptotic to pro-growth by impairing Hippo signaling, thereby causing overproliferation of polarity-deficient cells. These findings uncover the mechanism by which normal epithelial cells recognize oncogenic neighbors to trigger cell competition.

D1110B The subcellular distribution of Tribbles is linked to the regulation of growth and patterning by insulin and BMP signaling pathways. *L. L. Dobens*, Zachary Fischer, Jin-Yuan Fan, Alexander Nail. Univ Missouri, Kansas City, Kansas City, MO.

The pseudokinase Tribbles is a conserved adaptor protein that binds and mediates the proteasomal degradation of key signaling mediators to balance tissue growth and proliferation. Tribbles family members are found in all animals and share conserved targets, notably Akt kinase, which Tribbles binds and degrades to block insulin responses. Recently, mammalian Tribbles 3, has been shown to bind SMURF to block Smad

4 degradation and promote BMP signaling in tissue culture cells. We used a structure-function analysis of the highly conserved central pocket domain of Tribbles to identify a mutation Trbl[SLE/G] that changes the protein's subcellular distribution from cortical/nuclear to strongly cortical. This change in subcellular distribution of Trbl[SLE/G] results in a strong block of Akt phosphorylation and insulin-mediated growth. Misexpression of Trbl[SLE/G] in the wing unexpectedly disrupts cross vein formation suggesting that Tribbles may regulate BMP signaling and in support of this, we observe increased levels of phosphoMad levels in cell misexpressing Trbl[SLE/G]. We will present on-going work in several model tissues to test the notion that the conserved pocket domain of Tribbles regulates its subcellular distribution with consequent effects on BMP- and insulin-mediated growth.

D1111C Prominin-like, a homology of mammalian CD133, regulates body size by affecting dilps and inhibiting TOR pathway in *Drosophila*. *H. Zheng*[1], X. Wang[1], P. Guo[1], Y. Zhang[2], W. Ge[1], Y. Xi[1], X. Yang[1]. 1) ZheJiang University, HangZhou, CN; 2) Beijing Genomics Institute,ShangHai,CN.

CD133, a pentaspan membrane glycoprotein, is extensively used as a surface marker to identify and isolate stem-like cells. However, the molecular and biological functions of CD133 are not well understood. Here, we demonstrate that the *Drosophila* Prominin-like, a homology of mammalian CD133, regulates body size. We find that Prominin-like expression levels are regulated by ecdysone signaling and increase dramatically in the fat body during metarmorphsis. Interestingly, the *prominin-like* mutants exhibit bigger body size and excess body weight accompanied with higher fat deposits. Varied dilps transcriptional levels and up-regulated TOR are observed in the mutants. Whilst, overexpressing Prominin-like in insulin-producing cells (IPCs) induces a smaller body size. Taken together, these findings reveal that Prominin-like controls fly body size through affecting dilps and inhibiting TOR pathway, which may suggesting a novel function of CD133 on metabolism in cancer stem cells (CSCs) and cancers.

D1112A Acinus Links Autophagy and Hippo Signaling. *L. K. Tyra*, N. Nandi, H. Kramer. UT Southwestern Medical Center, Dallas, TX.

In a genome wide screen for interactors of Drosophila Acinus, a regulator of autophagy and endocytic trafficking, we discovered a strong genetic interaction between Acinus and members of the Hippo signaling pathway. For example, loss of one copy of Hippo suppresses the rough eye phenotype produced by GMR-Gal4 over-expression of Acinus. Additionally, over-expression of Acinus suppresses overgrowth caused by over-expression of the gain of function Yorkie-S168A. In order to better understand these genetic interactions, we screened Acinus gain and loss of function for developmental growth phenotypes. Over-expression of Acinus in the wing causes small wings with Engrailed-Gal4, Ms1906-Gal4, or Nubbin-Gal4. Similar to known negative regulators of Yorkie, knock-down of Acinus by two independent RNAi lines using the Engrailed-Gal4, Nubbin-Gal4, or Ms1096-Gal4 drivers causes wing over-growth. Finally, RNAi knock-down of Acinus in the wing causes increased expression of the *expanded, four-jointed,* and *thread (diap1) LacZ* reporters, which are used to measure Yorkie transcriptional activity. Taken together, these data suggest that Acinus is a negative regulator of the transcriptional output of the Hippo signaling cascade. A complex, yet poorly understood connection between autophagy and Hippo signaling has been shown in *Drosophila*; however a clear mechanism to connect these two critical processes remains unknown. Understanding if the connection between Acinus and Hippo signaling is autophagy dependent is a current focus of our research. Moreover, elucidating the mechanism by which Acinus is repressing transcriptional targets of Hippo signaling will provide valuable insight into its function in cellular processes critical for developmental cell growth, as well as cancer.

D1113B The interaction of social environment with genetic background, expression of Extra-Cellular Superoxide Dismutase and oxidative stress in *Drosophila melanogaster*. *J. D. Parker*[1,2], T. Segre[1], J. Tromblee[1], J. Binns[2]. 1) SUNY Plattsburgh, Plattsburgh, NY; 2) University of Southampton, Southampton UK.

Ruan and Wu (2008) discovered that social environment (specifically the presence of young individuals) can rescue the phenotype of a cytoplasmic superoxide dismutase mutant. We extended these findings by testing the presence of young individuals on an under expressing extra-cellular superoxide dismutase (EC SOD3) mutant fly line (Blackney et al. 2014), with and without an acute oxidative stress. We observed that young helpers extended the lifespan of the EC SOD3 mutants relative to the control line after both were exposed to paraquat. We also found that the presence of young helpers extended lifespan on one of two wild caught lines, but only after they were cleared of Wolbachia. We conclude that the observed positive social effects on aging seen in Ruan's study are dependent on other aspects of the enviornment including oxidative stress, endosymbiont infection and genetic background.

D1114C Hypoxia inhibits insulin signaling and regulates lipid metabolism in *Drosophila melanogaster* larvae through CDK8-dependent inhibition of the Gbb pathway. *z. Shen*, J. Martinez-Agosto. UCLA, Los angeles, CA.

How an organism responds to oxygen availability in order to modulate its own metabolism balance remains an unresolved question in the field of developmental biology. In our study, we use Drosophila larvae as a model to study how hypoxia disrupts metabolism homeostasis. We have previously shown that hypoxic conditions cause growth restriction and lipid aggregation in larger droplets in the larval fat body, the main site of fat metabolism. However, the mechanism of lipid aggregation remains unknown. Here we demonstrate that Gbb signaling decreases in larval fat body tissue under hypoxia conditions. Overexpression of the ligand, Gbb does not rescue these lipid metabolism defects under hypoxia conditions. However, overexpressing an activated form of Mad protein, the transcription factor downstream of GBB signaling, rescues hypoxia-induced lipid metabolism defects in larval fat body. Therefore, a decrease in Gbb signaling is responsible for the larval lipid metabolism defects observed under hypoxia conditions. Interestingly, down-regulation of CDK8 in the larval fat body restores both lipid metabolism defects and Mad activity under hypoxic conditions. Therefore, an increase in CDK8 activity decreases GBB signaling and plays an important role in

hypoxia-induced lipid metabolism defects.

We have previously demonstrated that the larval growth defects observed under hypoxic conditions are due to a block in insulin signaling. Drosophila insulin-like peptides (DILPs) are produced by insulin-producing cells (IPC) located in the larval brain. After production, they are secreted to promote protein synthesis and cell growth. Our laboratory has previously shown that hypoxia disrupts the insulin signaling pathway by causing retention of Dilp2 in the IPCs. Fat body specific over-expression of InR under hypoxia conditions does not rescue lipid metabolism defects under hypoxic conditions. However, knockdown of the downstream negative regulator of InR signaling, PTEN rescues hypoxia-induced fat body lipid loss. Interestingly, fat body specific knockdown of PTEN under hypoxic condition also increases Mad activity under hypoxia conditions. Therefore, inhibition of GBB and insulin signaling pathways regulates fat body lipid storage under hypoxic conditions.

In conclusion, a reduction in insulin signaling and enhanced activity of CDK8 in the fat body causes a decline in Gbb/BMP signaling that is required for the maintenance of proper lipid metabolism during times of limited oxygen availability.

D1115A Assessing the Role of *Drosophila melanogaster* HP1B Protein in Aging. *A. Thomas*, B. Mills, N. Riddle. UAB, Birmingham, AL.

Aging is marked by a gradual change in macromolecules that, over time, negatively affect biological processes such as gene expression and the maintenance of chromatin structure. Age-related aberrant gene expression can lead to a number of health complications, making age the single greatest risk factor for the development of many human diseases. Heterochromatin proteins play important roles in chromatin structure and gene regulation, suggesting a link to aging. To further investigate, we have chosen the *Drosophila melanogaster* protein HP1B, a member of the Heterochromatin Protein 1 (HP1) family of proteins. HP1 proteins are highly conserved across eukaryotes, playing a vital role in the formation and maintenance of heterochromatin. To probe for a connection between HP1B and aging, we assayed two *HP1b* null mutant strains for phenotypes related to aging. We measured longevity, as well as various forms of stress resistance. Our results show that fly strains lacking HP1B have both increased starvation and oxidative stress resistance. In addition, although they have shorter maximum lifespans compared to the wildtype, they have a longer average lifespan. These results support a potential connection between chromatin proteins and aging and suggest that chromatin proteins should be evaluated as targets for future aging therapies.

D1116B *Fs(1)h* is required in fat body for normal lifespan, metabolism, and immune function in *Drosophila*. *Jessica Sharrock*[1,2], Marc S. Dionne[2]. 1) Department of Immunobiology and Centre for the Molecular and Cellular Biology of Inflammation, King's College London, London SE1 1UL, UK; 2) Department of Life Sciences and MRC Centre for Molecular Bacteriology and Infection, Imperial College London, South Kensington Campus, London SW7 2AZ, UK.

Bromodomain containing proteins (BCPs) play important roles in transcriptional regulation and chromatin remodelling. The inhibition of these proteins affects the production of pro-inflammatory cytokines by macrophages, suggesting they play an important role in the regulation of immunity and inflammation. The main aims of this project were to identify how tissue specific knockdown of BCPs in *D. melanogaster* affects survival, the production of antimicrobial peptides and metabolic function. RNAi was used to specifically knock down each of the BCPs in the *Drosophila* genome in the fat body, an organ which plays important roles in the humoral immune response and metabolism. Following the RNAi screen one gene of interest was identified, *Female sterile (1) homeotic* (*Fs(1)h*). *Fs(1)h* has been shown to be critical for proper patterning of the early embryo, but its functions in the adult fly are essentially unknown. Flies with *Fs(1)h* knocked down in the fat body alone show reduced lifespan, increased expression of immune-response genes known as antimicrobial peptides, and strong metabolic changes. These metabolic changes include increased triglyceride levels and reduced free sugar and glycogen, and are accompanied by a severe reduction in phosphorylated AKT (pAKT), an important downstream effector of PI3 kinase. Remarkably, reduction of *foxo* in *Fs(1)h* knockdowns completely abolishes their short-lived phenotype. Furthermore, reduced *foxo* dosage also eliminated overexpression of antimicrobial peptides in uninfected *Fs(1)h* knockdowns; the effect on antimicrobial peptide expression after infection was heterogeneous. In conclusion, *Fs(1)h* is required in fat body for normal lifespan, metabolism and immune function; its effects on lifespan and uninfected immune activity are mediated by a requirement for *Fs(1)h* in regulation of Akt activity.

D1117C The microbiota affects ADH protein level and influences alcohol sensitivity in Drosophila. *M. A. Blundon*, A. M. Pyzel, T. W. Lau, S. L. Oliver, R. Eutsey, J. A. Cohen, J. H. Huang, N. L. Hiller, J. S. Minden, B. M. McCartney. Carnegie Mellon University, Pittsburgh, PA.

Symbiotic relationships between microbes and animals are ubiquitous in nature. The animal microbiota is a vast and diverse population of bacteria and other microbes living symbiotically with their hosts that has a profound influence on many aspects of host physiology, including metabolism, immunity, development, and behavior. However, little is known about the molecular crosstalk between microbes and host that mediate these effects, particularly in the area of brain function and behavior. To address this problem, we employed a proteomic technique call Two-dimensional Difference Gel Electrophoresis (2D-DIGE) to examine the protein differences in heads between conventionally-reared (CV) flies and "germ free" (GF) flies, those raised in a sterile environment. We found that the level of Alcohol Dehydrogenase (ADH), a key enzyme in alcohol metabolism, is elevated in the heads of GF males and females, suggesting that GF flies would be less sensitive to the effects of ethanol (EtOH) exposure. Indeed, we found that GF males are significantly less sensitive (T_{50}=16.4 mins) to the immobilizing effects of EtOH vapor than their CV counterparts (T_{50}= 11.8 mins). This increased EtOH sensitivity is partially reverted when restoring the normal Drosophila microbiota to GF flies 0-24 hours after eclosion. This suggests that the microbiota plays an important role in the response of Drosophila to EtOH vapor. We are currently testing whether the microbiota also affects EtOH recovery, tolerance, and preference in Drosophila. These data provide a new insight on the effect of the microbiota on alcohol metabolism that may lead to a deeper understanding of the microbiota's role in alcoholism. .

D1118A A temperature-dependent shift in dietary preference alters the viable temperature range of *Drosophila*. *M. Brankatschk*[1], T. Gutmann[2], B. Brankatschk[2], M. Grzybek[2], U. Coskun[2], S. Eaton[1]. 1) MPI-CBG, Dresden, Saxony, DE; 2) PLID, Dresden, Saxony, DE.

How cold-blooded animals adapt their behaviour and physiology to survive seasonal changes in temperature is not completely understood - even for well-studied model organisms like *Drosophila melanogaster*. Here, we show that *Drosophila* respond to high and low temperature extremes by modifying their feeding behaviour. Above 15˚C, *Drosophila* feed and lay eggs on yeast. In contrast, below 15˚C, *Drosophila* prefer to feed and lay eggs on plant material. The different lipids present in yeast and plants improve survival at high and low temperatures, respectively. Yeast lipids promote high temperature survival by increasing systemic insulin signalling. This expands the range over which developmental rate increases with temperature, suggesting that faster nutrient utilization is required to fuel biochemical reactions driven faster by kinetic energy. In addition to speeding development, yeast lipids increase fertility. Thus, yeast provide cues that could help Drosophila to exploit a transient summer food resource. Plant lipids, on the other hand, maintain membrane lipid fluidity at low temperature, and increase cold-resistance of larvae and adults. The cold-resistance and lowered insulin signalling conferred by feeding on plants allows adults to survive for many months at temperatures consistent with overwintering in temperate climates. Thus, temperature-dependent changes in feeding behaviour produce physiological changes that could promote seasonal adaption.

D1119B A genetic screen for novel neuronal genes regulating lifespan extension in *Drosophila melanogaster*. *T. Chen*, W. Lien, C. Chan. National Taiwan University, Taipei, Taiwan.

Rab27 is a neuron-specific GTPase expressing in a small subset of brain neurons in *Drosophila melanogaster*. Recently we found that loss of *rab27* leads to lifespan extension and this effect is dosage-dependent. To discover the genetic network regulating lifespan extension within *rab27*-expressing neurons, we perform an F1 modifier screen. The *rab27Gal4-KO* allele is not only a null, but also possesses Gal4 activity that allows for expression within *rab27*- expressing neurons including the Mushroom bodies and the Insulin-producing cells. In heterozygous *rab27KO* background, approximately 2000 GS lines would be expressed by *rab27Gal4-KO* to identify modifiers of *rab27*-independent longevity phenotype. Similarly, a screen in hemizygous *rab27Gal4-KO* background was performed to identify novel *rab27*-independent regulators of lifespan. Known lifespan regulators such as *hsp27* and *S6K* were isolated from the screen, indicating the validity of the screen. For secondary screen, we set a statistical cutoff to determine top candidates. To distinguish the neuron-specific lifespan extensors, genes that extend lifespan via expression from fat bodies were excluded. To examine whether these genes exerts neuronal or organismic protection, both paraquat- and starvation-induced oxidative stress tests were performed. To reveal the underlying mechanisms, further examinations are ongoing, including metabolic analyses of hemolymph glucose and stored energy of TAG. *In vivo* analyses of several neuron-specific stress-resistant genes will be presented.

D1120C Functional characterization of multiple promoter alleles of the *bellwether* gene in *Drosophila melanogaster*. *J. Frankenberg Garcia*[1,2], M. A. Carbonne[2], T. F. C. Mackay[2], R. R. H. Anholt[2]. 1) School of Biosciences and Medicine, Faculty of Health and Medical Sciences, University of Surrey, Guildford, UK; 2) Program in Genetics, W. M. Keck Center for Behavioral Biology, and Department of Biological Sciences North Carolina State University, Raleigh, NC, USA.

Lifespan varies among individuals, but the genetic factors that contribute to variation in lifespan are not completely understood. *Drosophila melanogaster* presents a powerful genetic model system to explore the genetic underpinnings of longevity, since its lifespan is limited and both the genetic background and environment can be controlled precisely. A previous study identified sequence variants associated with differences in lifespan between five long-lived lines originally selected for delayed reproduction (O lines) and their five unselected controls (B lines). Two single nucleotide polymorphisms in the promoter of the *bellwether* (*blw*) gene (A>G and G>T) were associated with differences in lifespan between the O and B lines. To assess whether associated polymorphisms in the *blw* promoter may contribute to differences in lifespan by modulating gene expression, we amplified 500 bp upstream promoter sequences containing all four possible haplotypes (AG, AT, GG, GT) and assessed promoter activity in an *in vitro* luciferase reporter system. Our results show that the AG haplotype characteristic of the B lines showed ~18% greater expression of luciferase than the GT haplotype, which is associated with the long-lived O lines. Current experiments are designed to assess to what extent alternative *blw* alleles modulate lifespan in a common genetic background. The *blw* gene codes for the alpha subunit of the mitochondrial ATP synthase, and thus may represent a possible molecular link between metabolic rate and lifespan.

Supported by NIH grant R01-AG043490..

D1121A Endogenous L-2-hydroxyglutarate synthesis coordinates aerobic glycolysis with epigenetic modifications in *Drosophila.* *Alexander Hurlburt*, Hongde Li, Maria Sterrett, Geetanjali Chawla, Jason Tennessen. Indiana University, Bloomington, IN.

2-hydroxyglutarate (2HG) has emerged as a potent oncometabolite that inhibits enzymes involved in metabolism, chromatin modification, and cell proliferation; however, neither the D-2HG nor the L-2HG enantiomers are tumor specific. In fact, both compounds are synthesized in a diversity of cells, but the presence of 2HG in healthy tissues is commonly disregarded as a byproduct of metabolic error. This presumption is further supported by observations that the only known causes of 2HG accumulation are hypoxia and mutations in either *Isocitrate Dehydrogenase* or in the enzymes that degrade these compounds. We have discovered that L-2HG is more than an aberrant metabolite, as *Drosophila* larvae generate millimolar concentrations of L-2HG during normal development. Larval L-2HG, however, does not accumulate simply to due defects in metabolic repair pathways. Rather, we have found that this compound is the direct product of aerobic glycolysis, as most L-2HG is generated from glucose and dependent on activation of the *Drosophila* Estrogen-Related Receptor, which promotes L-2HG synthesis by up-regulating *Lactate Dehydrogenase* (*Ldh*) gene expression. As a result, high levels of larval LDH activity directly synthesize L-2HG for 2-oxoglutarate. Furthermore, we have found that the resulting L-2HG pool is stabilized, in part, by lactate, which inhibits L-2-

hydroxyglutarate dehydrogenase (L-2HGDH) activity and controls L-2HG abundance. Finally, we demonstrate that L-2HG influences DNA methylation and position effect variegation, indicating that this compound coordinates metabolism with epigenetic modifications during fly development. In conclusion, our findings suggest that L-2HG is more than an aberrant compound produced by enzymatic infidelity, but rather acts as part of an ancient mechanism to coordinate glycolytic flux with chromatin formation.

D1122B Hemocytes regulate responses to nutrition via the Jak/STAT pathway. *K. Kierdorf*, J. Dou, M. S. Dionne. Imperial College, Department of Life Sciences and MRC Centre for Molecular Bacteriology and Infection, London, UK.

Hemocytes are the myeloid cells of the fly. In adult flies, 95% of hemocytes are plasmatocytes, which are similar to tissue resident macrophages in mammals. Upon infection or inflammation, hemocytes phagocytose invaders and release different cytokines. However, less is known about the physiological function of hemocytes and how they affect tissue homeostasis and metabolism. Recently, it was shown that resident tissue macrophages in the fly are major regulators of glucose metabolism and lifespan upon metabolic stress. Adult flies on a lipid-enriched diet showed enhanced storage of triglycerides, hyperglycemia, and decreased insulin sensitivity followed by a severe reduction in lifespan. In this context, hemocytes release the Jak/STAT activating cytokine *unpaired-3* (*upd3)* and over-activate the Jak/STAT pathway in various organs including gut and muscles; this is a major driver of shortened lifespan due to high-fat diet. *upd3* activation by lipid is dependent on the scavenger receptor *croquemort* and the Jun-kinase *basket*. Here, we further investigate the physiological consequences of macrophage cytokine release and dysregulation. We suggest that hemocytes might be a major nutritional sensor regulating tissue homeostasis via release of Jak/STAT-activating cytokines. We and others have observed that several tissues including adult muscle exhibit physiological Jak/STAT signaling in the absence of any overt inflammatory stimuli. As skeletal muscle is the major glucose consuming organ in most multicellular organisms, and lipid-driven *upd3* causes changes in glucose homeostasis, we are now exploring the impacts of hemocyte-derived cytokine signals on muscle metabolism and systemic health. Importantly, we suggest that cytokine signaling in this system is important in the response of muscles to nutritional changes, even in the absence of overt inflammatory stimuli.

D1123C The regulation of lipid storage by sex determination genes in *Drosophila*. *Cezary Mikoluk*[1], Alexis Nagengast[2], Justin DiAngelo[1]. 1) Penn State Berks, Reading, PA; 2) Widener University, Chester, PA.

Excess nutrients are stored as triglycerides mainly in the adipose tissue of an animal. These triglycerides are located in structures called lipid droplets within adipose cells. Previous genome-wide RNAi screens in *Drosophila* cells identified splicing factors that play a role in lipid droplet formation. Our lab identified the SR protein, 9G8, as an important factor in fat storage as decreasing its levels results in augmented triglyceride storage in the fat body. However, whether 9G8 interacts with other proteins to affect lipid metabolism is unclear. Previous *in vitro* studies have implicated 9G8 in the control of doublesex (DSX) splicing by binding to transformer (TRA) and transformer2 (TRA2) to regulate sex determination; any function of these proteins in regulating metabolism is unknown. The goal of this study is to determine whether 9G8 acts with TRA, TRA2, or DSX to regulate fat storage *in vivo*. To test this hypothesis, we measured triglyceride and glycogen levels in flies with TRA^{dsRNA}, $TRA2^{dsRNA}$, and DSX^{dsRNA} induced in the fat body. Decreasing TRA, TRA2 and DSX in the larval fat body has no effect on nutrient storage. However, decreasing the expression of these sex determination genes in the adult fat body resulted in an increase in triglyceride levels, a phenotype similar to the 9G8 knockdown flies. Interestingly, glycogen also accumulated when the sex determination genes were decreased in the adult fat body. To determine whether this increase in energy stores was the result of excess food consumption, we performed CAFÉ assays to measure feeding over a 24 hour period. Feeding was not increased in the TRA^{dsRNA}, $TRA2^{dsRNA}$, and DSX^{dsRNA} flies, suggesting the triglyceride and glycogen accumulation phenotype was not the result of increased food intake. Together, these results suggest a link between mRNA splicing, sex determination and lipid metabolism and may provide insight into the mechanisms underlying tissue-specific splicing and nutrient storage in the fat body.

D1124A Lipolytic effects on insulin signaling in the *Drosophila* larval fat body. *Emily Scott*, Stephen Roth, Nigel Muhammad, Michelle Bland. University of Virginia, Charlottesville, VA.

When nutrients are abundant, insulin-like peptides are secreted and promote the storage of glucose as triglycerides in lipid droplets in the fat body. During starvation, lipolysis is activated to provide energy for the body in the form of free fatty acids and glycerol. In mammals, fatty acids released during lipolysis also act intracellularly to dissociate the TORC2 complex, which is an upstream kinase in the insulin signaling pathway. Inhibiting lipolysis by adipocyte-specific deletion of *adipocyte triglyceride lipase* (*ATGL*) improves insulin sensitivity. Here we investigated whether lipolysis affects *Drosophila* insulin-like peptide (DILP) sensitivity in fruit fly larvae. We find that fat body-specific knockdown of the *Drosophila ATGL* homolog *brummer* (*bmm*) leads to triglyceride accumulation not only in the fasted but also in the fed state, indicating that *Drosophila* larvae exhibit basal lipolysis even during periods of nutrient intake. We examined whether loss of *bmm* affected DILP signaling in a model of inflammation-induced insulin resistance. Fat body-specific expression of the constitutively-active $Toll^{10b}$ receptor activates immune signaling and leads to reduced DILP signaling and, consequently, decreases in both triglyceride storage and cell size. We find that larvae expressing $Toll^{10b}$ in fat body are refractory to the triglyceride-elevating effects of *bmm* knockdown, suggesting that triglyceride storage defects in this background are due to reduced de novo lipogenesis and not elevated lipolysis. Accordingly, loss of *bmm* expression did not rescue cell size in clones of fat body cells expressing $Toll^{10b}$, indicating that elevated lipolysis does not play a role in DILP resistance on this background. DILP signaling can be stimulated acutely by incubating larvae at 37˚C for two hours, a stimulus that activates TORC2 through an unknown mechanism. Wild type type but not TORC2-deficient *rictor* null larvae exhibit a robust increase in phosphorylation at the TORC2 site on Akt (Ser505) following heat exposure. However, Ser505 phosphorylation is reduced when fasted, lipolytic larvae are exposed to heat, providing a new model in which to study lipolysis and insulin signaling. Together, our results suggest that the physiological states such as fasting immune

system activation, dictate the nature of the interactions that occur between the insulin signaling pathway and lipid anabolic and catabolic processes.

D1125B Studies of the *Drosophila Lactate Dehydrogenase* gene reveal compensatory metabolic networks that support larval development. *Jason M. Tennessen*, Geetanjali Chawla, Hongde Li, Maria C. Sterrett. Indiana University, Bloomington, IN 47405.

The metabolism of proliferating cancer cells not only generates energy, but also synthesizes the biomolecules required for growth. In response to these metabolic demands, cancer cells rely on a metabolic program known as aerobic glycolysis, which synthesizes biomass from carbohydrates. *Drosophila* also uses aerobic glycolysis to support the nearly 200-fold increase in body size that occurs during larval development and we are now using the fly to understand how the inhibition of aerobic glycolysis affects growth and physiology. Our initial studies have focused on the *Drosophila Lactate Dehydrogenase* gene (*Ldh*; also known as *ImpL3*), which encodes the hallmark enzyme of aerobic glycolysis. We have confirmed that LDH is widely expressed in larval tissues, with notably high levels occurring in the muscle and brain. Furthermore, this expression occurs independent of oxygen availability; however, LDH expression in the salivary glands and imaginal discs is enhanced under hypoxic conditions. Furthermore, we have generated *Ldh* loss-of-function mutations with the goal of understanding how this enzyme influences growth and biosynthesis. Our preliminary metabolic characterization reveals that *Ldh* mutants accumulate excessive glycogen stores and exhibit a 95% decrease in lactate production. However, despite these metabolic defects, *Ldh* mutants grow at a normal rate and experience an impenetrant lethal phase during the mid-L3. These relatively mild phenotypes suggest that larval metabolism can compensate for loss of LDH activity. To test this possibility, we analyzed the *Ldh* mutants using a combination of GC-MS-based metabolomics and RNAseq. These analyses revealed several putative compensatory metabolic networks that are activated in *Ldh* mutants. For example, loss of LDH activity induces a significant increase in glycerol-3-phosphate (G3P) metabolism, as mutant larvae exhibit a 300% increase in glycerol-3-phosphate levels and 4-fold increase in *glycerol-3-phosphate dehydrogenase* gene expression. Overall, these studies represent a unique opportunity to both understand how the disruption of aerobic glycolysis affects biosynthesis and to explore the metabolic plasticity that underlies larval growth.

D1126C The GATOR1 function in Drosophila development. *Youheng Wei*, Weili Cai, Mary Lilly. NICHD/NIH, Bethesda, MD.

Target of Rapamycin Complex 1 (TORC1) is a master regulator of metabolism in eukaryotes that integrates information from multiple upstream signaling pathways. The evolutionary conserved complex Gap activity towards Rags (GATOR) inhibits TORC1 activity in response to amino acid limitation. In yeast, GATOR1 mutants show proliferation defects during nitrogen source scarcity, but not when cultured in nutrient rich conditions. In humans, the GATOR1 complex has been implicated in a wide array of human pathologies including cancer and hereditary forms of epilepsy. These observations strongly suggest that in metazoans the GATOR1 complex has acquired functions beyond coordinating a response to amino acid limitation. However, the precise requirement of GATOR1 in animal physiology remains largely undefined. Here we generate null mutants of the GATOR1 components *nprl2*, *nprl3* and *iml1* in *Drosophila.* We find that all three mutants have inappropriately high TORC1 activity. Moreover the GATOR1 mutants are semi-lethal with a percentage of homozygous animals dying as pharate adults. Notably, the *nprl2* and *nprl3* mutant adults exhibit profound ataxia. This ataxia is metabolic in origin in that it is rescued by the expression of Nprl3 in the fat body, but not muscles or neurons, of *nprl3* mutants. Consistent with the theory that inhibiting TORC1 activity extends lifespan, the *nprl2* and *nprl3* mutants have shortened lifespan. Finally, our data confirm that in addition to its role in the development and physiology of Drosophila raised under standard culture conditions, the GATOR1 complex has retained a critical role in the response to nutrient stress. Notably, *nprl2* and *nprl3* mutants fail to activate autophagy in response to amino acid stress and are extremely sensitive to both amino acid and complete starvation. In summary we find that the TORC1 inhibitor GATOR1 contributes to multiple aspects of the development and physiology of Drosophila.

D1127A The contribution of host genetic variants to microbiota-mediated juvenile growth. *D. Ma*[1], Claire-Emmanuelle Indelicato[1], Maroun Bou-Sleiman[2], François Leulier[1], Bart Deplancke[2]. 1) IGFL, ENS de Lyon - CNRS UMR 5242 - INRA USC 1370, Lyon, Rhone-Alps, FR; 2) Laboratory of Systems Biology and Genetics (LSBG) EPFL-SV-IBI-LBSG,Station 19 CH-1015 Lausanne.

The metazoan gut microbiota comprises a rich and diverse community of commensal bacteria species. It plays a vital role to maintain systemic homeostasis in multiple host organs and thus sustains optimal host health. Consequently, various aspects of host development and physiology, ranging from juvenile growth to adult lifespan, are altered in germ-free (GF) animals. We have previous shown that on a low yeast diet, GF *Drosophila* experience retarded larval growth and delay in development. Interestingly, mono-associating axenic fly embryos with a single strain of the gut commensal species, *Lactobacillus plantarum* (**Lp^{WJL}**), can re-accelerate growth and partially restore developmental timing, and this growth-promotion effect is mediated through the host ToR signaling pathway.

To identify additional host genetic variants and networks that respond to the growth promotion effect via Lp^{WJL}, we conducted a genome-wide association study (GWAS) on the Drosophila Genetic Reference Panel (DGRP) based on the variation in larval growth difference between the GF and their Lp^{WJL} –monoxenic siblings among the strains. We obtained a set of polymorphisms associated to genes with novel and unknown functions, as well as genes involved in host metabolism, hormonal signaling and immune response. Here we present the validation of selected candidates implicated in host response to Lp^{WJL} –mediated juvenile growth. Specifically, we focus on the role of Dawdle, the activin-like TGF-β ligand that has been shown to regulate host metabolic adaptation to the nutritional environment. In summary, our finding suggests that the genetic basis of the juvenile host response to the presence of the intestinal microbiota is complex and poly-genic.

D1128B Genetic mapping and molecular characterization of the genes *lysine* and *red cell*. *S. L. St. Clair*[1], L. K. Golden[1,2], U. Ashraf[1], K. R. Cook[1,2], J. M. Tennessen[1]. 1) Indiana University, Bloomington, IN 47405; 2) Bloomington Drosophila Stock Center, Bloomington, IN 47405.

We are investigating a fifty-year-old observation that *lysine*^{1} *red cell*^{1} (*lys*^{1} *rc*^{1}) double mutants accumulate pigmented fat cells in the head and thorax of adult flies (Grell, 1961). Toward this goal, we have confirmed that *lys*^{1} *rc*^{1} mutants exhibit pigmented cells and have used GC-MS to determine that lysine levels are increased 50-fold in *lys*^{1} single mutants. These results demonstrate that the *lys*^{1} *rc*^{1} mutant phenotypes stem from a metabolic defect and implicate lysine catabolism in the development of adult adipose tissue. As a first step towards studying the molecular mechanisms that underlie these phenotypes, we used deficiency mapping to identify the genes that are disrupted by the *lys*^{1} and *rc*^{1} mutations. We have successfully used a GC-MS-based approach to map the *lys*^{1} mutation to an ~10,000 bp region of chromosome 2 that contains the gene *lysine ketoglutarate reductase/saccharopine dehydrogenase* (*LKRSDH*), which encodes an essential enzyme in lysine catabolism. Furthermore, we have determined that *lys*^{1} fails to complement *LKRSDH*^{MB10942} and have identified the causal mutation as a large insertion in the second exon of *LKRSDH*. We have also mapped *rc* based on a previous observation that *rc*^{1} single mutants accumulate pigmented fat cells if starved during the post-critical weight period of L3 development. We used this phenotype to demonstrate that *rc*^{1} is located within an ~60,000 bp region of chromosome 2 and we are now employing a whole-genome sequencing approach to identify the causal lesion. Overall, our studies suggest that degradation of the essential amino acid lysine influences the metabolism and development of adult adipose tissue.

Grell E.H. (1961). The genetics and biochemistry of red fat cells in *Drosophila melanogaster*. *Genetics* 46: 925-933.

D1129C Investigating the role of dietary iron on reactive oxygen species levels in *Drosophila*. *Rebecca A. Vaders*, Alexis A. Nagengast. Widener University, Chester, PA.

Aging is a complex process that has a variety of underlying causes. Reactive oxygen species (ROS) cause oxidative damage to proteins, lipids and carbohydrates, and contribute to aging. Although calorie restriction has been linked to an increased lifespan, our previous results showed that *Drosophila melanogaster* raised on a higher nutrient corn syrup-based diet lived longer than those on a lower nutrient molasses-based diet. We hypothesize that increased iron levels in molasses are contributing to increased ROS and the observed decreased lifespan. An indirect measurement of ROS levels was detected through superoxide dismutase (SOD) expression in males and females using quantitative polymerase chain reactions (qPCR), only to find SOD levels did not vary significantly between the two diets but varied between sexes. Through the use of a UAS-*MitoTimer* labeled reporter gene, ROS is measured more directly by the irreversible change from green to red fluorescence in the presence of mitochondrial oxidative stress. An evident trend between the expression of SOD and *MitoTimer* fluorescence has been detected and differences between *MitoTimer* fluorescence on the molasses, corn syrup and iron supplemented-corn syrup foods are being investigated. Using iron supplementation to further study the changes in lifespan and ROS opens windows to better understand how SOD reacts with other biochemical pathways in order to affect oxidative stress.

D1130A The *Drosophila* Estrogen-Related Receptor acts as a nutrient sensor to coordinate larval growth with nutrient availability. *M. C. Sterrett*, S. L. St. Clair, J. M. Tennessen. Indiana University, Bloomington, IN.

All growth during the *Drosophila* life cycle is restricted to larval development, when animals increase their body size ~200-fold over the course of four days. To support this exponential growth, larvae rely aerobic glycolysis, a unique metabolic program ideally suited to synthesize biomolecules from carbohydrates. Our previous work demonstrated that aerobic glycolysis is transcriptionally-activated during embryogenesis, when the *Drosophila* ortholog of the Estrogen-Related Receptor (ERR) class of nuclear receptors coordinately up-regulates genes involved in glycolysis, the pentose phosphate pathway, and lactate production. We have discovered that dERR activity is not restricted to embryogenesis; rather, dERR also promotes aerobic glycolysis during larval development. Our preliminary analyses demonstrate that dERR protein is expressed in key metabolic tissues, including the fat body, intestine, and muscle. This expression pattern suggests that dERR coordinates glucose-derived biosynthesis with growth conditions. Consistent with this model, we have discovered that the dERR ligand-binding domain (LBD) is activated when larvae are fed a yeast-based diet but not sugar-only or starvation media. Furthermore, the addition of insulin to larval organ cultures fails to activate the dERR LBD, suggesting that dERR represents a novel mechanism for linking dietary conditions with sugar metabolism. We have also determined that dERR is covalently modified under starvation conditions, suggesting that a nutrient-sensitive enzyme controls dERR activity. Finally, we have demonstrated that many dERR target genes are transcriptionally down-regulated upon starvation, indicating that diet-induced changes in dERR activation are functionally significant. Overall, our studies indicate that dERR promotes aerobic glycolysis in response to dietary compounds and suggest that mammalian ERRs also act as nutrient sensors that coordinate biosynthesis with rapid growth.

D1131B *reaper* expression in the wing imaginal disc causes non-autonomous larval growth inhibition. *C. D'Ancona*, A. Reyes, A. Kesick, A. Halme. University of Virginia, Charlottesville, VA.

In response to localized imaginal disc damage, *Drosophila* larvae can alter systemic developmental progression and growth in order to coordinate the regeneration of damaged tissues with the growth and development of undamaged tissues. Previously, we have demonstrated that targeted expression of the TNF homologue *eiger,* in the wing imaginal discs produces localized apoptosis and tissue damage, and limits the growth of undamaged imaginal discs. However, larval tissue growth is not affected by *eiger*-induced damage in the wing. In contrast, expression of the pro-apoptotic gene *reaper* in wing imaginal discs strongly restricts larval growth. *reaper*-induced damage in the wing is observed in early L1 stage larvae and persists throughout larval development, producing pupae that are significantly smaller than *eiger*-expressing or control pupae. Therefore, these two distinct apoptotic stimuli produce different non-autonomous effects on larval growth.

To better characterize which apoptotic pathways can produce this non-autonomous larval growth inhibition, we have begun to examine larval

growth after the expression of several different apoptotic stimuli. In *Drosophila*, *reaper*-induced programmed cell death is critical during development for sculpting final adult tissue shape, deleting pre-adult structures, and regulating cell number. Unlike *eiger*, which induces apoptosis through JNK signaling, *reaper* induces apoptosis through direct inhibition of Diap1. We observe that expression of other Diap1 inhibitors *hid* and *grim* in the wing discs also causes a strong non-autonomous larval growth inhibition. In contrast, disruption of the wing imaginal disc epithelia by inhibition of the neoplastic tumor suppressor *avalanche/Syntaxin-7* does not alter larval growth. Finally, preliminary tests with varied doses of X-irradiation suggest that a subset of irradiated larva may undergo similar growth inhibition. Therefore, the larval growth inhibition resulting from *reaper* expression in the wing disc is a specific damage response not seen with all apoptotic stimuli. This distinct systemic response may reflect a different mode of tissue repair in response to *reaper*-induced damage.

D1132C *Drosophila* Adipokinetic hormone regulates food intake, metabolic rate, and expression of neuropeptide genes with metabolic functions. *Martina Gáliková*, Peter Klepsatel, Yanjun Xu, Ronald P. Kühnlein. Max Planck Institute for Biophysical Chemistry, Research Group Molecular Physiology, Am Faßberg 11, D-37077 Göttingen, Germany.

Adipokinetic hormones (AKHs) induce mobilization of energy reserves in insects, acting thus analogously to the human hormone glucagon. Experiments in the model insect *Drosophila melanogaster* have recently shown that loss of AKH results in adulthood-specific onset of obesity coupled with hypoglycemia. Nevertheless, not much is known about the exact mechanism whereby AKH affects fly physiology. Therefore, we investigated the physiological roles of this hormone, focusing on the metabolic rate and food intake control, and on the interactions between AKH and other fly neuropeptides known to regulate metabolism. Our gain- and loss-of-function experiments show that despite its anti-obesity effect, AKH is an orexigenic peptide. This hormone also affects expression of several other neuropeptide genes involved in feeding behavior, including orexigenic neuropeptides *CCHamide-2* and *neuropeptide F.* In addition, AKH affects metabolic regulators like *corazonin, limostatin,* and *insulin-like peptides 2, 3, 5* and *6.* Altogether, our work shows that next to the regulation of the feeding behavior and metabolic rate, AKH signaling controls *Drosophila* metabolism also by affecting metabolic regulators from the family of insect neuropeptides. AKH should be thus viewed as a central regulator of energy homeostasis and neuroendocrine signaling in *Drosophila* adults.

D1133A The Membrane Attack Complex / Perforin-like protein Torso-like regulates *Drosophila* growth and developmental timing. *Michelle Henstridge*[1], Travis Johnson[1,2], Christen Mirth[1], James Whisstock[2,3], Coral Warr[1]. 1) School of Biological Sciences, Monash University, Clayton VIC 3800 Australia; 2) Department of Biochemistry and Molecular Biology, Monash University, Clayton VIC 3800 Australia; 3) ARC Centre of Excellence in Advanced Molecular Imaging, Monash University, Clayton VIC 3800, Australia.

Membrane Attack Complex / Perforin-like (MACPF) proteins are best known for their roles in mammalian immunity, where they function to disrupt cell membranes by forming oligomeric pores. However, several MACPF proteins perform essential, but poorly understood, roles in development. The sole *Drosophila* MACPF protein, Torso-like (Tsl), is well known for its role in early embryonic patterning where our studies suggest it enables secretion of a specific growth factor, Trunk, the ligand for the Torso receptor tyrosine kinase[1]. We and others have recently discovered that *tsl* is also expressed in the major fly endocrine gland, the prothoracic gland, where it has an additional role in the regulation of growth and developmental transitions[2,3]. We have further shown that this role of Tsl is independent of Trunk and Torso[3], raising the possibility that Tsl also influences the secretion of other growth factors. *tsl* null mutants exhibit a delay in time to pupariation and reduced adult body size, phenotypes that closely resemble those observed when insulin signalling is reduced. To investigate a role for Tsl in insulin signalling we performed genetic interaction experiments between *tsl* and components of the insulin signalling pathway. Over-expression of PI3K in the prothoracic gland results in a shorter time to pupariation. This phenotype is suppressed in a *tsl* mutant background, providing evidence that Tsl interacts with the insulin signalling pathway. We are currently performing additional genetic interaction experiments to determine where in the pathway Tsl functions, and in addition, whether secretion of insulin-like peptides is impaired in *tsl* mutants. Finally, we are also screening other candidate growth factors, neuropeptides and their receptors for roles in the prothoracic gland, and testing for interactions with Tsl. Our studies of Tsl will provide fundamental insight into the regulation of important insect growth pathways, many of which play highly conserved roles in humans.

D1134B Relationship between Heme Biosynthesis and Ecdysone Production during *Drosophila* Larval Development. *Nhan Huynh*[1], Qiuxiang Ou[1], Kirst King-Jones[1], Kim F. Rewitz[2], Michael B. O'Connor[3]. 1) Department of Biological Sciences, University of Alberta, Edmonton, AB, Canada; 2) Department of Biology, University of Copenhagen, Copenhagen, Denmark; 3) Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, USA.

The steroid hormone ecdysone plays a key role in insect development. In *Drosophila*, ecdysone pulses trigger all major developmental transitions including hatching, molting and puparium formation. While the downstream actions of ecdysone have been well studied, we only have a limited understanding of how ecdysone production is regulated so that distinct pulses are formed during development. We recently started to examine the relationship between heme biosynthesis and ecdysone production, because the majority of steroidogenic enzymes, the cytochrome P450s, require heme as a cofactor. From a genome-wide RNAi screen that we had conducted in collaboration with Mike O'Connor's and Kim Rewitz's labs, we carried out a secondary screen aimed at identifying genes involved in the regulation of heme production. This screen was limited to the prothoracic gland (PG), the principal source of larval ecdysteroids, and led to the identification of the 34 candidate genes. PG-specific RNAi against these genes caused larval or pupal arrest and/or significant delays in development. Importantly, all RNAi lines displayed enlarged ring glands, 20 of which exhibited strong red autofluorescence in the PG, consistent with fluorescent heme

precursor accumulation in this tissue. Here, we present preliminary findings for two candidate genes, Su(Var)2-10 and AGBE, and how they relate to heme and ecdysone regulation.

D1135C Identifying new growth regulatory receptors in *Drosophila melanogaster*. *Melissa J. Saligari*[1], Patrick Farrell[1], Michelle A. Henstridge[1], Karyn A. Moore[1,2], Travis K. Johnson[1,2], James C. Whisstock[2,3], Coral G. Warr[1]. 1) School of Biological Sciences, Monash University, Clayton, Victoria, Australia; 2) Department of Biochemistry and Molecular Biology, Monash University, Clayton, Victoria, Australia; 3) Australian Research Council Centre of Excellence in Advanced Molecular Imaging, Monash University, Clayton, Victoria, Australia.

In animals, control of the rate and duration of growth is coordinated by endocrine systems which produce secreted peptide hormones and steroid hormones. Many of the key growth pathways that are crucial for human development, such as the insulin signaling pathway, were first identified and characterised in *Drosophila*. In insects, developmental transitions are regulated by pulses of production of the steroid hormone ecdysone in the larval prothoracic gland (PG). Multiple environmental factors and signaling pathways regulate ecdysone production. To find new regulators of growth we used RNAi to knockdown a set of candidate neuropeptide and growth factor receptors in the PG using *phantom-Gal4*. We found that knocking down Adipokinetic hormone receptor (AkhR) causes larval lethality. Knocking down Pigment-dispersing factor receptor (Pdfr) causes a severe developmental delay and increases adult weight. Neither receptor has previously been shown to have a role in the PG. We tested amorphic alleles of *AkhR* and *PdfR* (*AkhR*^{1}, Gronke *et al.* 2007; *PdfR*^{5304}, Hyun *et al.* 2005) and found that homozygous mutants were developmentally delayed and larger than their heterozygous controls. We are currently investigating how these specific receptors perturb growth and interact with the PTTH/Tor and insulin pathways, which are known to operate in the PG to control ecdysone production. Identifying novel growth factor receptors and signaling pathways that regulate developmental timing and body size in *Drosophila* is not only interesting in its own right, but may prove vital in deepening our understanding of human growth disorders, obesity and cancer.

Gronke et al. 2007, PLoS Biol. **5**(6): e137; Hyun et al. 2005, Neuron **48**(2): 267-278.

D1136A The influence of the RU486 steroid on *Drosophila* feeding and lifespan. *Erin S. Keebaugh*[1], Ryuichi Yamada[1], Sonali A. Deshpande[1], Margaux R. Ehrlich[1], Alina Soto Obando[1], Frédéric Marion-Poll[2], William W. Ja[1]. 1) The Scripps Research Institute, Jupiter, FL 33458, USA; 2) Evolution, Génomes, Comportement & Ecologie, CNRS, IRD, Université Paris-Sud, Université Paris-Saclay Gif-sur-Yvette, France; AgroParisTech Paris, France.

Insects that develop and feed on plants are exposed to a wide range of plant-derived steroidal compounds. The perception of plant steroids can influence insect food choice and feeding behaviors; furthermore, some plant steroids serve as insecticides and are toxic to plant-feeding insects. RU486 is a synthetic steroid that is added to *Drosophila* food to activate transgenes using the powerful GeneSwitch system, which facilitates the spatial and temporal control of transgene expression. Because of the structural similarity between RU486 and plant-derived steroids, and since GeneSwitch assays may be influenced by altered food intake, we tested if RU486 influences fly feeding behaviors. We found that flies show a reduced proboscis extension response (PER) towards RU486 mixed into a variety of diets. Furthermore, flies show reduced feeding on food containing RU486. Since changes in food consumption can have an impact on aging and health, we next tested if RU486 influences the lifespan of multiple *Drosophila* lines exposed to RU486 across a variety of diets. We found that RU486 can modulate lifespan in a diet-dependent manner, especially on diets where dietary restriction-mediated longevity is observed. Our findings demonstrate that RU486 is taste-aversive to flies and can influence feeding behavior and lifespan. Thus, future studies using the GeneSwitch system should consider the impact of potential RU486-specific effects.

D1137B Analysis of the effects of acetyl-para-aminophenol on *Drosophila melanogaster* development. *Terry Blaszczak*, Raluca Ciupuliga, Stephanie Fonseca, Fareha Nazneen, Mary Kimble, Elyse Bolterstein. Northeastern Illinois University, Chicago, IL.

Acetyl-para-aminophenol (acetaminophen) is a known toxin in humans, but the extent of its toxicity is not fully understood. The difference between an effective dose and an overdose of acetaminophen is very minimal, and acetaminophen overdoses resulting in hospitalizations are relatively common. This study investigates the effects of acetaminophen on the development of *Drosophila melanogaster* exposed to different light/dark conditions to better understand the mechanisms and antioxidant pathways that are affected by acetaminophen. Our objectives include determining the dose-response relationship of acetaminophen on *Drosophila* development under different light conditions and measuring the antioxidant activity in adults raised on acetaminophen food to determine oxidative stress levels. This research will increase our understanding of the toxic effects of acetaminophen on developing organisms.

To determine the acetaminophen dose-response relationship, instant food was added to fly vials and rehydrated with 30mM to 70mM acetaminophen solutions. Oregon R wild type flies were added to each vial and placed in different light cycle conditions. Once the eggs hatched, the rate of larval development was monitored and the number of adults emerging was recorded every day until all flies had eclosed (emerged). A separate trial placed collected eggs in vials containing acetaminophen food of different concentrations. Vials were placed either in constant dark or twelve-12 hour light/dark cycles. The number of flies eclosed was recorded every 12 hours until all flies had emerged. Our results show that acetaminophen doses less than 30 mM had minimal effect on development. Doses of 30 mM to 60 mM affected survival percentages and time to eclosion, and doses greater than 70 mM showed very low survival rates. Additionally, light cycles affect survival and development rates, with cultures exposed to a twelve-hour light/dark cycle experiencing the least effect of acetaminophen. Currently, assays testing oxidative stress of adult flies raised on acetaminophen food are underway. Flies will be separated according to day eclosed, sex, light conditions, and acetaminophen dosage. Fly homogenates from the most recent dosage study will be used to extract proteins and determine the relative antioxidant activity in flies exposed to different light conditions and acetaminophen concentrations. Because flies develop more

slowly and show greater response to acetaminophen when reared in constant darkness, it is predicted that exposure to higher concentrations of acetaminophen and constant darkness will result in greater antioxidant activity.

D1138C BLM and WRNexo protect against aging and tumorigenesis in Drosophila. *Elyse Bolterstein*[1], Rob Salomon[2], Mitch McVey[3], Deirdre Cassidy[1], Matthew Kuo[1], Joshua Kruithof[1], Imad Rebiai[1], Luhan Zhou[1]. 1) Northeastern Illinois University, Chicago, IL; 2) Tufts Medical Center, Boston, MA; 3) Tufts University, Medford, MA.

Members of the RecQ family of helicases are known as the "guardians of the genome" due to their essential roles in DNA repair, replication, and recombination. Mutations in the RecQ helicases, WRN and BLM, cause Werner and Bloom syndrome respectively. These autosomal recessive diseases are characterized by patients' increased risk of cancer and early onset of aging-related pathologies. Similar to Bloom syndrome patients, *Blm* mutant flies have shortened lifespans and a higher incidence of tumors, particularly in the gut and ovaries of aged females. We have found that flies mutant in the Drosophila homolog of WRN, *WRNexo*, also exhibit decreased lifespans and higher tumor incidence compared to age-matched wild type controls. In contrast to *Blm* mutants, *WRNexo* flies accumulate tumors in the testes, suggesting tissue-specific mechanisms of these two proteins. *WRNexo* mutants also exhibit other physiological signs of aging such as degeneration of the flight muscles and decreased locomotor activity. Additionally, we observed that mutant flies have increased antioxidant activity that declines with age, suggesting that the aging phenotypes may be due to increased oxidative damage. We propose that WRNexo and BLM physically interact with one another to protect against physiological signs of aging, which is a hypothesis supported by our recent finding that *WRNexo* and *Blm* mutants share similar phenotypes in response to replication stress. To this effect, we are investigating these interactions by performing a co-immunoprecipitation assay using *WRNexo* transgenic mutants.

D1139A The Interaction of Wolbachia and Oxidative Stress with Genetic Background in *Drosophila Melanogaster*. *F. Capobianco*, S. Nandkumar, J. Parker. SUNY Plattsburgh, Plattsburgh, NY.

It is recognized that the rate of aging varies among individuals according to genetic background. The intracellular bacterium, Wolbachia, is found in most arthropods and nematodes, including *D. melanogaster*. Here we explore how Wolbachia infection and oxidative stress interact on aging with infected and uninfected *D. melanogaster* in two different genetic backgrounds.

Two wild caught lines, naturally infected with Wolbachia, were cleared of the bacterium. Infected and uninfected flies from the wild caught lines were acutely treated with oxidative stressors (Paraquat, Hydrogen Peroxide) and a nitric oxide stressor (L-Arginine). When treated with paraquat, levels of superoxide anions increase within the cells. Treatment with hydrogen peroxide causes accumulation of itself outside of the cells. L-Arginine increases the amount of nitric oxide within the cells.

It was discovered that Wolbachia increases the sensitivity of oxidative stress in a manner dependent on the genetic background and that the effect Wolbachia itself has on lifespan varies according to genetic background. It was also seen that Wolbachia increases the sensitivity to hydrogen peroxide based on genetic variation and length of the fly line's lifespan. We propose that Wolbachia may be working like Superoxide Dismutase, only in long lived fly lines.

The system factors that can govern aging (infection and oxidative stress) are not universal, but are specific to the individual's genetic makeup. This raises the possibility that selection on Wolbachia infection is related to the lack of selection predicted by the mutation accumulation hypothesis for aging.

D1140B Oxidative insult induces clock-dependent, rhythmic expression of stress-related genes in *Drosophila*. *E. Chow*, R. Kuintzle, T. Bonar, D. Hendrix, J. Giebultowicz. Oregon State University, Corvallis, OR.

Circadian rhythms provide temporal coordination between organisms and their environment, and contribute to healthy aging in animals from flies to humans. Clock genes regulate many biological processes, and a disrupted circadian system increases risk for oxidative damage, neurodegenerative diseases, and metabolic disorders. Expression of many genes appears to be clock-dependent in young flies. However, as aging weakens circadian rhythms and synchrony, it has been unclear how expression of clock-controlled genes may change with age. Using RNA-Seq to obtain a large-scale overview of transcriptome differences around the clock in heads of young and old flies, we found a group of genes that had constitutively low expression in young, but were greatly upregulated and rhythmic in heads of old flies. Genes showing this expression pattern were called "Late Life Cyclers," or LLCs. Further investigation revealed that many LLCs were involved in stress response, specifically oxidative stress. These included, among others: small heat shock protein *Hsp22*, cytokine *bnl*, dehydrogenase *ImpL3*, and Hsp40-like *CG7130*. Since the most robustly rhythmic LLCs' expression peaked at lights-off, or Zeitgeber Time (ZT)12, we tested whether this would be affected by longer or shorter periods of light during a 24h cycle. In flies collected in light:dark (LD) 16:8 or LD 8:16, the peak expression of most LLCs tested by qRT-PCR shifted to follow the time of lights off. In constant darkness (DD), expression was low and arrhythmic, suggesting that light is a factor in regulation of these genes. To mimic oxidative stress known to occur in old flies, we exposed young flies to 100% hyperoxia (HO). We found that LLCs were indeed upregulated and rhythmically expressed upon HO exposure in LD12:12, similar to what was seen in old flies. When flies were exposed to HO in DD, these genes were barely upregulated compared to normoxia controls, again resembling expression in old flies in DD. The inability of these genes to be overexpressed and rhythmic in the absence of light despite strong oxidative insult led us to investigate the role of the photoreceptive protein encoded by the gene *cryptochrome* (*cry*). CRY, a flavoprotein, has a key role in circadian regulation by causing degradation of the core clock protein TIM in the presence of blue light. However, other possible roles for *cry* remain unknown. We tested whether CRY was necessary for LLC upregulation, by measuring their expression profiles in young *cry*-null mutants, cry^{01} and cry^{02} held in LD under HO. We observed a loss of typical LLC rhythms and their reduced overall expression compared to wild type controls. Our data suggest that CRY has a novel role in stimulating expression of neuroprotective genes in response to light and oxidative stress.

D1141C The *fluted*^{1} (*fl*^{1}) mutation is a deletion in the CG5873/cysu gene and is required for wing integrity. *E. P. Spana*, Bio414 Team fluted (2012-2016). Duke University, Durham, NC.

The Drosophila wing makes an excellent model system for many developmental processes. From growth control and proliferation through patterning and signal transduction to eventually cell fate establishment and differentiation, the wing magically presents something for everyone. We have used this system in an undergraduate course in Genetics and Development to identify genes responsible for proper wing development.

The *fluted* (*fl*^{1}) mutation was discovered by Helen Redfield in 1921 and over 90 years later we have molecularly mapped that mutation to the genome and further characterized its phenotype. After reviewing the historical mapping data, students in the Bio414L course designed deficiency and transposon insertion complementation tests and identified insertions in CG5873 that failed to complement *fl*^{1}. Whole genome sequencing revealed that the lesion in *fl*^{1} is an approximately 1 kb deletion that removes most of exon 1 and the start of translation—not surprising since *fl*^{1} behaves as a genetic null. What is surprising is that *fl*^{1} is temperature sensitive. At 25° the wings have longitudinal creases between L3 and L4 and between L4 and L5. At 18°, these creases are much more severe, and at 29° the wings are almost wild-type. We used time-lapse imaging to identify when the creases present and found that after inflation, the wings were perfectly flat, but during the drying stage the wings creased and withered. These wings then slowly disintegrated over time where after a week, much of the intervein tissue had broken away.

The CG5873/cysu gene encodes for a Heme Peroxidase and has been linked to the Duox gene in wing development (Hurd et al, 2015 PLoS Genetics 11(11): e1005625) where it functions to remove the reactive oxygen species (ROS) created by Duox. It is possible that in *fluted* wings, an excess of ROSs are created that causes the deterioration of the wing. Increasing the temperature could alleviate this by causing the ROSs to volatilize at a higher rate.

D1142A Alternative splicing and isoform expression in the honeybee flight muscles. *A. J. Ayme-Southgate*, L. Galloway, E. Risner, J. Vance. Col Charleston, Charleston, SC.

Phenotypic plasticity allows individuals to, for example, adapt their physiological responses to their environment, as well as to the stage of their life cycle. Within a honeybee colony, worker bees start their adult life as nurses involved with building the honeycombs, feeding the larvae, and cleaning the hive. As such, nurse bees only need to fly limited distances and for short amounts of time. Some of the nurse bees transition later in life (around 21 days) to foragers whose job is to collect water and nectar, and as such foragers need to be excellent flyers. The nurse-forager transition event is a model system for understanding the molecular implication of phenotypic plasticity. This event necessitates major changes in the bee's behavior, but also in the efficiency and power generated by the flight muscle system. RNA sequencing analysis of flight muscle tissues isolated from nurse and foragers at different ages reveal differential gene expression of genes involved in several biological processes, including stress response, immunity, and protein synthesis. Proteins involved in muscle sarcomere structure, in particular proteins of the myofilaments undergo shift between isoforms during the transition. Quantitative RT-PCR analysis for proteins of the troponin complex, as well as the elastic C-filament will be presented. The generation of these alternative splice variants depends on the activity of regulatory splicing factors, such as muscleblind, lark, and others. The initial analysis of *Apis mellifera* splicing machinery and in particular regulatory splicing factors will be discussed in the context of the nurse-forager transition.

D1143B *Cellular senescence and oxidative stress are aging mechanisms that depend on genetic background*. *P. Bejo*, F. Capobianco, J. Parker. SUNY Plattsburgh, Plattsburgh, NY.

Cellular senescence (CS) is a state of metabolically active cells that experience an irreversible growth arrest upon some type of stress. Recently CS has been tied to age-related diseases (Zhu et al, 2015). Physiological aging is also associated with increased levels of ROS, but it is not understood how senescence and oxidative stress react to induce aging. We assessed the effect of senolytic drugs (that selectively kill senescent cells) on the longevity of wild-type *Drosophila melanogaster*. In our study, we show that a combination of senolytics (Dasatinib and Quercetin) increase the lifespan of one wild-type line Drosophila melanogaster, with no effect on the other. Previous experiments of our lab show a difference in oxidative stress response between these two genetic backgrounds. We are now using this combination of senolytic drugs and paraquat treatment to understand the relationship between oxidative stress and CS on physiological aging.

D1144C Epigenetic Regulation of Aging in *Drosophila melanogaster* . *Q. Brent Chen*[1,2], Trudy F. C. Mackay[1,2]. 1) Department of Biological Sciences and Program in Genetics, North Carolina State University, Raleigh, NC 27695, USA; 2) W. M. Keck Center for Behavioral Biology, North Carolina State University, Raleigh, NC 27695, USA.

As the average lifespan of the world population continues to increase, deciphering the biological underpinnings of natural variation in aging and lifespan are becoming critical to managing aging-related diseases. While many genes regulating lifespan have been identified, the epigenetic factors regulating lifespan and aging are largely unexplored. Here, we use five *Drosophila melanogaster* lines selected for postponed reproductive senescence for over 170 generations (O lines) and five lines from the same base population without selection maintained (B lines) to assess differential epigenetic modifications. The O lines live approximately twice as long as the B lines. We are using ATAC-seq to determine changes in open chromatin from a variety of tissues in both sexes of the O and B lines at several developmental and adult time points; and ChIP-seq to target histone modifications at different ages in these divergent lines. In conjunction with previous genomic, transcriptomic, metabolomic, and phenotypic data, we will derive putative causal relationships between epigenetic modifications and natural variation in lifespan.

D1145A Histone deacetylases affect aging-related muscle fiber loss.. *E. Gerberich*, A. Bryantsev. Kennesaw State University, Kennesaw, GA.

Progressive loss of individual muscle fibers in the elderly is a characteristic hallmark of aging-related muscle wasting condition – sarcopenia. We recently developed a model to address aging-related fiber loss (ARFL) on the basis of *Drosophila* jump muscle. In this study, the ARFL rates were analyzed in the muscles with depleted chromatin-remodeling factors, histone deacetylases (HDACs). *Drosophila* and human HDAC3 and HDAC4 share significant homology and are expressed in various muscle tissues. We used RNAi to down-regulate these HDACs in adult flies by means of a jump-muscle specific Gal4 driver. Our results show that the decreased expression of either HDAC3 or HDAC4 strongly promotes muscle fiber loss in aging flies. We hypothesize that this effect might be mediated by changes in HDAC-controlled expression of apoptotic factors. Our study identifies HDACs as important regulators of muscle longevity and survivorship, with potential implications in the development of human sarcopenia.

D1146B The Role of Activin Signaling in Drosophila Cardiac Aging. *Ping Kang*[1], Rolf Bodmer[2], Karen Ocorr[2], Hua Bai[1]. 1) Iowa State University, Ames, IA; 2) Sanford Burnham Medical Research Institute, La Jolla, CA.

Our previous study suggests that activin regulates muscle aging via autophagy. In this studywe investigated whether genetic manipulation of activin signaling within fly hearts affect cardiac functions during aging. Cardiac-specific expressed activin type I receptor Babo led to pre-matured cardiac aging phenotypes and altered cardiac functions at young age. In contrast, cardiac-specific knockdown the expression of key activin genes, daw and babo results in preserved cardiac function with age (e.g. prevents the age-dependent increases of heart period and diastolic intervals, as well as the incidence of arrhythmia). Interestingly, reduction in cardiac activin prolongs lifespan. These data suggest that activin signaling plays a key role in cardiac aging.

D1147C Regulation of dense-core granule replenishment by autocrine BMP signalling in *Drosophila* secondary cells. *Siamak Redhai*[1], Josephine Hellberg[1], Mark Wainwright[1], Sumeth Perera[1], Felix Castellanos[1], Benjamin Kroeger[1], Carina Gandy[1], Aaron Leiblich[1], Laura Corrigan[1], Thomas Hilton[1], Benjamin Patel[1], Shih-Jung Fan[1], Freddie Hamdy[2], Deborah Goberdhan[1], Clive Wilson[1]. 1) University of Oxford, Oxford, GB, Department of physiology, anatomy and genetics; 2) University of Oxford, Oxford, GB, Nuffield Department of Surgical Sciences, John Radcliffe Hospital.

Regulated secretion typically involves the trafficking of specific secretory products into dense-core granule (DCG) compartments, which mature and are then released by exocytosis after stimulation. These compartments must subsequently be rapidly replenished to retain secretory capacity. However, the mechanisms involved are largely unexplored. We have studied this problem in fixed and live secondary cells (SCs) of the *Drosophila* accessory gland (AG), which contain huge secretory compartments (> 5 µm diameter), thus providing a unique system to study DCG biogenesis and secretion. Here we demonstrate that each SC contains approximately ten large DCGs loaded with the Bone Morphogenetic Protein (BMP) Decapentaplegic (Dpp). When flies mate, roughly four DCG compartments are rapidly released from SCs, and autocrine BMP signalling, as measured by nuclear pMad staining, is immediately increased. Two of the secreted compartments are restored within 6 hours and by 24 hours, complete replenishment is achieved. The release of secretory compartments is dependent on their maturity, limiting the secretion of additional DCGs during rapid multiple matings. Interestingly, the replenishment of DCGs is regulated by BMP signalling, which is also required for secretion of these compartments, potentially through its effects on DCG maturation. Our study therefore highlights a central function for Dpp in matching biogenesis of new DCGs to elevated release of these compartments from SCs after mating. Notably, BMP signalling is crucial for secretion in other cell types, including insulin-secreting pancreatic beta cells and *Drosophila* motor neurons. Our new model potentially reflects a more general role for BMPs in providing a read-out for DCG release that ensures DCG numbers are maintained following regulated secretion.

D1148A Male proteins mediate the binding of sex peptide binding to sperm to prolong post-mating responses in *D. melanogaster* females. *Akanksha Singh*[1], Geoffrey D. Findlay[2], Mariana F. Wolfner[1]. 1) Department of Molecular Biology and Genetics, Cornell University, Ithaca, NY, USA; 2) Department of Biology, College of the Holy Cross, Worcester, Massachusetts, USA.

Drosophila melanogaster seminal proteins induce several post-mating responses in mated females, some short-term and others lasting for days. The long term post-mating responses, which include elevation of egg-laying, regulation of sperm release from storage, and changes in mating receptivity and behaviour, are mediated by the seminal protein Sex Peptide (SP), which is retained in the female by its binding to sperm. To test whether male-derived proteins are sufficient for SP binding to sperm, we examined the extent of this binding in ejaculates (produced by fru-GAL4;UAS-dTRP-A1 males in the absence of females), compared to that seen in the bursa and seminal receptacle of mated female. By immunofluorescence and Western blotting we see that SP can bind to sperm in ejaculates, indicating that male contributions are sufficient for this step. However, the level and distribution of this SP-sperm binding differs a bit from that seen on sperm isolated from the bursa or seminal receptacle, suggesting possible assistance by female components. Some male-derived seminal proteins needed to bind SP to sperm are known. To identify the full suite, and any sperm proteins that are required for SP binding, we used a comparative genomic method to pinpoint proteins whose evolutionary rates across the *Drosophila* phylogeny co-vary with the SP network proteins. Twenty-six such candidates are being tested for effects on the persistence of post-mating response and for their effects on SP binding to sperm.

D1149B Exploring chronic drug delivery regimes for aging studies in *Drosophila*. *H. Stratton*, A. Bryantsev. Kennesaw State University, Kennesaw, GA.

Drosophila has been instrumental in advancing studies on aging. Combination of the genetic methods available for *Drosophila* together with pharmacologic approaches can provide even deeper insight into the mechanisms of aging. Here, we studied the effects of chronic administration of the proteasomal inhibitor MG132 on muscle morphology. Besides testing for drug effects, we also specifically probed the feasibility of different oral drug administration regimes. Several conditions were employed:

1. MG132 present constantly in the fly food,
2. MG132 supplied on sucrose-soaked discs as an alternative supplement along with standard fly food,
3. MG132 obligatory supplied during overnight sessions, twice a week

The trials went for 4 weeks at 29^{o}C and then the effects of MG132 were scored by evaluating the abundance of polyubiquitylated proteins on cryosections and in muscle tissue lysates. According to preliminary results, chronic administration of MG132 improves muscle morphology in aged flies. The only successful feeding regime was when the drug was constantly present in the food. Additionally, we found that dimethyl sulfoxyde, a common organic solvent for many drugs, acts as a strong feeding repellent to flies, thereby reducing drug consumption rates. The results of our study emphasize the importance of proper drug administration planning in pharmacologic studies.

D1150C Sestrin, a novel target in the mTOR pathway that mediates benefits of exercise. *A. Sujkowski*[1], M. Kim[2], B. Kim[2], J. Lee[2], Robert Wessells[1]. 1) Wayne State University, Detroit, MI; 2) University of Michigan, Ann Arbor, MI.

Modern lifestyle, often characterized by over-nutrition and lack of exercise, causes prolonged activation of mTOR complex 1 (mTORC1)/S6K and chronic suppression of mTORC2/AKT, which together promote age-related muscle pathologies including insulin resistance, fat accumulation, mitochondrial dysfunction and functional decline. Using *Drosophila* as a model organism, we recently found that Sestrin acts as an important regulator of both mTOR complexes, and that the absence of Sestrin brings about several age-associated pathologies including mitochondrial dysfunction and skeletal/cardiac muscle degeneration. Sestrin dependent regulation of mTOR complexes is important for maintaining muscle health throughout life. We hypothesize that Sestrin can be a novel molecular target in the mTOR signaling network that can limit chronic mTORC1 activation and preserve mTORC2 activity in muscle, thereby promoting life- and healthspan. Transgenic induction of Sestrin in skeletal and cardiac muscle can prevent age-dependent loss of endurance and mobility, while increasing speed, endurance and cardiac performance. Importantly, endurance exercise induces Sestrin expression, while Sestrin deficiency nullifies the effects of long-term exercise in improving mobility and metabolism. These data suggest that Sestrins may mediate the beneficial effects of exercise in preserving muscle health, making the Sestrin protein family a potential therapeutic target for preserving mobility and improving quality of life in later ages.

D1151A Lateral Abdominal Muscles as a model for studying muscle atrophy in *Drosophila* . *N. Tamba*, A. Bryantsev. Kennesaw State University, Kennesaw, GA.

Drosophila has been notoriously instrumental in the uncovering of genetic mechanisms of muscle development, however it is generally considered less attractive for studying post-developmental plasticity of muscles. This is because the most studied muscles, flight and jump muscles, remain unchanged in size and morphology throughout the life of adult flies. We recently found that Lateral Abdominal Muscles (LAMs), small muscles underlying the abdominal wall, can undergo atrophic changes in response to starvation, aging, and experimentally-induced cancer cachexia. The relative ease of abdominal preparations, as well as the multitude of LAMs per fly, makes this model suitable for quantitative analysis. Using genetic approach, we demonstrate that experimental up-regulation of muscle structural gene expression can ameliorate LAM atrophy in aging flies. Our study indicates that LAMs can be a useful model for studying genetic components of muscle atrophy.

D1152B *Mondo/dChREBP* functions in the *Drosophila* intestine to regulate nutrient storage. *Niahz Wince*, Justin DiAngelo. Penn State Berks, Reading, PA.

After a meal, digestion occurs and nutrients are absorbed through the walls of the intestine and transported throughout the body to provide energy for cellular functions. Excess energy is stored as triglycerides and glycogen. Several enzymes act to break down complex macromolecules so they can be absorbed through the intestinal epithelia. However, the full complement of genes that function in the intestine to regulate nutrient absorption and storage are not fully understood. Carbohydrate response element binding protein (ChREBP) is a transcription factor known to function in the liver as a nutrient sensor that stimulates triglyceride storage in response to elevated nutrient levels. In addition to being expressed in the liver, ChREBP expression is enriched throughout the small intestine; however, whether ChREBP functions in the intestine to regulate nutrient absorption or storage is unknown. The *Drosophila* genome contains a single ChREBP homolog known as *Mondo*, and our lab has shown that this gene functions in the fly brain, muscle, and fat body to regulate feeding, nutrient storage, and muscle function. To test whether Mondo functions in the intestine, we measured levels of triglycerides and glycogen in flies where *Mondo* has been decreased specifically in the intestine using RNAi. We have found that lowering *Mondo* levels in the intestine results in a decrease in triglyceride and glycogen levels. This altered nutrient storage phenotype does not seem to be due to less nutrient intake as food consumption is not altered in *Mondo*-knockdown flies. Together, these data suggest that Mondo functions in the fly intestine to regulate nutrient absorption or transport in response to nutrient availability. .

D1153C Kruppel homolog 1 represses dFOXO transcriptional activity and lipolysis. *Hua Bai*[1], Kang Ping[1], Kai Chang[1], Marc Tatar[2]. 1) Iowa State University, Ames, IA; 2) Brown University, Providence, RI.

Insulin/insulin-like growth factor signaling (IIS) plays important roles in animal growth, metabolism, stress resistance and aging. It functions through the downstream forkhead transcription factor FOXO and interlays with many other key signaling pathways. The interaction between FOXO and its co-factors enhances the transcriptional specificity of insulin/FOXO signaling. Here, we identified transcriptional co-regulation of insulin signaling and lipolysis through the interaction between kruppel-like factor Kr-h1 and dFOXO in Drosophila. In fasting larvae, Kr-h1 co-localize with dFOXO in nuclei of fat body cells. Kr-h1 physically binds to dFOXO *in vitro* and acts as a repressor of dFOXO to regulate the transcriptional activation of insulin receptor (*InR*) and adipose TAG lipase *brummer*. The binding of Kr-h1 to the promoters of *InR* and *brummer* requires dFOXO. Juvenile hormone (JH) signaling, a major insect developmental regulator and an upstream regulator of Kr-h1, interacts with dFOXO to control lipolysis and the transcription of *brummer* lipase, and thus, lipolysis. Transcriptome analysis further reveals that Kr-h1 targets many metabolic genes that overlap with dFOXO targets. Thus, the interaction between Kr-h1 and dFOXO may represent a broad mechanism by which metabolic signaling integrates with JH-regulated developmental programs to coordinate organism growth. .

D1154A Transcriptional co-regulation of lipid metabolism by Drosophila dFOXO and Kruppel homolog 1. *K. Chang*, H. Bai. Iowa State University, Ames, IA.

Multiple transcription factors often interact at their genomic binding sites and these interactions enhance transcription specificity and pleiotropic functions in the regulation of diverse cellular processes. Insulin/insulin-like growth factor signaling (IIS) plays important roles in animal growth, metabolism, stress resistance and aging. It functions through the downstream forkhead transcription factor FOXO and interlays with many other key signaling pathways. The interaction between FOXO and its co-factors enhances the transcriptional specificity of insulin/FOXO signaling. We recently identified an intriguing interaction between dFOXO and zinc finger transcription factor Kruppel homolog 1 (Kr-h1). In the study, we further characterized this interaction at the genomic level to identify their direct target genes using Next-Gen sequencing approaches (ChIP-Seq and RNA-Seq). Pathway analysis of identified target genes revealed that dFOXO and Kr-h1 co-regulate a large set of metabolic genes, especially those involved in sphingolipid andglycerolipid metabolism. Our results provide addition evidence supporting the notion that cellular metabolic processes are coordinately regulated by diverse transcriptional programs.

D1155B Loss of *rab27* in the αβ pioneer neurons of the mushroom body extends lifespan by deactivating TOR signaling in *Drosophila*. *W. Lien*[1], Y. Chen[1], C. Wu[2,3], C. Chan[1]. 1) Graduate Institute of Physiology, National Taiwan University, Taipei, Taiwan; 2) Department of Biochemistry and Graduate Institute of Biomedical Sciences, College of Medicine, Chang Gung University, Taoyuan, Taiwan; 3) Department of Neurology, Linkou Chang Gung Memorial Hospital, Taoyuan, Taiwan.

The mushroom body (MB) is the regulatory center of several brain functions including learning, memory, and sleep in *Drosophila*. Whether MB regulates lifespan has not been investigated. MB is composed of Kenyon cells, calyces and five distinct lobes including the vertical α, α', medial β, β', and γ lobes. Further functional analysis subdivides the αβ neurons into at least 3 subsets: αβ pioneer (αβp), αβ surface (αβs), and αβ core (αβc). Here, we show that Rab27 controls lifespan in the αβp neurons of MB. Rab27 is an evolutionarily conserved Rab GTPase mediating the exocytic machinery in neuroendocrine cells. We characterized the *rab27* knockout (KO) flies, and no obvious developmental defect was observed, except that loss of *rab27* significantly extended lifespan. Specifically, *rab27* knockdown in the αβp neurons promoted longevity. To reveal the signal transduction, we first examined the insulin/IGF signaling (IIS) pathway. *rab27* knockdown in the median neurosecretory cells (mNSCs) by *dilp2-Gal4* did not extend lifespan and suppression of IIS in *rab27KO* background further extended lifespan. Moreover, the level of phosphorylation of AKT (pAKT), a downstream component of IIS, was not decreased in *rab27KO* brains. Thus the longevity phenotype was not due to reduced IIS. Rather, reduction of *rab27* leads to decreased phosphorylation of S6 (pS6), a downstream component of target of rapamycin (TOR) signaling. Consistently, suppression of TOR signaling by feeding rapamycin or expressing either TSC2 or $S6K^{DN}$ does not further increase the longevity of *rab27KO*, indicating that Rab27 functions through TOR signaling but not IIS pathway. We propose that reduction of *rab27* attenuates TOR signaling at the level of pS6. Further molecular evidence will be presented. Taken together, the results pinpointed αβp neurons of MB as an important region to control longevity. We discovered a novel site of TOR function in a specific neuronal circuitry for lifespan extension.

D1156C Activin-Beta/TGF-Beta signaling in skeletal muscle controls insulin signaling, metabolism and final body size. *Lindsay Moss-Taylor*, Michael O'Connor. University of Minnesota, Minneapolis, MN.

Inter-organ communication is essential for regulating development and homeostasis. Mutations in Drosophila *Activin-Beta* (*Act-Beta*) cause accelerated pupariation and reduced final body and organ size. To determine how Act-Beta affects size and timing, we first looked at which cells express Act-Beta and found expression in the Insulin Producing Cells (IPCs), neuroendocrine cells and motor neurons. Overexpression of Act-Beta in either neuroendocrine cells or motor neurons increases body size. Muscle-specific knockdown of the TGF-Beta signaling transducer/transcription factor dSmad2 reduces body size, indicating muscle is a target tissue of the Act-Beta signal. Additionally, levels of phospho-dSmad2 are reduced in skeletal muscle samples of *Act-Beta* mutants and increased in animals overexpressing *Act-Beta* from motor neurons. Levels of phospho-S6K in *Act-Beta* mutants are correlated with phospho-dSmad2 levels, suggesting TGF-Beta signaling regulates insulin signaling. Because insulin signaling controls metabolism, we used GC/MS analysis to identify and quantify levels of metabolites in whole-larval samples of *Act-Beta* mutants. We found intermediates of the energy-producing steps of glycolysis and lactic acid are reduced, indicating reduced flux through glycolysis. Overall, this indicates neuronally-derived Act-Beta signals to the skeletal muscle to regulate levels of insulin signaling and subsequent glycolysis. We have identified over 300 downstream targets of dSmad2 using RNA-seq of *Act-Beta*

mutant skeletal muscle. We are testing *impL2*, an insulin binding protein, as a potential dSmad2 target gene regulating systemic insulin signaling.

D1157A Toll signaling acts through the transcription factor Dif to block DILP-dependent growth in the *Drosophila* fat body. *Nigel Muhammad*, Stephen Roth, Michelle Bland. University of Virginia, Charlottesville, VA.

In *Drosophila* and mammals, activation of the innate immune system leads to insulin resistance. Infiltration of macrophages with active Toll-like receptor 4 signaling into obese adipose tissue leads to reduced insulin signaling and metabolic defects in mammals. In *Drosophila*, expression of constitutively-active Toll^{10b} receptors in the larval fat body activates the innate immune system and leads to reduced Akt activity, and decreases in fat body cell size, triglyceride storage, and whole-animal growth compared with flies expressing control transgenes. Toll signaling disrupts DILP signaling by interfering with phosphorylation of the kinase Akt. However, it is not known whether transcription factors in the Toll signaling pathway are required for the development of insulin resistance. Here we examine the role of the Toll pathway transcription factor and NF-KB homolog Dif in growth regulation in the *Drosophila* fat body. We find that expression of Toll^{10b} or elevated expression of Dif in the larval fat body is sufficient to induce expression of Toll target genes such as *Drosomycin*, *IM2*, *Dif*, and *cactus*, as measured by quantitative RT-PCR. Knockdown of Dif in fat bodies expressing Toll^{10b} restores low, wild-type expression of these genes, with the exception of *cactus*. When Toll^{10b} is expressed in clones of fat body cells, nuclear area and cell size are reduced, phenotype that are reversed by co-expression of constitutively-active myristoylated-Akt. Cell growth phenotypes are also rescued when Dif is knocked down in clones that express Toll^{10b}. Clones of fat body cells expressing constitutively-active PI3K (Dp110^{CAAX}) exhibit massively increased nuclear area, which is completely blocked by co-expression of Toll^{10b} but only partially blocked by elevated expression of Dif. Taken together, these data indicate that the transcription factor Dif is necessary but not sufficient for the Toll signaling pathway to reduce Akt-dependent cell growth. This indicates that an additional factor or factors contribute to growth inhibition even when Dif is over-expressed. This may indicate a requirement for post-translational modification of Dif that is not met unless the Toll pathway is activated at the receptor level or that another transcription factor is activated by Toll signaling for the full response. Further, our data suggest that transcription of unknown genes is likely required for Toll signaling to inhibit DILP signaling. Identification of such genes should shed light on the pathology of inflammation-induced insulin resistance.

D1158B Neprilysins control insulin signaling via cleavage of regulatory peptides. *R. Schiemann*[1], B. Hallier[1], L. Dehnen[1], E. Cordes[1], J. Vitos-Faleato[2], S. Walter[3], A. Malmendal[4], A. Paululat[1], H. Harten[1]. 1) University of Osnabrueck, Zoology & Developmental Biology, Osnabrueck, Germany; 2) IRB Barcelona, Department of Biomedical Research, Barcelona, Spain; 3) University of Osnabrueck, Mass spectrometry, Osnabrueck, Germany; 4) University of Copenhagen, Biomedical Sciences, Copenhagen, Denmark.

Insulin and IGF signaling play important roles during development and growth, but also in the daily life of mature organisms where they regulate metabolism, reproduction, stress responses, aging or lifespan. Despite these critical physiological functions, mechanisms that control insulin production and release are still only partially understood. By showing that modulating expression of a *Drosophila* neprilysin considerably interferes with proper expression of major insulin-like peptides, we provide novel mechanistic insight into this issue and relate neprilysin activity to the regulation of insulin signaling for the first time. Concomitant phenotypes of impaired Neprilysin 4 expression include reduced body size, premature lethality and characteristic changes in the metabolite composition of respective transgenic animals. Significantly, ectopic expression of a catalytically inactive protein variant does not elicit any of the phenotypes, which proves aberrant enzymatic activity and thus impaired peptide hydrolysis as critical parameter. In a screen for novel substrates of Neprilysin 4 we identified numerous peptides known to be involved in regulating insulin-like peptide expression, feeding behavior, or both, and thereby provide a conclusive explanation for the depicted phenotypes. The high functional conservation of significant factors renders the characterized principles applicable to numerous species, including higher eukaryotes and humans.

D1159C Localized epigenetic silencing of a damage-activated WNT enhancer limits regeneration in maturing *Drosophila* imaginal discs. *Robin Harris*, Iswar Hariharan. University of California, Berkeley, Berkeley, CA.

For many organisms, the ability to regenerate damaged tissues diminishes with increasing maturity. The mechanisms responsible are unknown, but their identification is essential to promote tissue regeneration in adult organisms. *Drosophila* imaginal discs, when damaged *in situ*, are able to regenerate, but this ability diminishes dramatically during the third larval instar. This decline correlates with a reduction in the ability to upregulate *wingless* (*wg*, *WNT1*) and *WNT6* expression following damage. Since WNT proteins are upregulated following injury in diverse taxa, the mechanisms that regulate WNT expression following tissue damage are likely conserved.

To understand how damage-induced *wg* expression is activated, we have characterized an enhancer that regulates the expression of two flanking genes, *wg* and *WNT6,* during regeneration. Deletion of this enhancer permits normal development but compromises regeneration. Dissection of the genomic region reveals a bipartite structure that includes a damage-responsive module and a silencing element. The damage-responsive module is robustly activated following various damaging stimuli, requiring the JNK pathway. Notably, this activity is undiminished with increasing maturity. In contrast, an adjacent element, which has no enhancer activity on its own, can progressively attenuate expression mediated by the damage-responsive module by nucleating highly localized epigenetic silencing at the enhancer. Cas9-mediated deletion of this silencing element abolishes silencing and restores damage-induced WNT expression in mature discs, demonstrating that the silencing element is indeed responsible for the age-related loss of damage-induced WNT expression *in vivo*. Importantly, this epigenetic silencing remains restricted to the enhancer, thus allowing adjacent enhancers that are regulated by developmental signals to remain accessible.

As the majority of genes implicated in regeneration also function during development, until now it has been difficult to explain how a maturing organism can limit the capacity to regenerate without compromising normal growth and differentiation. The localized silencing of

damage-responsive enhancers is a mechanism that can prevent the activation of genes following injury, while still allowing those same genes to be expressed by developmental signals. In addition to *wg* and *Wnt6*, this mechanism likely regulates many other regeneration genes. Using sequence motif analysis we have identified a similar bipartite enhancer within the *MMP1* gene. Alongside genome-wide chromatin structure analysis, we will use these approaches to identify other such regulatory regions, and thus comprehensively define the genetic basis for declining regenerative capacity of maturing tissue.

D1160A Establishing a model of BM damage and analyzing its repair. *Angela Howard*, Gautam Bhave, Andrea Page-McCaw. Vanderbilt University , Nashville, TN.

The basement membrane is a sheet-like extracellular matrix that wraps around muscle fibers and underlies epithelia. Because it has been difficult to study in vivo, the basement membrane is often considered to be static, analogous to cement. However, there are indications that the BM is a dynamic system. Basement membrane is able to grow, shrink, repair, and move to assist in tissue attachment as needed. We want to develop a system to analyze basement membrane repair in adult animals. In both mammals and flies, the gut appears to be a relatively dynamic basement membrane suggesting it could be a good system for analyzing repair.

We will analyze basement membrane repair using an adult gut injury model. The gut has a well-defined architecture of epithelial cells (enterocytes) residing on top of a basement membrane sheet, wrapped in visceral muscles also surrounded by basement membrane. To injure the gut, flies are fed Dextran Sodium Sulfate (DSS); DSS administration has been previously used as a model for ulcerative colitis in mice although the etiology is unknown. In Drosophila, DSS induces morphological changes in the architecture of the gut consistent with basement membrane damage. Using both electron and super-resolution microscopy, we observe an increase in BM thickness. Furthermore, preliminary data suggests that DSS becomes lodged in the gut BM. Interestingly, inhibiting or knocking down a collagen-IV crosslinking enzyme, peroxidasin, mimics the tissue changes seen in response to DSS. Currently, we are analyzing how this damage is repaired and the requirements for its repair. We plan to knock down multiple basement membrane components after flies reach adulthood to test their role in repair.

D1161B Systemic influences of methionine metabolism in fat body for *Drosophila* imaginal disc repair. *S. Kashio*[1], F. Obata[1,2], L. Zhang[1,3], T. Katsuyama[1,4], T. Chihara[1,4], M. Miura[1,4]. 1) The University of Tokyo, Tokyo, JP; 2) The Fancis Crick Institute, London, UK; 3) University of Toronto, Ontario, CA; 4) AMED-CREST, Tokyo, JP.

Regeneration and tissue repair is a fascinating process that allows organisms to maintain homeostasis after tissue injury. Molecular mechanisms for tissue repair and regeneration within damaged tissue have been extensively studied. However, the systemic regulation of tissue repair remains poorly understood. To elucidate tissue nonautonomous control of repair process, it is essential to manipulate genes in uninjured parts of the body, independent of local tissue damage.

In this study, we develop a system in *Drosophila* for spatiotemporal tissue injury using a temperature-sensitive form of Diphtheria toxin A domain (DtA^{ts}) driven by the Q system to study factors contributing to imaginal disc repair. This system enables us to induce reproducible tissue damage and to perform genetic screening with Gal4 system in uninjured tissues. Using this system, we demonstrate that methionine metabolism in the fat body, a counterpart of mammalian liver and adipose tissue, supports the repair processes of wing discs. Local injury to wing discs decreases methionine (Met) and S-adenosylmethionine (SAM), whereas it increases S-adenosylhomocysteine (SAH) in the fat body, implying that SAM consumption is increased at the early stage of tissue repair. Fat body-specific genetic manipulation of methionine metabolism results in defective disc repair, but does not affect normal wing development. These results indicate the contribution of tissue interactions to tissue repair in *Drosophila*, as local damage to wing discs influences fat body metabolism, and proper regulation of methionine metabolism in the fat body, in turn, affects disc repair.

D1162C The Loss of Regenerative Potential in the Aging Drosophila Germline Stem Cell. *R. E. Kreipke*, H. Ruohola-Baker. University of Washington, Seattle, WA.

Aging is a complex biological process, comprised of a large number of both cellular and organismal changes that, together, lead to the progressive decline in tissue and organ function. In addition to declining function in somatic cells, aging tissues are also marked by a decrease in the proliferative capacity of pluripotent cells, hampering their regenerative capacity and ability to respond properly to injury and insult. However, the mechanisms that govern the regenerative competence of aging stem cells still remain unclear. The *Drosophila melanogaster* germline stem cell (GSC) niche offers a powerful model with which to study developmentally regulated changes in stem cell regeneration and their response to insult. In the young fly, GSCs are resistant to the apoptotic effects of ionizing radiation. Dying daughter cells release a protective signal that inhibits the apoptotic machinery in germline stem cells, prompting them to become quiescent rather than apoptotic. The GSCs are able to later re-enter the cell cycle and repopulate the daughter cells. This protective mechanism highlights a key difference between the proliferative capacities of somatic and germline cells. To date, though, the ability of the aged ovary GSC has not been probed. We compared the ability of 2-, 4-, and 6-week old germline stem cells to regenerate daughter cells following exposure to ionizing radiation. We found that, while aged GSCs were able to survive exposure to ionizing radiation, their ability to exit quiescence and re-enter the cell cycle to repopulate the germaria were compromised when compared to young GSCs. This suggests that the mechanisms that preserve the regenerative capacity of GSCs may degrade with age. To identify novel regulators of GSC regeneration, we used newly developed techniques of protein knockdown to disrupt protein function. This will allow us to screen for genes that regulate GSC regeneration following exposure to ionizing radiation and begin to identify genes that contribute to age-related decline in GSC proliferation.

D1163A Spatiotemporal regulation of cell fusion by JNK and JAK/STAT signaling during *Drosophila* wound healing. *J. Lee*, C. Lee, K. Choe. Yonsei University, Seoul, South Korea.

Cell-cell fusion is widely observed during development and disease conditions, including fertilization, myogenesis, and trophoblast formation. Cell fusion brings a dramatic change to participating cells so it should be tightly controlled, but the underlying mechanism is poorly understood. We found that the JAK/STAT pathway suppressed cell fusion during wound healing and delimited the event to the vicinity of the wound in the *Drosophila* larval epidermis. In the absence of JAK/STAT signaling, a large syncytium containing 3-fold the number of nuclei observed in wild-type tissue formed in wounded epidermis. JNK was activated in the wound vicinity and activity peaked at approximately 8 h after injury, whereas JAK/STAT signaling was activated in an adjoining concentric ring and activity peaked at a later stage. Cell fusion occurred primarily in the wound vicinity, where JAK/STAT activation was suppressed by fusion-inducing JNK signaling. We found that the balance of JAK/STAT and JNK signaling determined whether cell fusion was executed or not. JAK/STAT signaling was both necessary and sufficient for the induction of βPS integrin expression, suggesting that the suppression of cell fusion was mediated by integrin protein.

D1164B Effects of exercise and heat shock on lifespan and health span of $A\beta_{1-42}$ *Drosophila melanogaster*. *S. Alsolami*, A. Ospina, I. Silva. California State San Bernardino University, San Bernardino, CA.

Alzheimer's Disease (AD) is an age-dependent neurodegenerative disease pathologically characterized by the formation of amyloid plaques and neurofibrillary tangles. Amyloid Beta 1-42 (Aβ1-42) has been shown to be the most likely peptide to form these plaques that ultimately inhibit neuronal communication and induce neuronal death. Drosophila melanogaster is a model organism that has been used to study numerous neurodegenerative diseases including AD, Parkinson's disease, and ALS. In this study, a Drosophila melanogaster strain expressing human Amyloid Beta 1-42 transgene has been used as an experimental group and a genetically matched line (00C) has served as the control. Previous research has indicated that both exercise and heat shock can increase the lifespan and health span of Drosophila melanogaster. Both Aβ1-42 and 00C strains of Drosophila melanogaster were exercised and heat shocked, each strain was exercised five days a week for three weeks, and heat shocked at 37˚C for twenty minutes twice a week for three weeks. Survival and climbing assays along with heart rate measurements were used to assess lifespan and health span. The survival, climbing, and heart rate assays indicated that exercise and heat shocking the 00C strain improved its lifespan and health span compared to untreated controls while in the Aβ1-42 strain, exercise and heat shock resulted in decreased lifespan, deteriorated health span, and resulted in the impairment of their cognitive capacity compared to the negative control. We've found that exercising and heat shocking the 00C strain improved their cognitive and motor functions and thus increased their lifespan and health span. However, exercising and heat shocking the Aβ 1-42 strain resulted in decreased cognitive ability, and motor function, and as such did not benefit their health span. At this point, it is not clear why the Aβ1-42 flies did not benefit from the treatments, as did their matched controls. Future studies will include heart tissue analysis to identify if other biomarkers associated with heart function were compromised.

D1165C *Characterization of fried/HEATR2 expression and phenotypes*. *Margaret Fisher*, Elina Sigal, Miranda Colman, Jason Morris. Department of Natural Sciences, Fordham University, New York, NY.

fried loss-of-function mutants were first identified in a clonal screen for oogenesis defects. Subsequently, we found that *fried* mutants exhibit behavioral defects during larval stages and eventually die as late larvae or early pupae. Mapping, sequencing and rescue of *fried* mutants showed that *fried* encodes HEATR2, a protein that others have shown to be required for ciliary axoneme formation and to be expressed in mechanosensory neurons in embryos (Diggle, et al., 2014). Here we present the mRNA expression pattern of *fried/HEATR2* in larval and adult tissues based on mRNA *in situ* hybridization using an mRNA null allele as a negative control. We show that *fried/HEATR2* mRNA is strongly expressed in salivary glands and adult egg chambers along with an array of other tissue types. We also discuss loss of function phenotypes in *fried* larvae and pupae.

D1166A The influence of diet and mtDNA genotype on sexual conflict in *Drosophila melanogaster*. *W. C. Aw*[1], M. R. Garvin[2], J. W. O. Ballard[1]. 1) The University of New South Wales, Randwick, NSW, AU; 2) University of Alaska Fairbanks, Juneau, AK, USA.

W.C. Aw[1], M. R. Garvin[2] and J. W. O. Ballard[1]

[1]School of Biotechnology and Biomolecular Sciences, The University of New South Wales, Sydney, Australia

[2]Fisheries Division, School of Fisheries and Ocean Sciences, University of Alaska Fairbanks, Juneau, AK, USA

The aim of the study is to identify the influence of diet and mtDNA haplotype on sexual conflict in strains of *Drosophila melanogaster* harbouring the same genetic background. Here we focus on sexual conflict conferred by mitochondria as a result of the organelle's maternal mode of inheritance in the majority of metazoans. We hypothesise that changes in diet could be an important factor that affects sexual conflict between males and females. We fed female and male flies one of four diets that differed in their protein: carbohydrate ratios and tested the sexual conflict by examining five organismal (fecundity, longevity, starvation resistant, lipid proportions and paraquat resistance) and four cellular traits (mitochondrial respiration, ROS production, SOD activity and mtDNA copy number). Traits were assayed at 11d and 25d of age. Here, we show that female physiological traits are more susceptible to dietary changes than males suggesting that diet mediates the change in the degree of sexual conflict. We also found that flies harbouring different mtDNA haplotypes have haplotype specific life-history traits. Finally, we reveal sex specific differences in mitochondrial and biochemical functions and suggest these may be associated with sex-specific differences in ageing.

D1167B Intestinal microbes shorten the host lifespan through increased intestinal permeability in *Drosophila melanogaster*. *H. Lee*, S. Lee, W. Seo, K. Min. Inha University, Incheon, INCHEON, KR.

Intestinal microbes that live in a symbiotic relationship with their host are well known to affect host fitness such as metabolism, obesity, and inflammation. However, the effects of intestinal microbes on host lifespan are not well characterized. In this study, we investigated the effects and mechanisms of intestinal microbes on host lifespan using the *Drosophila melanogaster* as a powerful model animal to study host-microbes interaction. We generated axenic flies by dechorionation of eggs with sodium hypochlorite, and measured its lifespan. The lifespan of flies was increased under axenic condition, and it was decreased by the oral ingestion of the extracts of guts from female flies, indicating that the microbes existing in the gut of flies affect host lifespan. To investigate which commensal bacteria affect the host lifespan, adult flies was subjected to oral ingestion with the single species of microbes such as *Lactobacillus brevis*, *Acetobacter persici*, *Lactobacillus plantarum* and *Acetobater malorum* which are dominated in the guts of young or old flies. We hypothesized dysbiosis of the intestinal microbiota leads to systemic influences on aging files with increased intestinal permeability. The incidence of intestinal dysfunction was increased by aging and intestinal dysfunction increased the permeability of microbes in the gut of flies. In addition, we interestingly observed that *L. plantarum, Sphingomonas yunnanensis, L. brevis,* and *Acetobacter indonesiensis* were founded in the hemolymph of flies with intestinal barrier dysfunction. Taken together, our findings suggest the possibility that intestinal microbes decrease the host lifespan with increased intestinal permeability by aging.

D1168C Growing faster or growing too fast? Effects of *Lactobacillus plantarum* on Drosophila fitness. *Mélisandre Téfit*[1,2], François Leulier[1,2,3,4]. 1) IGFL, Lyon, FR; 2) ENS de Lyon, FR; 3) CNRS, FR; 4) UCBL, FR.

In nature, organisms are constantly associated with a variety of microorganisms. The interactions between these microbes and their host can vary along a continuum of different types, with outcomes ranging from obligate symbiosis to lethal infection. In this spectrum, the microbiota occupies the central and balanced part, covering microbial species that establish commensalistic or mutualistic relationships with each other and with the host organism. There is increasing evidence that the microbiota plays a crucial role in different aspects of the host physiology, and disruption in its composition has been linked to several types of pathological situations.

In order to elucidate the fine-tuned dialogue governing the relationships between the microbiota and its host, we use the model *Drosophila melanogaster* associated with one of its natural commensals, *Lactobacillus plantarum*. This rather simple gnotobiotic system allowed us to reveal a growth-promoting effect mediated by *L. plantarum* in nutritionally challenged drosophila larvae. In case of nutrient scarcity, larvae associated with *L. plantarum* develop twice faster than the germ-free ones, giving rise to adults of similar weight and size. However, adjusting development to environmental cues is key to organismal fitness, and yet here animals are growing fast even though the nutritional conditions are poor. What seems like an advantage could then be deleterious at later stages, and the *L. plantarum*-mediated growth acceleration upon nutritional challenge could in turn adversely impact adult fitness.

In this light, we studied different life history traits and showed that adults emerging from the fast-growing, *L. plantarum*-associated larvae perform as well as their slow-growing axenic siblings. They were able to resist starvation equally well and produced equally numerous and fit progeny. In addition, males kept on a low-yeast diet and associated with *L. plantarum* had a markedly increased median lifespan in comparison to the germ-free males. We are now investigating the physiological basis of this differential response, by analysing the metabolic state of these males. In summary, *L. plantarum* acts as a true mutualist of *D. melanogaster*, as it allows the precocious emergence of mature and fertile adults without fitness drawbacks. Furthermore, in certain conditions, this commensal can even increase the lifespan of nutritionally challenged males.

D1169A A Molecular Genetic Analysis of the role of Carbonic Anhydrases in Tracheal Development of *Drosophila melanogaster*. *Grace Jean*[1*], Mark Keroles[1], Ben Russel[1], Sarah McGriff[1], Jyoti Nair[1], Christopher Kowalczyk[1,2], Jaclyn Arvedon[1], James Baker[1]. 1) University of Miami, Coral Gables, FL; 2) Nova Southeastern University, Fort Lauderdale, FL.

The respiratory system of *Drosophila* develops as a fluid-filled epithelium. Late in embryonic development, the fluid is rapidly replaced with gas, an event that occurs within minutes and is independent of contact with outside air. The mechanisms underlying this phase transition remain enigmatic, but carbonic anhydrases may play a crucial role in the process by producing CO_2 gas while simultaneously promoting reabsorption of fluid by the surrounding epithelium.

A bioinformatics study of the carbonic anhydrase gene family in *Drosophila* showed that though humans and flies possess similar numbers of carbonic anhydrase genes (13 and 15 respectively), most of these have evolved after divergence. Based on our analyses, we elected to study two genes that are unique to insect lineages, cah2 and CG6074. Both genes are expressed in the trachea, and have probable signal peptides, suggesting that they are secreted. Also consistent with secretion, Cah2 protein, is glycosylated and has a likely GPI linkage site. These two genes are developmentally and tissue specifically regulated, showing high expression in the tracheal epithelium at the time of tracheal filling.

To functionally characterize these genes, fly lines containing mutagenic MiMIC insertions in both CG6074 and cah2 were obtained from the Bloomington Stock center. Both insertions are in introns and are oriented properly to create early terminations in each of the proteins. The cah2 mutation proved to be lethal in the late embryonic to early larval stages; presenting with a variety of defects in tracheal filling and maintenance of the open airway. Excision lines completely revert the phenotypes indicating that the MiMIC insertion is the cause of the observed defects. We are in the process of generating lines to rescue mutants by tissue specific expression, and generating an endogenously tagged version of the cah2 gene to allow us to directly observe the temporal and spatial expression of the protein. These experiments will enable us to directly test the hypothesis that carbonic anhydrases mediate transitions between fluid-filled and gas-filled states.

D1170B Jak/Stat functions in reproductive aging. *M. Giedt*, D. Harrison. University of Kentucky, Lexington, KY.

Aging is a complex process, subject to genetic and environmental influences. Regulators of aging include cell signaling, nutrient sensing, DNA repair, protein homeostasis, changes in behavior, and stem cell maintenance. Reproductive tissues also display signs of aging, separate from the organism and aging in reproductive tissues can serve as a model for the study of aging overall. Although initially fertile, males mutant for the Jak/Stat ligand Upd3 experience premature loss of fertility, suggesting a minimum level of Jak/Stat activity is required for regulation of reproductive maintenance. However the Jak/Stat pathway is important for a number of different processes that could contribute to reproductive aging. Given the genetic complexity of aging, and its variation between individuals, the genetic architecture of reproductive senescence can be determined by a genome-wide association study (GWAS). Using the DGRP, we performed a GWAS of male reproductive lifespan to identify potential regulators of reproductive aging with links to Jak/Stat signaling. Our results identified candidates that are known targets or regulators of the Jak/Stat pathway. Among these were *pox-neuro (poxn)* a known target of Stat92E in the male posterior lobe. This gene has known functions in chemosensory bristle specification, courtship behavior, and male genitalia development, making it a logical candidate for validation. Ptp61F, a known negative regulator of Jak/Stat signaling was also identified in our analysis. Other loci that are known or predicted modifiers of HSPGs or other extracellular signaling regulators were identified and could have previously undocumented roles in regulation of Jak/Stat activity or other cell signaling processes regulating reproductive maintenance with age. We are currently validating these candidates for their roles in reproductive maintenance through knock down or misexpression of candidates using the Gene Switch system. Data from these analyses will be presented.

D1172A Patterns of Transposable Element Expression in Heads During *Drosophila* Aging. *G. A. Reeves*, C. Highfill, S. Macdonald. University of Kansas, Lawrence, KS.

Transposable elements (TEs) are mobile, selfish genetic factors that are present in large numbers in the genomes of many organisms. TE insertions can lead to deleterious consequences for organism function, and indeed TE proliferation has been linked to a decline in function of the central nervous system and the onset of neurological disease. In addition, age-dependent changes in the expression of certain TE families has been seen in *Drosophila* brain tissue. In order to determine the effects of TE expression and mobilization in the aging brain it is critical to first detail the pattern of TE expression change during the aging process.

Here, we use mRNAseq to evaluate the regulation of TE expression throughout the lifespan of multiple, genetically-distinct, inbred *Drosophila* genotypes, focusing on head-specific expression. In our first experiment we made use of samples of young and old mated females collected from multiple DSPR (*Drosophila* Synthetic Population Resource) strains aged under standard laboratory conditions. Following RNA extraction, library generation and sequencing, we tested for gene expression differences between young and old flies, and for age-related expression changes at 126 TEs. We confirmed previous reports that *Hsp22* expression increases markedly in the heads of old flies, and validated work showing that expression of antimicrobial genes also increases as flies age. We found that 8 TEs show a significant change in expression during aging ($p < 0.05$), all but one of which are Class I retrotransposons. However only 2/8 show the predicted increase in expression with age. For example, while expression of the *Tabor* element (an LTR retrotransposon) increases with age, expression of the *GATE* element (another LTR element) is reduced with age. We found no evidence for the previously reported increased expression of *R1* and *R2* LINE-like retrotransposons or *gypsy* LTR retrotransposons in aged heads of any strain examined.

Concerns with this experiment are the lack of replication within strains, and the use of just two samples of head tissue - young and old - per strain. To both increase our power and more precisely describe the change in TE expression during lifespan, we generated large numbers of mated females from two strains with marked differences in overall lifespan, and sampled flies for mRNAseq at several points throughout the aging process. We anticipate this new experiment will provide a more accurate picture of age-related changes in TE expression in the *Drosophila* head.

D1173B Atypical Paternal Centrioles are Essential for Progeny Embryogenesis. *T. Avidor-Reiss*, A. Khire, E. Fishman, K. Jo. University of Toledo, Toledo, OH.

Centrioles are conserved, self-replicating, microtubule-based 9-fold symmetric subcellular organelles that are essential for proper cell division and functions. Most cells have two centrioles and maintaining this number of centrioles is important for animal development. However, how animals gain their first two centrioles during reproduction is only partially understood. It is well established that in most animals, the centrioles are contributed to the zygote by the sperm. However, in humans, insects, and many other animals, the sperm centrioles are modified in their structure and protein composition, or they appear to be missing altogether. In these animals, the origin of the first centrioles is not clear.

We have discovered that *Drosophila melanogaster* sperm has a novel and atypical second centriolar structure that we named the proximal centriole-like structure (PCL). The PCL contains centriolar proteins but lacks microtubules and has a structure distinct from a typical centriole. Nevertheless, the PCL functions analogously to a centriole in the zygote; after fertilization, it recruits PCM, forms astral microtubules and found in one of the spindle pole, and provides a platform for the formation of a new centriole. Therefore, our data suggests that insect sperm provides two centrioles and suggest a universal mechanism of centriole inheritance among animals that include atypical centrioles.

We have also discovered that both the typical and atypical centrioles of *Drosophila melanogaster* sperm centrioles are remodeled during spermiogenesis. The ultrastructure and protein composition of the two centrioles is modified during spermiogenesis, resulting with two atypical centrioles in the spermatozoa. Paternal protein mutants that regulate this remodeling affect the resulting embryo. Altogether, our findings demonstrate that atypical paternal centrioles play a role in pre- and post-fertilization to ensure embryogenesis.

D1174C The multifunctional transcription factor Suppressor of Hairy-wing is required in spermatogenesis. *T. Duan*. University of Iowa, Iowa City, IA.

Drosophila Suppressor of Hairy-wing [Su(Hw)] is a polydactyl zinc-finger transcription factor that functions as an insulator, activator and repressor protein. Su(Hw) is nearly ubiquitously expressed in all tissues throughout development. One exception is the testis, wherein Su(Hw) is down-regulated mid-way through spermatocyte growth, at a time prior to the onset of the testis-specific transcriptional program. These observations prompted us to test whether Su(Hw) has a role in spermatogenesis. We found that loss of Su(Hw) causes age-dependent male sterility that is accompanied by defects in sperm production. The *su(Hw)* mutant testes are characterized by formation of bulges at the posterior end, which are filled with individualized sperm. Concomitant with pre-mature sperm release within testes, seminal vesicles are small. Based on the timing of Su(Hw) expression and its genome-wide localization within Lamin-associated domains, we hypothesized that Su(Hw) contributes to the developmental program in the testis by conferring transcriptional repression of testis-specific cluster genes in early spermatogenesis. This postulate was tested using microarray analysis to compare gene expression in $su(Hw)^{+/+}$ and $su(Hw)^{-/-}$ testes. Data obtained from these studies revealed that few (2%) of ~300 mis-regulated genes correspond to genes inside the testis clusters. Instead, the majority of these genes correspond to de-repressed neuronal genes, reminiscent of the transcriptional effects associated with Su(Hw) loss in the ovary. Our working model is that expression of one or more Su(Hw) target genes is altered in $su(Hw)^{-/-}$ testes, which interferes with normal spermatogenesis. Current investigations are focused on identifying genes responsible for this block.

D1175A Assessment of age-dependent effects on sperm quality and male fertility in *Drosophila melanogaster*. *H. Elwa*, S. Pitnick, S. Dorus. Syracuse University, Syracuse, NY.

The evolutionary trade-off between investment in somatic maintenance and reproduction predicts that the allocation of energy resources into reproductive traits should increase in an age-dependent manner. As an individual ages, the opportunity for future reproduction decreases; thus, despite resource limitation, individuals should allocate more resources to reproduction to maximize their potential reproductive output. Variation in the amount and timing of resources allocated to reproduction is expected to have significant fitness consequences. However, analyses of age-dependent changes in reproductive fitness often results in conflicting observations. We have examined the effect of male aging on different measures of sperm quality in *Drosophila melanogaster*; including sperm morphology, sperm competitiveness, reproductive output, and larval viability. Young (7-day old) and old (30-day old) RFP sperm-tagged wild type males, who were provided regular opportunities to mate during their lifetime, were used in all experiments. Sperm length measurements revealed an increase in length variation in old males, but no difference in average length between age cohorts. Single mating fertility assays, using standardized females, indicated that the total number of fertilized eggs laid does not differ in relation to male age, but did show a significant deficit in progeny surviving to eclosion for old males. Double mating competitive fertilization experiments were also conducted using a non-virgin wild type male with GFP-tagged sperm as a standard competitor. This revealed that the total number of sperm in the female reproductive tract and the seminal receptacle were reduced in matings with old males. Ongoing experiments are determining whether this is due to reduced sperm production or transfer by old males, or whether more sperm from old males is displaced by competing sperm and ejected by the female. Overall, our results document substantial fertility deficits associated with aging.

D1176B Roles for tissue-specific ATP synthase subunits in mitochondrial shaping and ATP synthase dimerization in *Drosophila*. *K. G. Hales*, E. C. Brunner, M. Bannon, N. Suresh, L. Regruto, B. Jepson, E. M. Sawyer. Davidson College, Davidson, NC.

Mitochondria in post-meiotic early round *Drosophila* spermatids aggregate and fuse into the Nebenkern, which consists of two interwoven large mitochondrial derivatives that together form a spherical structure equal in size to the nucleus. Homozygous *knon* males are sterile, showing defective internal Nebenkern structure and subsequent faulty elongation of mitochondrial derivatives along the growing spermatid axoneme. *knon* encodes a testis-specific isoform of an ATP synthase subunit that, based on its size and structure, may alter ATP synthase dimerization, a phenomenon known to mediate cristae morphology in many systems. We hypothesize that tissue-specific ATP synthase dimerization dynamics may underlie the unusual mitochondrial shaping within the Nebenkern. To test the role of Knon in mitochondrial dynamics and ATP synthase dimerization, we exogenously expressed it in flight muscle and larval brain using the GAL4-UAS system; we assessed mitochondrial structure via fluorescence microscopy, and ATP synthase dimerization via immunoblots of blue native gels. While preliminary data in flight muscle show no large scale alteration of mitochondrial shape, Knon exogenous expression did shift the balance of ATP synthase dimers and monomers, though less than when peripheral stalk components are knocked down via RNAi. Knon expression in flight muscle with simultaneous knockdown of the paralogous broadly-expressed subunit does not restore wild type ATP synthase complex formation as detected by BN PAGE, suggesting that Knon cannot substitute for its paralog in this tissue. Further studies of *knon* and other testis-specific ATP synthase subunit paralogs may help elucidate the basis for unusual mitochondrial dynamics in the Nebenkern.

D1177C Importin α1 is required for maintaining germline stem cells in *Drosophila melanogaster* testes. *G. R. Hime*[1], F. Casagranda[1], K. L. Loveland[2], J. R. Heaney[1]. 1) Dept. of Anatomy and Neuroscience, University of Melbourne, Parkville, Victoria, Australia; 2) Dept. of Anatomy and Developmental Biology, Monash University, Clayton, Victoria, Australia.

Importin-α proteins are required for transporting proteins from the cytoplasm into the nucleus via interaction with Importin-β in all tissues but also have roles in transcriptional regulation and organisation of chromatin and have been suggested to act as developmental switches during germline development. The *Drosophila melanogaster* genome encodes four *Importin-α* genes, also designated *Karyopherin* (*Kap*) genes. We have identified a specific requirement for *Kap-α1* in maintenance of male germline stem cells and spermatogonial differentiation. Loss of function *Kap-α1* mutants are male sterile. They lose germline stem cells (GSCs) and this loss can be rescued by germline specific expression of

Kap-α1 but the rescued animals are still infertile indicating a secondary role of Kap-α1 in spermatogenesis. The GSC loss is accompanied by development of germ cell cysts that contain aberrant numbers of germ cells suggesting that cysts may be differentiating prematurely. The pre-meiotic *Kap-α1* mutant phenotype can be phenocopied by germline expression of a dominant-negative Kap-α1 protein that lacks the Importin-β binding domain. We identified genes known to be expressed in the testis that produce proteins containing a consensus nuclear localisation sequence and screened for the ability of the dominant-negative allele to prevent protein transport into spermatogonial nuclei. From this screen we identified CycH and CG12909 as potential targets of Kap-α1. Germline specific knockdown of CG12909 produces a phenotype similar to that of *Impα1* alleles. The mammalian ortholog of CG12909, LYAR, has been associated with recruitment of the methyltransferase PRMT5 to specific regions of chromatin and symmetric dimethylation of histone H4 Arg3. We are currently investigating if *Kap-α1* mutants genetically interact with CG12909 or have defects in histone dimethylation.

D1178A Functional characterization of a gene family essential for *Drosophila* spermatogenesis. *Benjamin Nicholson*, Maxwell Kearns, Geoffrey Findlay. College of the Holy Cross, Worcester, MA.

Several of the most abundant proteins found in the proteome of mature sperm in *Drosophila melanogaster* are encoded by a single gene family. To examine the functional consequences of the gene duplication events that gave rise to this family and to test whether these genes act redundantly, we used RNA interference to knock down expression of each gene in male testes. For most of the genes, knockdown males exhibited complete or near complete infertility. To investigate the nature of these fertility defects, we produced knockdown males that made sperm labeled with green fluorescent protein (GFP). These males transfer no (or very few) sperm to females during mating, and testis dissections revealed that knockdown males were unable to produce mature sperm. These results suggest that this family of proteins, in addition to being a major component of mature sperm, is also essential for spermatogenesis. Current experiments are focused on determining the stage(s) of spermatogenesis at which each member of this gene family acts, which may allow us to determine the pattern(s) of neofunctionalization or subfunctionalization that occurred after the gene duplication events.

D1179B Analyzing the role of the *aghino* gene in protein and vesicular trafficking during acrosome biogenesis in *Drosophila melanogaster*. *I. Paz*[1], H. Park[2], N. Rigler[2], B. Wakimoto[2]. 1) Heritage University, Toppenish, WA; 2) University of Washington, Seattle, WA.

The *aghino* (*agho*) gene was initially defined by a single male sterile mutation. Previously, we reported that *agho* is one of several genes required for sperm activation during fertilization. Here we show that *agho* is the earliest acting of five known genes in the sperm activation pathway. Analysis of new *agho* alleles recovered by reverse genetics showed that two mutations resulted in defects in biogenesis of the acrosome, a Golgi-derived organelle that is normally localized to the apical tip of mature sperm. We found that in *agho* mutants, sperm lacked acrosomes, but entered the egg efficiently then failed to undergo sperm plasma membrane breakdown, an event required to complete fertilization and initiate embryogenesis. Using a transgene expressing an Agho-Green Fluorescent Protein fusion, we detected the protein at the Trans-Golgi Network, the region of the Golgi that sorts and packages membrane and secreted proteins into vesicles for transport to post-Golgi destinations. Based on these observations, we propose that Agho acts in spermatids to regulate acrosomal protein and vesicular trafficking. We are currently asking whether Agho influences trafficking of non-acrosomal cargos in spermatids. Because Agho is widely expressed, we are also investigating whether mutations affect trafficking in other cell types. In addition to elucidating the steps required for acrosome formation and function, our results should define Agho's normal function in both *Drosophila* germ line and somatic cells.

D1180C Functional consequences of a selfish X-chromosome in *Drosophila neotestacea*. *K. Pieper*[1], K. Dyer[1], R. Unckless[2]. 1) The University of Georgia, Athens, GA; 2) University of Kansas, Lawrence, KS.

Genetic conflict is ubiquitous across the tree of life and can have significant consequences for the genome. The *sex-ratio* X-chromosome (SR) of the fruit fly *Drosophila neotestacea* is a selfish sex chromosome that promotes its own transmission at the expense of the Y-chromosome. In the testes of males that carry SR, half of the sperm fail to develop through an unknown mechanism and thus no Y-bearing sperm are produced. The offspring of these males are nearly all daughters, with the only sons being sterile X0 males. SR produces this selfish phenotype equally strongly against all tested genetic backgrounds, and there are no known phenotypic effects other than halved sperm production in males. Our goals are to characterize the mechanism of the SR phenotype, identify candidates for the causal loci on the SR chromosome, and understand the downstream effects of SR. As a first step, we performed whole transcriptome sequencing of the testes and carcass (whole body minus testes) of SR-carrying males and males carrying the standard X-chromosome. We compared gene expression levels to find transcripts differentially expressed in the testes of SR males but not the carcass, which are candidates for involvement in the selfish mechanism. Transcripts that are on the X-chromosome are particularly strong candidates for the causal loci, whereas autosomal genes that are differentially expressed in the testes may be activated downstream of the SR mechanism or regulated in trans by genes located on SR. Genes that are differentially expressed in the carcass may represent previously unknown pleiotropic consequences of SR. We also examine the differential expression of genes already known to be involved in different stages of spermatogenesis to identify when the SR mechanism activates to cause developmental failure. Overall, our results quantify the functional consequences of SR, identify potential candidates for the molecular mechanism, and lay a foundation for future investigations of the evolutionary genomic consequences of genetic conflict.

D1181A 3'UTR regulation may be involved in germ cell differentiation in drosophila. *L. Shan*. IGDB, Beijing, Beijing, CN.

Alternative cleavage and polyadenylation (APA) is a widespread phenomenon that generates transcript isoforms with alternative 3'UTR. Through alteration of 3'UTRs, APA potentially regulates the stability, cellular localization, and/or translation efficiency of target mRNAs. Previous work in our lab demonstrated that Tut, Bam, and Bgcn can form a physical complex to promote germ cell differentiation in *Drosophila*. Surprisingly, *mei-P26* has alternative 3' UTR in fly testes, longer in *tut*, *bam* or *bgcn* mutant while shorter in wild type. We aim to explore the relationship between the change of 3'UTR length and germline differentiation and how differentiation-related 3'UTR is regulated. At the first step, we analyzed the 3'UTR profiles of wild type, *tut*, *bam*, or *bgcn* mutant testes by Poly(A) Site Sequencing (PAS-Seq). We found that hundreds of genes' 3'UTR were lengthened in *tut, bam,* or *bgcn* mutant testes. Our data indicate that 3'UTR length is mis-regulated in spermatogonia-enriched mutant testes, suggesting that APA may be involved in germ cell differentiation. Due to the different cell types between the wild type control and these mutant testes in PAS-Seq, we will clarify whether the change of 3'UTR in *tut, bam*, or *bgcn* mutant testes is caused by germ cell differentiating stages. Meanwhile, we will examine the 3'UTR profiles at different stage of germline differentiation to further survey the relationship between the change of 3'UTR length and germline differentiation. In order to elucidate how differentiation-related 3'UTR is regulated, the mRNA target(s) of the Tut-Bam-Bgcn complex will be identified to clarify how the Tut-Bam-Bgcn complex regulates 3'UTR.

D1182B Which parent is damaged? Can Progeny show consequences? *E. Arroyo*[1], P. Ramos[1], A. Muñoz[1], R. Camacho[2], M. Altamirano[3]. 1) Faculta de Ciencias-UNAM,Ciudad de México, México; 2) IIB-UNAM, Ciudad de México, México; 3) Fes Zaragoza-UNAM, Ciudad de México, México.

Germ cells will become eggs or sperms, as result of a prolonged process of division and differentiation, compartmentalized in time and space. The exposure of the organisms to mutagens can affect this process, modifying the type and proportion of gametes produced, damaging their integrity and their ability to contribute to the formation of the next generation. This contribution is not similar for both parents and that is why in this study we compared the effect of the mutagen Methyl-Methanesulphonate (MMS) in the germ cells from female and male of *D. melanogaster* through the ability of germ cells to produce progeny and, by using markers linked to X, was determined the distance between the white-miniature genes from classic mapping to assess the type and proportion of gametes produced that contribute to the next generation. Wild-type females w+m+/w+m+ were mated with hemizygous males wm/Y of *D. melanogaster* to obtain F_1 larvae of 72±4h that were fed food enriched with successive dilutions of MMS (0.24 µM - 1mM) or distilled water (negative control), so that the maturation of germ cells occur in the presence of the mutagen. Survival (S) of treated flies was compared to the negative control. Of flies recovered of treatment 50 virgins ♀♀ (T) and 50 ♂♂ males (T) were selected for each concentration and were mated individually with untreated flies (NT) as follows: T X T, T X NT and NT X T. The progeny was classified and counted by phenotype to calculate fertility, average amount of progeny and recombination frequency. Higher concentrations of MMS were lethal. The Fertility and amount of progeny decreased in the crosses: T XT y NT XT. The frequency of recombination between the w-m genes in the progeny of exposed individuals were modified in certain concentrations depending on the parent exposure (female or male). The progeny more affected was from T X T crosses (both exposed) but when only one parent was treated, the germ cells from F_1 males exposed were more affected than the germ cells of F_1 females treated. Probably the treatment with MMS interfered with the process of maturation of the germ cells or even, one part of the germinal cells of the parent treated were eliminated without contribute in the formation of the new individuals. Yaneli Trujillo-Varela by technical support.

D1183C Spargel/dPGC-1 is involved in Insulin-TOR signaling, nutrient sensing and Oogenesis. *M. A. BASAR*, Kishana Williamson, Atanu Duttaroy. Howard University, Washington, DC.

Peroxisome proliferator-activated receptor gamma co-activator *1* (PGC-1) is a transcriptional co-activator that is expressed abundantly in tissues with high- energy demand, including the brown adipose tissue, heart, skeletal muscle, kidney, and brain. In vertebrates PGC-1 has been linked to mitochondrial biogenesis and oxidative metabolism. Spargel/dPCG-1, the fly homolog of PGC-1 also regulates the expression of mitochondrial OXPHOS genes, mitochondrial O_2 consumption and ATP production. Earlier studies claimed that spargel (srl) belongs to insulin-TOR pathway and thus facilitate nutrient sensing by TOR. Gene array data suggested that among all adult tissues *srl* mRNA is abundantly expressed in the ovary. Using an anti-srl antibody we now have proof that srl expression is strictly limited to the ovary while the rest of the body expresses negligible quantities of srl. Female germline specific knockdown of *spargel* completely shuts down the egg chamber's growth at midstage afterwards the egg chambers die through caspase-3 activation. Most interestingly, feeding excess yeast doesn't change ovarian growth when spargel is ablated, which proves that spargel serves as a critical facilitator between nutrition and growth. Our analysis reveals that germline depletion of spargel causes coagulation of Notch protein in germ cell cytoplasm and Notch mediated *E(spl)* gene activation is negatively affected in the follicle cells. Although, Notch mediated Hindsight expression kicks off earlier. Finally, we now have proof that the RNA Recognition Motif (RRM) of spargel plays an important role in healthy egg development. In summary, spargel is indispensable in coordinating ovarian growth and development.

D1184A Characterizing highly conserved genes of unknown function in the *Drosophila* female germline. *Varsha Bhargava*, Courtney Goldstein, Juliana Pineider, Kevin Gonzalez, Michael Buszczak. University of Texas Southwestern Medical Center, Dallas, TX.

(VB and CG are co-first authors)

Germ cells transfer genetic information across generations. Any change in germ line DNA is inherited by succeeding generations. Therefore germ cell DNA must be protected from both internal and external assault. An advantage of sexual reproduction stems from the ability to

generate variation by exchange of chromosomal segments during meiosis. During meiosis, hundreds of double-stranded DNA breaks are initiated at once, which if generated in most other cell types would introduce chromosomal aberrations. Germ cells, however, execute the formation of these breaks while preventing their deleterious effects from becoming pervasive throughout the genome. The mechanisms underlying the robustness of germ cells in the face of DNA damage, however, are poorly understood. We have initiated an in vivo CRISPR-Cas9 knockout screen for genes highly enriched in the *Drosophila* female germ line. Mutants from the screen were assayed for increased gamma-His2Av, a marker for DNA damage. This led to the identification of an uncharacterized but highly conserved protein that contains a Spr-T domain. We have elected to name this gene bedlam, based on its tumorous phenotype. Through experiments in yeast and in cell lines, it has been shown that other members of the Spr-T family are involved in DNA-protein adduct repair. This study aims to characterize a potentially germ line-specific, conserved DNA protein adduct repair pathway, using genetic and molecular biological approaches. Thus, characterizing bedlam function may provide key insights into DNA break repair in multicellular organisms.

D1185B Proteomic analysis of CTP synthase filaments in *Drosophila*. *A. Chakraborty*, P. Y. Wang, W. C. Lin, L. M. Pai. Chang Gung University, Tao-Yuan, TW.

De novo pyrimidine pathway utilizes CTP synthase (CTPsyn) as a rate limiting enzyme for the biosynthesis of cytidine triphosphate (CTP). In nutrient depletion conditions, CTPsyn assembles into filamentary structures. This self- assembly, higher ordered structure suggests a key regulation of metabolism in the cell. The question that allures us the most is why this metabolic enzyme needs to form filaments? Is this an easy way to tune in the production of CTP whenever required? There has been already an ongoing debate on whether this specialized structure is catalytically active or just a protein aggregate. Our lab has demonstrated that CTPsyn filaments are regulated by ubiquitination and support S phase during endocycles in follicle cells. Recently it has been reported that IMPHD2 co-localizes with the CTPsyn filaments in human cell lines. Moreover, in *Drosophila*, the DAck was also found to co-localize with the CTPsyn filaments in the germ cells where the structure maintains the integrity of cell membrane through phospholipid production. It is possible that the structure has different associated proteins at different physiological conditions which can regulate their enzymatic activity. Therefore, it would be very important to identify the structural components of these filaments and elucidate their activities. Here we use a system in which CTPsyn is tagged to a genetically engineered peroxidases, APEX2. APEX2 can oxidise the biotin-phenol to generate a very short-lived biotin-phenoxyl radical which covalently tags the endogenous proteins adjacent to the APEX2 protein. Using the above approach we have successfully labelled the CTP synthase filaments in the live *Drosophila* ovary tissues with biotin and have successfully identified the biotinylated "targets" of the filament structure in germline cells, and in the follicle cells using mass spectrometry. Currently we are examining the involvement of the candidates in CTPsyn filament formation using co-localization or knockdown approaches.

D1186C Polar cells are required for formation of a functional micropyle. *M. Giedt*, D. Harrison. University of Kentucky, Lexington, KY.

The polar cells are a pair of specialized somatic cells at each end of the developing egg chamber. While their importance in follicle cell specification and border cell migration are understood, relatively little is known about their functions in late stages of oogenesis. The micropyle is a conical structure with a central lumen at the anterior of the egg and serves as the entry point for sperm during fertilization. Its formation is known to be dependent upon the timely migration of the border cells. If border cell migration is delayed, the micropyle exhibits defects, among which are blockage of the central lumen. Here we present evidence that the polar cells have a critical role in formation of a functional micropyle. It has been described that the polar cells form an extension into the developing micropyle, but the function or mechanisms driving its formation are unknown. We observed that *upd3* mutants have an increased incidence of unfertilized eggs and failure to form the micropyle channel. The polar cell/border cell cluster still migrates to the anterior of the oocyte, but the polar cell extension misses the micropyle resulting in blockage. Using live imaging and fixed ovaries with GFP labeled polar cells, we characterized the dynamics of polar cell extension and micropyle development in wild type eggs. Results show that extension morphology during micropyle formation is highly dynamic and predictable. Furthermore, the polar cell extension forms prior to appearance of the micropyle and seems to mark the location where the micropyle will form. We are currently characterizing polar cell behavior in wild type and *upd3* mutant egg chambers and these results will be reported. While autocrine Jak/Stat activity in the polar cells is not required for process formation but, its reduction does affect process morphology and polar cell adhesion. To determine when polar cell involvement is required for micropyle formation, we are impairing polar cell functions through genetic manipulation of cytoskeletal dynamics, signaling, and viability to examine the nature and timing of polar cell formation of the micropyle channel. Results from these experiments will be reported.

D1187A Analysis of CASK gene expression and function in *Drosophila* oogenesis. *T. L. Hoffman*, C. M. Brown, R. E. Boody, C. W. Smith, M. D. Popil, S. N. Bentley, T. R. Miller, J. L. Sanford. Ohio Northern University, Ada, OH.

CASK is a Ca^{2+}/CaM-dependent serine protein kinase belonging to the family of **M**embrane **A**ssociated **Gu**anylate **K**inases (MAGUK), all of which contain PDZ (PSD-95, Dlg, Zo-1), SH3 (Src Homology 3), and GK (guanylate kinase) domains. These domains function as protein scaffolding domains at cell-cell junctions and function to cluster channels and receptors. Previous work on CASK has focused on its role in the central and peripheral nervous systems, epithelial cell junctions, and neuromuscular junctions. However, recent work has suggested a role for CASK in *Drosophila* oogenesis. Specifically, a recent RNA interference screen identified CASK as a contributor to border cell migration. Border cell migration is a process by which two specialized polar cells are carried by 8-10 surrounding "border cells" from the anterior of the egg chamber to the oocyte where they form the micropyle, the site of sperm entry in the *Drosophila* egg. This work suggests that CASK may have an important role in development of the fully mature female egg. Moreover, because border cell migration is used as a model of collective cell migration, studies of CASK protein function and binding partners can lead to novel insights into the mechanisms that regulate how cells move

en masse. As a means of establishing a general framework for future investigations into CASK's role in *Drosophila* oogenesis, CASK isoform expression and the affect of CASK knockout on fecundity and fertility were assayed. To establish which CASK isoforms are expressed in ovaries, reverse-transcriptase PCR (RT-PCR) was conducted on total fly and ovary extracts from the wild-type w1118 fly line using isoform specific primers to all seven *Drosophila* CASK isoforms (CASK-A, -B, -D, -E, -F, -G, -H). This work has confirmed the expression of CASK-A, -B, -G, -H and –E in *Drosophila* ovaries; work confirming the presence or absence of isoforms –D and –F is still underway. In order to assess a possible role for CASK in fecundity and fertility we took advantage of an available CASK knockout fly line. Fecundity was measured by counting the number of eggs laid by individual CASK knockout female flies at 24 and 48 hours (n= >30 for both wild-type and knockout fly lines). These results demonstrated that CASK knockout does not affect the rate of egg laying in female flies. Further work will assess whether CASK knockout affects fertility by measuring embryo viability. This work represents a vital first step in the characterization of CASK protein function in *Drosophila* oogenesis and the process of border cell migration.

D1188B The relationship between egg size and terminal filaments in *Drosophila melanogaster* lines selected for divergent egg size. *D. Mohan*, C. Quintanilla, C. Miles. Augustana University, Sioux Falls, SD.

Egg size is a complex, adaptive, and highly polygenic trait. Paired ovaries in *Drosophila* females consist of multiple, independent, oocyte-producing modules called ovarioles. Changes in egg size are thought to influence maternal fitness, which is correlated with ovariole number in adults. Ovariole number is reported to be determined during the larval-pupal transition phase (LP-phase) by morphogenesis of somatic structures called terminal filaments. Terminal filaments (TFs) are stacks of terminal filament cells (TFCs) that each give rise to an ovariole. Previously, we generated replicate populations of *D. melanogaster* artificially selected for large and small egg volumes (Miles et al., 2011), and inbred lines were derived from the selected populations. Adult females from multiple inbred lines from the large-egg populations had fewer ovarioles than those from small-egg lines (Jha et al., 2015). Here we use antibody staining and confocal microscopy to examine developing ovaries dissected from LP stage females from these same inbred lines. We expected that the number of TFs would predict the number of ovarioles in adults (Hodin and Riddiford, 2000). Surprisingly, we found that the number of terminal filaments was not an accurate predictor of adult ovariole number in many of these inbred lines. Several of the large-egg lines have significantly more TFs at the LP stage relative to adult ovariole numbers. We include discussion of the implications of this finding. .

D1189C Germline regulation of *Sex lethal* in *Drosophila melanogaster*. *R. Goyal*, K. Baxter, M. Van Doren. Johns Hopkins University, Baltimore, MD.

In *Drosophila*, sex-determination is under the control of the "switch" gene *Sex lethal* (*Sxl*). While in some species the sex of the soma is sufficient to determine the sex of the germline via inductive signaling, sex-determination in the *Drosophila* germline also occurs cell-autonomously via intrinsic signaling dictated by the germline sex chromosome constitution. Interestingly, when *Sxl* is expressed in XY germ cells, these germ cells are able to produce eggs upon transplantation into a female somatic gonad, demonstrating that even in the germline, *Sxl* is the "switch" and is sufficient to activate female identity [1]. In both the germline and soma the presence of two X chromosomes leads to *Sxl* expression. However, its control is different in the germline than in the soma at both, *cis*- and *trans*- regulatory levels, and we are studying how this is regulated in the germline. The DNA elements responsible for the activity of *Sxl*'s sex-specific promoter (*SxlPe*) in the germline have not been identified. To identify these elements, we are cloning different DNA fragments covering the entire region upstream of the *Sxl* transcriptional start site into an enhanced GFP (eGFP) reporter vector to test for sex-specific expression in the germline. Further, we are investigating the *trans*- acting factors that control *Sxl* expression in the germline. Based on previous studies, the X chromosome "counting genes" important for activating *Sxl* in the soma are not required in a dose-dependent manner in the germline. However, we have found that knocking down *sisterlessA* (*sisA*) specifically in the female germline results in an ovarian tumor phenotype, similar to masculinization of the germline due to loss of *Sxl* function. Encouragingly, *Sxl* expression is lowered in *sisA* RNAi ovaries. Previously, our lab has found that germ cells without SXL exhibit a derepression of *Phf7*, a male germline sexual identity gene. We are investigating if *Phf7* is expressed in *sisA* RNAi ovaries but have already found that *Phf7* RNAi rescues the ovarian tumor from *sisA* RNAi. Finally, we are searching for additional *trans*-regulators of *Sxl* through an RNAi screen of genes expressed sex-specifically in the undifferentiated germline. Our studies will further our understanding of how the 'sex' of the germline is coordinated with the 'sex' of the soma. Since a failure to match germline and somatic sex leads to defects in gametogenesis in both flies and humans, this work is important for our understanding reproductive biology and human health.

D1190A The novel Tudor-domain protein TDRD5P regulates male germline sexual identity. *Caitlin Pozmanter*, Shekerah Primus, Mark Van Doren. Johns Hopkins University, Baltimore, MD.

The process of sex determination in *Drosophila* is regulated by the RNA-binding protein Sex lethal (Sxl) in both the germline and the soma. While the mechanism by which SXL brings about sexual dimorphism in the soma is well studied, its function in the germline is less well understood. To identify genes that are regulated by SXL in the germline, RNA sequencing was done in a *bam* mutant background to compare *Sxl*-RNAi ovaries to control ovaries. Analysis of this expression data uncovered a previously uncharacterized gene CG15930 with a 16-fold increase in expression in *Sxl*-RNAi females. Comparison of *bam* mutant testes and ovaries also showed a 16-fold higher expression level in males suggesting that SXL functions in the female germline to repress CG15930. CG15930 contains a single tudor domain and is most closely related to the mouse *TDRD5* and the Drosophila *TDRD5* homolog *tejas*, so we have named it *tdrd5-prime* (*tdrd5p*).

To elucidate the function of TDRD5P in the male germline, we generated mutant alleles using CRISPR/CAS9 along with an HA tagged genomic

BAC construct for analysis of the TDRD5P protein. The *tdrd5p* mutant testes show several phenotypes such as hub displacement, germline loss, and a 50% reduction in fecundity indicative of an important role for TDRD5P in germline differentiation. Confocal microscopy of HA-TDRD5P testes shows an interesting localization of the protein to discrete cytoplasmic punctae near the nuclear periphery. This suggests that TDRD5P may localize to an RNA body such as the P-body or nuage similar to other tudor domain containing proteins. Since tudor domain proteins are known to function in the piRNA pathway, RT-PCR was conducted for numerous transposons in *tdrd5p* mutants and found no change in expression. We are currently conducting RNA-seq to compare *tdrd5p* mutants to wildtype to investigate whether TDR5P regulates the levels of other cellular RNAs. To determine what type of RNA body TDR5P functions in, we are conducting co-immunoprecipitation followed by mass spectrometry. Additionally, to understand the mechanism by which TDR5P functions we plan to do a series of truncations to identify potential important regions of the protein that have yet to be annotated. Based on this data we propose that the previously uncharacterized TDR5P functions to ensure the proper development of the male germline and must be repressed by SXL to allow for female germline development.

D1191B Male-specific development of the gonad stem cell niche regulated by *doublesex* and *fruitless*. *H. Zhou*, C. Whitworth, M. Van Doren. Johns Hopkins University, Baltimore, MD.

In *Drosophila melanogaster*, sexual differentiation of the male and female gonads is controlled by the key sex-specific transcription factor Doublesex (DSX). While homologs of DSX are known to control sexual development in virtually all animals, including humans, the downstream mechanism and targets for these proteins remain largely unknown. Previously, our genomic analysis of DSX identified *fruitless (fru)* as a candidate downstream target of DSX to direct male gonad development. FRU is expressed in key somatic cells of the testis stem cell system (the hub, cyst stem cells and early cyst cells) but is not found in the ovary. It is well known that *fru*, is regulated by sex-specific alternative splicing to promote male-specific expression. Surprisingly, we found that male-specific FRU expression in the gonad is not caused by TRA/TRA-2 mediated alternative splicing and, instead, DSX^M is necessary and sufficient to turn on FRU in the gonad regardless of the chromosomal sex. Our genomic analysis indicates that DSX directly binds to *fru* P3 and P4 promoters to regulates *fru* expression at the transcriptional level.

A key step in establishing gonadal sex identity is the formation of sexually-dimorphic gonad stem cell niche. We previously found that *dsx* is required at 3rd larval instar to actively maintain the male niche identity and inhibit transdifferentiation into a female niche. The temporal expression pattern of FRU correlates with this process and our genetic analysis indicates that *fru* is required to maintain male niche identity. We also found that *fru* is required in the adult for both cyst stem cell maintenance and cyst cell differentiation. We propose that *fru* functions downstream of *dsx* in the male gonad as a masculinizing factor to maintain the hub identity and cyst stem cell homeostasis.

D1193A Identification and Characterization of Novel Genes in the *Drosophila* Heart. *TyAnna Lovato*, Dylan Brown, Devon Lagueux, Richard Cripps. Univ New Mexico, Albuquerque, NM.

Drosophila is an effective model for understanding the genetic factors and pathways that direct the formation of the heart. Using fluorescent-activated cell sorting (FACS) of embryonic heart cells followed by RNA sequencing, we were able to identify novel genes expressed during embryonic heart development. In this project, we have chosen to characterize CG8147, CG9336, and CG7033. CG8147 has predicted alkaline phosphatase activity while CG7033 is a predicted chaperone protein with ATP binding capability. CG9336 currently has no known conserved functional domains. To understand the how these genes might affect heart development, we are utilizing CRISPR/Cas9 technology to generate mutant fly stocks in order to further investigate their role in development. .

D1194B Altering expression of JAK/STAT pathway components in air sac primordia of *Drosophila melanogaster*. *N. A. Powers*, A. Srivastava. Western Kentucky University, Bowling Green, KY.

JAK/STAT signaling facilitates vital developmental processes in a diverse array of mammalian and invertebrate species. One such species, *Drosophila melanogaster*, appears to be a strong candidate for investigating and modeling mechanisms for early morphogenetic changes common to both humans and fruit flies. Of particular interest are the potential roles that signaling pathways implicated in invasive growth patterns, such as JAK/STAT, serve in oncogenesis and metastasis of tumors. In *Drosophila*, progenitors of adult air sacs, which supply oxygen to flight muscles, are known as air sac primordia (ASP), and function in a manner comparable to human lungs. Because these ASP propagate into wing imaginal discs invasively, we have begun investigating possible roles that JAK/STAT signaling proteins might play in the directed morphogenesis of these structures. Our current research focuses on enhancing or suppressing expression of three components in the JAK/STAT signaling cascade of *Drosophila*: the JAK (*hopscotch*), ligand receptor (*domeless*), and STAT (*Stat92e*).

D1195C *GATAe* regulates intestinal stem cell maintenance and differentiation in *Drosophila* adult midgut. *T. Adachi-Yamada*[1], K. Takeda[1], M. Kuchiki[1], M. Akaishi[1], K. Taniguchi[1], T. Okumura[1,2]. 1) Gakushuin Univ, Tokyo, JP; 2) Waseda Univ, Tokyo, JP.

Adult intestinal tissues, exposed to the external environment, play important roles including barrier and nutrient-absorption functions. These functions are ensured by adequately controlled rapid-cell metabolism. GATA transcription factors play essential roles in the development and maintenance of adult intestinal tissues both in vertebrates and invertebrates. We investigated the roles of *GATAe*, the *Drosophila* intestinal GATA factor, in adult midgut homeostasis with its first-generated knock-out mutant as well as cell type-specific RNAi and overexpression experiments. Our results indicate that *GATAe* is essential for proliferation and maintenance of intestinal stem cells (ISCs). Also, *GATAe* is involved in the differentiation of enterocyte (EC) and enteroendocrine (ee) cells in both Notch (N)-dependent and -independent manner. The results also indicate that *GATAe* has pivotal roles in maintaining normal epithelial homeostasis of the *Drosophila* adult midgut through interaction of N signaling. Since recent reports showed that mammalian GATA-6 regulates normal and cancer stem cells in the adult intestinal tract, our data also provide information on the evolutionally conserved roles of GATA factors in stem-cell regulation.

D1196A A functional genomics approach to identify targets of Forkhead domain transcription factors involved in cardiogenesis. *Shaad M. Ahmad*[1,2], Ye Chen[3], Xujing Wang[3]. 1) Department of Biology, Indiana State University, Terre Haute, IN; 2) The Center for Genomic Advocacy, Indiana State University, Terre Haute, IN; 3) National Heart, Lung and Blood Institute, NIH, Bethesda, MD.

While mutations in four genes encoding Forkhead (Fkh/Fox) domain transcription factors (TFs) have been linked to human congenital heart defects and eight Fkh TFs are required for proper cardiac development in mammals, little is known about the molecular mechanisms or the downstream target genes by which these Fkh TF-mediated cardiogenic functions are brought about. Our prior work identified the cardiogenic roles of two *Drosophila* Fkh genes, *jumeau* (*jumu*) and *Checkpoint suppressor homologue* (*CHES-1-like*). Mutations in these genes result in numerous heart defects, including disruptive changes in cardiac cell types and numbers, errors in cardiac progenitor cell specification and division, and defects in cardiac cell position. Furthermore, Fkh TF binding sites are significantly enriched in combination with those of other known cardiogenic TFs in the enhancers of cardiac genes. Collectively, these results indicate that these two Fkh TFs integrate diverse cardiogenic processes by regulating a large number of downstream target genes, thus raising the question of what these target genes are and what their individual functions might be during heart development. To address this question we have utilized RNA-sequencing to compare genome-wide transcriptional expression profiles of flow cytometry-purified mesodermal cells from wild-type, *jumu* loss-of-function, *CHES-1-like* loss-of-function, and *jumu* and *CHES-1-like* dual loss-of-function embryos. The putative Fkh targets identified by our analysis, i.e. genes exhibiting significant differential expression in *jumu* and/or *CHES-1-like* mutants can be divided into four classes: (i) 985 genes that are regulated only by *jumu* but exhibit no significant change in expression levels in *CHES-1-like* mutants, (ii) 318 genes that are regulated solely by *CHES-1-like*, (iii) 287 genes that are differentially expressed both in individual *jumu* mutants and in *CHES-1-like* mutants, and (iv) 541 genes exhibiting significantly altered expression levels in embryos lacking both Fkh gene functions, but not in either individual *jumu* or *CHES-1-like* loss-of-function mutants, indicating that they are regulated by the two Fkh TFs in a mutually redundant manner. Gene ontology enrichment analyses suggest multiple cardiogenic roles for these putative Fkh targets (specification of cardiac mesoderm, establishment of heart lumen, proper positioning of different heart cell types, sarcomere and myofibril formation, assembly of mitochondrial subunits and processes, cardiac progenitor cell divisions, etc.) that are being experimentally tested.

D1197B The Forkhead transcription factors CHES-1-like and Jumu mediate correct positioning of cardiac cells. *Shaad M. Ahmad*[1,2], Neal Jeffries[3]. 1) Department of Biology, Indiana State University, Terre Haute, IN; 2) The Center for Genomic Advocacy, Indiana State University, Terre Haute, IN; 3) National Heart, Lung and Blood Institute, NIH, Bethesda, MD.

The development of a complex organ requires the specification of appropriate numbers of each of its constituent cell types as well as the correct positioning of these cell types within the organ. Our previous work on *Drosophila* embryonic heart development had shown that the Forkhead (Fkh/Fox) transcription factors Checkpoint suppressor homologue (CHES-1-like) and Jumeau (Jumu) both specify cardiac progenitors by regulating the expression of the fibroblast growth factor receptor Heartless and the Wnt receptor Frizzled and determine the correct number of different cardiac cell types by regulating the subsequent division of the cardiac progenitors through a Polo-dependent pathway. Here we show that *CHES-1-like* and *jumu* are also required for the correct positioning of these cardiac cell types: loss-of-function mutations in or RNA interference knockdown of either gene results in the misalignment and incorrect locations of both cardial and pericardial cells within a hemisegment. Since defective cardiac progenitor cell divisions in *CHES-1-like* and *jumu* loss-of-function mutants frequently result in individual hemisegments having different numbers of cardiac cells than their partner across the dorsal midline, we initially examined this asymmetry as a possible cause of incorrect positioning. Our statistical analyses revealed that steric constraints imposed by the differing number of heart cells in contralateral hemisgments are not sufficient to explain all of the observed defects in heart cell positioning: statistically significant increases in the number of incorrectly positioned cardiac cells are also observed in Fkh mutants compared with wild-type embryos when only members of contralateral hemisegment pairs having the same number of each cardiac cell type are compared. In order to identify the genetic subnetworks utilized by CHES-1-like and jumu to bring about correct positioning, we next compared genome-wide transcription expression profiles of purified mesodermal cells from wild-type embryos and embryos either lacking *CHES-1-like* or *jumu* or overexpressing either of these Fkh genes. Gene ontology (GO) enrichment analysis of differential expressed genes in these Fkh mutants or Fkh-overexpressing embryos suggests that *CHES-1-like* and *jumu* could be regulating components of at least two known pathways involved in proper cardiac cell positioning: one involving Uncoordinated5 and NetrinB, and the other involving heterotrimeric G proteins and septate junction proteins. We are experimentally testing these hypotheses at present.

D1198C Improving the molecular toolkit to study muscle differentiation. *E. R. Czajkowski*[1], R. Cripps[1], A. Bryantsev[2]. 1) University of New Mexico, Albuquerque, NM; 2) Kennesaw State University, Kennesaw, GA.

During myogenesis, multinucleate muscle fibers arise from the fusion of single nucleate myoblasts. In *Drosophila*, myoblast fusion is initiated by a specific kind of myoblast called founder cells (FCs), which determine the differentiation program for the nascent muscle fibers. Much of the information about muscle fusion and general muscle development is obtained via a toolkit of genetic drivers that are used to manipulate gene expression in a cell-specific manner. Typically, genetic drivers express the yeast transcriptional factor Gal4 to activate expression from artificial transgenic constructs containing Gal4-responsive upstream activating sequence (UAS). rP298 is a FC-specific genetic driver, but its practical use is very limited because it quickly becomes inactive upon the first fusion between FCs and myoblasts. We demonstrate that by adding a self-activating transgene UAS-Gal4 to rP298, it is possible to prolong Gal4 expression beyond myoblast fusion, into more advanced developmental stages including the adulthood. The idea is that Gal4, once initiated by rP298, activates itself though the UAS promoter and maintains continuous Gal4 expression. Thus, by allowing the Gal4 gene to maintain expression in post-fused muscle fibers, we now can study those regulatory genes that only become activated in FCs and which are likely to control the muscle differentiation program.

D1199A Examining the role of Elongin B in *Drosophila* muscle development. *K. C. Dobi*[1], M. K. Baylies[2]. 1) Baruch College, New York, NY; 2) Memorial Sloan Kettering Cancer Center, New York NY.

Skeletal muscles come in a variety of shapes and sizes important for functions like running or eye blinking; however, we do not yet understand the mechanisms that generate muscle fibers with discrete morphologies. To determine how muscles with distinct shapes and sizes are formed, we have focused on the transcription elongation factor and E3 ubiquitin-ligase complex member Elongin-B. Elo-B is conserved from yeast to humans, and was recently identified in a whole-genome screen for novel factors in Drosophila muscle development. Elo-B mutants display somatic muscle defects including muscle loss and misattachment. To learn more about the role of Elo-B in muscle development, we are examining the muscle pattern of Elo-B mutants, as well as mutants for proteins that interact with Elo-B. Taken together, these experiments are providing a clearer picture of the network of gene activity required for muscle development.

D1200B Mechanisms Regulating Gonad Development and Function. *J. C. Jemc*, D. Silva, M. Bednarz, C. Lenkeit, E. Chaharbakhshi, E. Temple-Wood, A. Droste, A. Dabbouseh, S. Moqeet. Loyola University Chicago, Chicago, IL.

Fertility depends on the establishment and maintenance of interactions between germ cells and somatic cells within the gonad. During embryonic development, primordial germ cells (PGCs) and somatic gonadal precursor cells (SGPs) are specified at distal locations, and they must migrate, coalesce, and interact to form a gonad with the proper architecture. This work focuses on the characterization of the molecular mechanisms that regulate the migration of the SGPs, their interactions with each other, and their interactions with the PGCs during *Drosophila* gonadogenesis. A genetic screen resulted in the identification of a number of genes linked to the cytoskeleton genetically or molecularly that are required for gonad morphogenesis, including two transcription factors, *ribbon* (*rib*) and *longitudinals lacking* (*lola*). *rib* and *lola* encode members of the BTB (Broad complex, Tramtrack, Bric-à-Brac) family of proteins, and are required for the coalescence and compaction of SGPs and PGCs into a cohesive, spherical gonad. Both genes are expressed in the embryonic gonad, and genetic studies reveal that these genes may function in a common pathway to promote gonad morphogenesis. As BTB proteins form homo- and heteromeric complexes, we tested the ability of these proteins to interact via their BTB domains and observe both homo- and heterodimerization of the BTB domains of both proteins, suggesting that these proteins may cooperate to regulate a common set of target genes. Studies are underway to determine if these proteins function predominantly in transcriptional activation or repression and to identify the downstream targets through which they function. In addition, previous studies by *Davies et al. 2013* demonstrated a requirement for Lola in the adult testis. Therefore, we examined a potential role for Rib in homeostasis in the adult gonad. We observe expression of Rib in the germ cells and somatic cells of the adult testis. Current studies are focused on identifying the role of Rib in these cell types in the adult testis. These studies suggest that Rib and Lola cooperate to regulate early gonad morphogenesis, and that Rib may function similarly to Lola to regulate homeostasis in the adult.

D1201C Variable Effects of eRpL22 Family Paralogue Depletion on Eye Development in *Drosophila melanogaster*. *B. W. Gershman*, V. C. Ware. Lehigh University, Bethlehem, PA.

In *D. melanogaster* ribosomal protein (Rp) eRpL22-like has a tissue-specific expression pattern in the testis and eye (Kearse *et al*., 2011), compared to its ubiquitously expressed paralogue eRpL22. Consistent with a ribosomal role, these paralogues are structurally similar within the rRNA binding domain (C terminus). Yet, considerable sequence divergence within the N terminal domain of each paralogue suggests the possibility of functionally divergent roles as components of ribosomes or as proteins functioning in other pathways. The developmental significance of differential expression of eRpL22 paralogues is poorly understood. Here we focus on the requirements for eRpL22 paralogues in three stages (3rd instar larva, midpupa, adult) of eye development using an RNAi-mediated Gal4-UAS strategy for tissue-specific paralogue knockdown, followed by immunohistochemistry to determine paralogue localization and score differences in eye development phenotypes for each paralogue. eRpL22 is ubiquitously expressed, but eRpL22-like localization is tissue/cell-specific depending on developmental stage. In 3rd instar larva, eRpL22-like is detected at low levels within the cytoplasm of the eye disc proper; however, within the peripodial membrane, the cytoplasmic distribution of eRpL22-like is polarized toward the disc. In pupal stages, eRpL22-like is highly enriched within the developing inter-ommatidial bristle (IOB) complex. In adult tissue, localization of eRpL22-like shifts from the IOB complex to the ring of accessory cells surrounding each ommatidia (2° pigment, 3° pigment, IOB complex). Non-overlapping localization patterns in different cell/tissues is suggestive of specific functional roles for eRpL22 paralogues. We then compared eRpL22 paralogue localization during eye development following paralogue knockdown. *eyeless*-Gal4 induced knockdown affects early mitotic ells while GMR-Gal4 induced knockdown affects differentiated cells. *eyeless*-Gal4- mediated eRpL22 depletion results in ablation of head and eye structures. In contrast, no notable effect on gross eye morphology or the head is apparent with *eyeless*-Gal4 mediated eRpL22-like depletion. GMR-Gal4 mediated eRpL22 depletion leads to ommatidia disorganization and generation of a late onset eye lesion; however, eRpL22-like knockdown with GMR-Gal4 generates a bristle-specific defect. Notably, a different phenotype results from paralogue-specific knockdown using the same Gal4 driver, suggesting non-redundant (and specialized) roles for each paralogue during eye development. Future work will include attempts to rescue paralogue-specific knockdown phenotypes with overexpression of the cognate paralogue to determine the degree, if any, of functional redundancy in the eRpL22 family.

D1202A Organ-Specific Transcriptional Co-regulation of Growth and Form in the *Drosophila* Embryo. *R. Loganathan*[1], J. Lee[2], M. B. Wells[1], E. Grevengoed[1], M. Slattery[2], D. Andrew[1]. 1) Johns Hopkins University, Baltimore, MD; 2) University of Minnesota.

Tubular organogenesis is critically dependent on the coordinate regulation of growth and form as the size and shape of tubular tissues are the prime determinants of their functional complexity. Transcription factors, which regulate the spatiotemporal patterns of gene expression during development, affect multiple aspects of organogenesis. In this work, we describe the distinct role of Ribbon (Rib) during organogenesis of

epithelial tubes. Our investigations of the embryonic salivary gland (unbranched tubular organ) and the trachea (branched tubular organ) demonstrate that Rib co-regulates growth and form during tubular organogenesis. In *rib* null embryos, we observed remarkable changes in cell shape and size of both organs, which underlie the characteristic tube elongation defects. Notably, the changes in growth and form in the *rib* mutants occurred without effects on cell specification, proliferation, apoptosis, apicobasal polarity or junctional integrity. How does Rib selectively co-regulate growth and form in these tubular epithelia? To identify the transcriptional targets of Rib, we performed whole embryo microarray gene expression analysis comparing RNA samples (1.5X minimal fold change, $P < 0.05$) from age-matched wild-type and *rib* null embryos. Microarray gene expression analysis showed that 774 genes were potentially activated whereas 1176 genes were potentially repressed by Rib. To distinguish direct tissue-specific Rib targets, we performed ChIP-seq analysis in embryos driving *rib* expression specifically in the salivary gland and the trachea. Superposition of potential Rib targets obtained from the microarray gene expression and ChIP-seq analyses resulted in a total of 60 genes (20 activated, 40 repressed) subject to direct Rib regulation in the salivary gland. Interestingly, Rib was subject to transcriptional autoregulation during salivary gland formation. Meanwhile, 242 genes (54 activated, 188 repressed) were subject to potential direct Rib regulation in the trachea. A subset of potential Rib targets in both organs was validated by *in situ* hybridization and qRT-PCR. Intriguingly, Rib targets in both tubular organs functionally clustered around cell growth and morphogenesis, suggesting that the co-regulation of growth and form is the primary role for Rib during tubular organogenesis. Moreover, the mechanism by which Rib mediates co-regulation of growth and form is organ-specific as revealed by distinct target clusters in the salivary gland (translational machinery) and the trachea (growth factor signaling machinery). Collectively, our results suggest organ-specific mechanisms in the transcriptional co-regulation of growth and form by Rib in the *Drosophila* embryo.

D1203B The molecular process of epidermal cuticle formation in *Drosophila* larvae. *Y. Pesch*[1,2], M. Behr[2]. 1) LIMES-Institute, University of Bonn, Germany; 2) Institute of Biology, University of Leipzig, Germany.

The proper architecture of an outer body wall is fundamental to animals and plants. The insect cuticle provides exoskeletal stability and protection against wounding, desiccation, invading pathogens and other potential harms. In order to adapt to increasing body growth the insect cuticle is periodically shedded in a molting process. Molting and wounding requires organized cuticle rearrangement. It has been discussed that chitin microfibrils as a main component of the cuticle may undergo spontaneously self-assembly, but how exactly the complex architecture of the cuticle is arranged and reorganized during growth, molting and wound healing is not known.

We discovered a molecular mechanism of cuticle formation, maturation and protection in the *Drosophila* larval epidermal cuticle.

Upon cuticle synthesis chitin is secreted by the epidermal cells and forms to fibrils of various lengths at the apical cell surface. The chitin binding protein Obstructor-A (Obst-A) binds these nascent chitin-fibrils and forms a scaffold for their proper integration into the lamellar cuticle structure. The Obst-A scaffold is required to recruit and localize the deacetylases Serp and Verm for matrix assembly and maturation. Loss of *obst-A* leads to severe growth defects, impaired epidermal cuticle integrity and death before the molt to second instar larval stage. In summary, the molecular Obst-A core unit is essential to form, mature and keep an intact cuticle in insects.

For cuticle organization Chitinases process chitin-fibrils into fragments of different lengths. Surprisingly, our results indicate that Chitinases also play a role in maintaining structural and mechanical integrity of the cuticle. The Chitinase 2 is necessary for lamellar organization and for proper function of Obst-A at the apical cell surface.

All molecular mechanisms of cuticle formation are primarily concentrated at the apical cell surface in a so far completely uncharacterized region - the cuticle assembly zone. Our findings place the assembly zone in the center of cuticle organization. Due to protein sequence conservations this may hold true for insects and most chitinous invertebrates.

Finally, our data provide first evidence for a novel feedback mechanism how the cuticle assembly zone protein Obst-A regulates ecdysone signaling for larval molting and growth control.

D1204C Regulation of Air Sac Primordium Development by a Cathepsin-L in *Drosophila melanogaster*. *C. J. Fields*[1], Qian Dong[1], Breanna Brenneman[1,2], Ajay Srivastava[1]. 1) Western Kentucky University, Bowling Green, KY; 2) University of Virginia, 1335 Lee Street, Charlottesville, VA 22903.

In *Drosophila*, the adult thoracic Air Sacs supply oxygen to the flight muscles. These Air Sacs develop from a group of larval cells that form the Air Sac Primordium (ASP). The ASP is located superficially over the larval wing imaginal disc and in response to Fibroblast Growth Factor (FGF) signal, migrates and invades into the wing imaginal disc to occupy a more deep seated position. The regulation of invasive behavior during ASP development is not well understood. Data are presented that implicate a Cathepsin-L in ASP development and invasive cellular behavior. Utilizing immunohistochemistry and confocal microscopy we assessed the expression of Cathepsin-L in larval wing imaginal discs. The knockdown of Cathepsin-L in ASP was achieved by UAS-Gal4 driven RNAi and the overexpression of Cathepsin-L was performed using the UAS-Gal4 system of gene expression in *Drosophila*. We found that a single Cathepsin-L is upregulated in the ASP and downregulation of this gene results in aberrant ASP development, loss of Filopodia from ASP and suppression of invasive behavior. Furthermore, we demonstrate that overexpression of Cathepsin-L results in degradation of the Basement Membrane (BM). Our data demonstrate that a Cathepsin-L is involved in the development of ASP by regulating the invasive cellular behavior and by degrading the BM. These data are particularly significant given that Cathepsin-L is also expressed during early human lung development and invasive cellular behavior and degradation of the BM are critical events during tumor metastasis.

D1205A Novel growth factors regulate tube morphogenesis in the *Drosophila* ovary. *Sandra G. Zimmerman*, Anne E. Sustar, Celeste A. Berg. University of Washington, Seattle, WA.

During development, flat epithelia give rise to tubular structures that exhibit a spectacular variety of shapes, sizes, and functions. Although tubes are essential for multi-cellular life, relatively little is known about the genetic and molecular mechanisms that create tubes. A tractable model for tubulogenesis in *Drosophila,* one that resembles primary neurulation in vertebrates, is the formation of dorsal appendages (DAs), eggshell structures that facilitate gas exchange for the embryo. DAs are secreted by cellular tubes that form during oogenesis in the egg chamber. An egg chamber consists of one oocyte and 15 germline nurse cells surrounded by a somatic follicular epithelium: columnar cells cover the oocyte and squamous "stretch" cells cover the nurse cells. Cues from these different cell types facilitate DA formation, which occurs when two dorsal patches of columnar cells fold into tubes and elongate by migrating over the stretch cells, all in the absence of cell division or cell death. Mutations in the genes encoding the SOX transcription factor, Bullwinkle (BWK), which functions in the germline, or non-receptor tyrosine kinases SHARK and SRC42A, which function in the stretch cells, lead to DA cell adhesion defects, aberrant cell migration, open tubes, and moose-antler-like DAs. Other components of the pathway are unknown. To discover new genes that regulate tubulogenesis downstream of *bwk*, we used mass spectrometry to identify differentially expressed proteins in the stretch cells of *bwk* vs. wild-type egg chambers. Members of a novel family of growth factors, Imaginal disc growth factors (IDGFs), were upregulated in the stretch cells of *bwk* egg chambers. IDGFs are catalytically inactive, chitinase-like proteins that have human orthologs and arose through gene duplication. Due to a conserved mutation that renders them inactive as chitinases, IDGFs have acquired new functions through evolution. Using stretch-cell specific overexpression, RNAi, and CRISPR/Cas9-mediated gene deletions, we found not only that IDGF upregulation is sufficient to cause DA defects, but that IDGF expression is also required normally at optimal levels for proper DA morphogenesis. Our data suggest that IDGFs may function redundantly in this context. Although previous studies demonstrate that IDGFs interact synergistically with insulin to modulate growth and polarization of cultured cells, our data suggest that the insulin signaling pathway is not the central mode of action for IDGFs in DA formation. Determining how these novel growth factors function will be a key to understanding the genetic and molecular basis of tubulogenesis.

D1206B Dissecting the mechanism of calcium wave during *Drosophila* egg activation. *Qinan Hu*, Mariana Wolfner. Cornell University, Ithaca, NY.

Egg activation is the critical step in which the developmentally arrested oocytes shifts to begin embryogenesis. This process is characterized by a rise of intracellular free calcium levels, beginning at one region of the oocyte and sweeping across the whole egg. This Ca^{2+} rise triggers downstream events including meiosis resumption and changes in the transcriptome and proteome. Although in vertebrates and marine invertebrates fertilization triggers the Ca^{2+} rise, in *Drosophila* it is triggered prior to fertilization in the form of a wave that starts at pole of oocytes. This calcium wave is induced by physical forces that occur during ovulation. Genetic studies and inhibitor tests suggest that these forces activate mechanosensitive ion channels in the oocyte that then let in Ca^{2+} from extracellular environment. Currently we are using chemical, physical, and genetic means to identify the ion channels that introduce Ca^{2+} into the oocyte, and to determine how and where they act and are regulated.

D1207C Identifying protease targets of the *Drosophila* serine protease inhibitor Serpin42Da. *J. R. Kannangara*, M. A. Henstridge, T. K. Johnson, J. C. Whisstock, C. G. Warr. Monash University, Clayton, AU.

Serine protease inhibitors, or serpins, are a family of protease inhibitors that use a complex mechanism of conformational change in order to inhibit target proteases. Although the structural mechanism of serpin function is well characterised, the biological roles and targets of many serpins remains elusive. The genome of *Drosophila melanogaster* contains 29 serpin-encoding genes*,* however very few have been functionally characterised. Among the few characterised *Drosophila* serpins, Serpin42Da (Spn42Da) is of particular interest as it encodes 10 different isoforms that are predicted to have distinct sub-cellular localisations and different target specificity. To investigate the roles of Spn42Da to help predict target proteases we over-expressed Spn42Da transgenes in various *Drosophila* tissues. We found that over-expressing the Spn42Da-A isoform in ovarian follicle cells using *slbo*-Gal4 causes embryos to be laid with a fragile eggshell due to defects in the cross-linking of the inner-most eggshell layer, the vitelline membrane. As Spn42Da-A has previously been shown to inhibit the serine proteases Furin1 (Fur1) and Furin2 (Fur2) *in vitro*, we examined these proteases as candidate targets for Spn42Da-A. Genetic interaction experiments between *spn42Da-A* and the Furin proteases revealed that *spn42Da-A* interacts with *Fur2* in the follicle cells during eggshell biogenesis. We are currently performing additional genetic interaction experiments between *spn42Da-A* and *Fur1,* and investigating the effect of both *Fur1* and *Fur2* RNAi knockdown on eggshell biogenesis. Finally, we have also generated a *spn42Da* null mutant which we are currently testing for interactions with *Fur1* and *Fur2*. Taken together, this study will provide fundamental insight into the molecular mechanisms surrounding *Drosophila* eggshell biogenesis, and lead to a greater understanding of the serpins and proteases involved in producing this complex structure.

D1208A Differentiate or die: the role of *Dm ime4* in embryogenesis and gametogenesis. *C. F. Hongay*[1], Kangning Li[1], Jill Pflugheber[2], Aquilla Chase[1]. 1) Clarkson Univ, Potsdam, NY; 2) Saint Lawrence University, Canton, NY.

My previous work on *Dm ime4* showed its importance for oogenesis (Hongay and Orr-Weaver, PNAS 2011). Recent work in my laboratory demonstrates that this gene is crucial during embryogenesis and continues to be essential in adults for fertility. We used a balanced stock where *ime4+* can be traced with GFP, and the *ime4*$^{(hypomorph)}$ allele is unmarked. We scored under several microscope magnifications, using DAPI and other stainings, GFP(+) and GFP(-) embryos in all stages of development and found statistically significant decreases -measured as departures from the expected Mendelian ratios of GFP(-) to GFP (+) and analyzed by Chi square tests-starting at gastrulation. Furthermore, GFP(-) embryos display high levels of apoptosis, aberrant DAPI stainings, and other severe malformations. In addition, we localized *Dm ime4*

mRNA by *in situ* hybridization and *Dm* IME4 by antibody staining in wild-type embryos and found very informative and specific localizations that strongly support its role en embryogenesis.

For our gamatogenesis analyses in adult gonads, we used the "live or dye" staining system together with other stem/germ/somatic markers to determine the role of *Dm* IME4 in germ and somatic cell differentiation. Our findings are in line with recent reports on the role of *Dm ime4* orthologs (*e.g*., mttl3 mutants are embryonic lethal in mice), but with the use of hypomorphic mutants and RU-486 inducible RNAi, we are able to get detailed and valuable information on its role in Drosophila development.

Given the evolutionary conservation of *Dm ime4*, our findings will inform future studies in vertebrate systems.

D1209B An Lmx1 homolog is required for *Drosophila* ovary support structure development. *A. Allbee*, B. Biteau. University of Rochester, Rochester, NY.

Lmx1a and Lmx1b are examples of highly conserved LIM homeobox transcription factors with clearly established requirements for the patterning, differentiation and adult function of diverse tissues in mammals. Not surprisingly, these transcription factors are implicated in a wide variety of human pathologies, including Nail Patella Syndrome, Parkinson's disease, renal disease and ovarian carcinoma. However, few examples exist where precise target genes, binding partners and downstream cellular functions are known. CG32105 is a *Drosophila* homolog of both Lmx1a and Lmx1b, and has never been studied.

Using CRISPR, we have generated flies carrying a full deletion of the CG32105 open reading frame. Surprisingly, homozygous adults are viable with no obvious defects in external morphology or behavior. However, females are sterile with collapsed ovaries. Looking as early as larval stages, we show this phenotype likely arises from a primary defect in the development of ovarian support structures. Consistent with this, lineage-tracing analysis reveals that a CG32105 putative enhancer drives expression in what is possibly a common somatic ovary progenitor. Furthermore, by driving knock down and over-expression of the transcript, we find this same enhancer is sufficient to both recapitulate and rescue the knock out phenotype, respectively. Taken together, these data argue a requirement for this Lmx1 homolog in the development of *Drosophila* ovary support structures, and indicate we have the tools necessary to address function at precise temporal and cell-specific levels. Using both a candidate approach and a simple, non-biased screening approach, we expect rapid and precise dissection of the mechanisms through which this Lmx1 homolog mediates *Drosophila* ovary development. Interestingly, while *Drosophila* oogenesis is a highly studied process with major contributions to cell biology, very little is known with regards to the genetic mechanisms through which the ovary develops. We therefore anticipate contributing not only to the understanding of LIM homeobox transcription factors, but also to the understanding of this largely understudied developmental process, which could be used as a powerful, genetically tractable model in developmental biology.

D1210C Controlling reproduction through microRNAs: lessons Drosophila might have taught mammals. *J. A. Sanchez-Lopez*[1], I. Carmel[1], D. Spiller[2], M. White[2], Y. Heifetz[1]. 1) The Hebrew University of Jerusalem, Rehovot, IL; 2) The University of Manchester, Manchester, UK.

Mating induces a rapid change in the *Drosophila* female's physiology and behavior. The female increases her oviposition rate and avoids other males, and the morphology of her reproductive tissues changes rapidly. Mating-induced physiological responses are modulated by major changes in the expression profile of the female reproductive tissues. In the lower female reproductive tract (lower RT) miRNAs are involved in the regulation of this rapid response to mating. It has been demonstrated that miRNAs also regulate reproductive processes in mammals, such as mouse, pig and human. In human, for example, miRNAs regulate responses to gametes and modulate communication between the embryo and the maternal tract during implantation and pregnancy. miRNAs are highly conserved across species and thus might play a role in regulating the basic modules of reproduction which are broadly conserved.

To better understand the role of miRNAs in female reproductive success, we compared the miRNA expression profiles of unmated and mated Drosophila lower RTs with reported changes in miRNA profile of human endometrium in preparation for implantation to identify candidate miRNAs. We found two miRNAs, *let-7a* and *miR-9a,* whose expression was significantly altered in both organisms. Using a miR-sensor, we tested miRNA spatial localization *in vivo* in Drosophila females. We showed that the expression of *miR-9a* in Drosophila is reduced specifically in the spermathecal secretory cells (SSC) at 6h post-mating. This is the time when the reproductive tract is preparing for fertilization and egg laying. We then devised a miR-sensor system for use *in vitro* in mammalian cells to test *in vitro* the interaction of trophoblast spheroids (simulating the embryo) with human endometrial cells. We observed that the human endometrial cell line reacted to the presence of the trophoblast spheroids by increasing the expression of *miR-9a*. These results suggest that *miR-9a* might be an important miRNA for reproductive success as it seems to mediate the reproductive mechanisms of both species. Using our miR-sensor system, we further performed time lapse analysis to follow the interactions of the trophoblast and endometrial cells in real-time. We observed that the endometrial cells react to the presence of the trophoblast through miRNA-dependent and independent mechanisms. Understanding the role of conserved miRNAs in reproductive tissues will provide insight into mechanisms of female reproductive success.

D1211A Investigating the role of intracellular pH in epithelial stem cell differentiation. *M. Benitez*, B. Ulmschneider, B. Grillo-Hill, D. Barber, T. Nystul. University of California-San Francisco, San Francisco, CA.

Transitions in the fate or morphological state of epithelial cells are central to metazoan development, homeostasis, and tissue repair. We are using the follicle stem cell (FSC) lineage in the Drosophila ovary as a model to investigate the potential role of intracellular pH (pHi) in cellular differentiation in an adult stem cell lineage. We found that pHi increases naturally during follicle cell differentiation and that blocking this increase interferes with differentiation toward the polar/stalk cell fate. To investigate how pHi is controlled during follicle cell differentiation, we performed an RNAi screen through a collection of 20 genes that are predicted to regulate pHi. Our preliminary studies identified three genes from this collection that are required for follicle cell differentiation. We found that RNAi knockdown of CG8177, CG13384 and CG32081

prevents proper FSC development, leading to abnormal and ectopic polar/stalk cell formation. We are currently investigating how the knockdown of these genes affects follicle cell pHi. Lastly, we are investigating whether changes in pHi promote follicle cell differentiation by inhibiting Hedgehog pathway activity. Collectively, these studies will provide insight into a novel form of regulation of cellular differentiation in an epithelial stem cell lineage.

D1212B The Control of Germline Sexual Identity in *Drosophila melanogaster.* *Pradeep Kumar Bhaskar*, Raghav Goyal, Kelly Baxter, Mark Van Doren. Department of Biology, Johns Hopkins University, Baltimore, MD.

Sexual dimorphism is common throughout the animal kingdom, with males and females exhibit phenotypic characters specific for their sex. While a great deal is known about the establishment of sexual identity in somatic cells, this process is much less well understood in the germline. Germline sexual identity is critical for sex-specific development of germline stem cells and production of sperm vs. eggs. Thus, it is an essential aspect of animal sexual reproduction and human fertility. Germ cells depend on both signals from the somatic gonad as well as their own sex chromosome genotype to determine their sex. Therefore, when the "sex" the germline fails to match the "sex" of the soma, germline development is severely disrupted. How somatic signals and germ cell intrinsic cues act together to regulate germline sex determination is a key question about which little is known in any organism. We have previously identified the JAK/STAT pathway as a key male determining signal from the soma to the germline; evidence exists for a similar signal in females, but this signal has not been identified. Further, the RNA-binding protein Sex-Lethal (SXL) and the chromatin factor PHF7 have been identified as key components promoting female vs. male germline identity, respectively. We propose that the JAK/STAT pathway is a direct activator of PHF7 expression in the male germline, and that this pathway is inhibited by SXL in the female germline. Further, male-specific expression of PHF7 appears to be regulated at the levels of both transcription and translation to ensure its proper male-specific expression. Additionally we have evidence suggesting signals from the soma can affect PHF7 function, whereas SXL function in the germline seems to be exclusively regulated by intrinsic factors. We are investigating the regulation of the key germline sex determination factors PHF7 and SXL and how they are controlled by both somatic signals and germ cell intrinsic factors.

D1213C Inhibition of the RTK PVR in the hub cells of the *Drosophila* testis stem cell niche. *N. Bui*, J. Leatherman. University of Northern Colorado, Greeley, CO.

An adult stem cell is an undifferentiated cell, found among differentiated cells in a tissue or organ. The specific microenvironment of each tissue that adult stem cells reside in is called the stem cell niche. In a living organism, adult stem cells maintain and repair the tissue in which they reside. In the *Drosophila* testis niche, there are two different stem cell populations including the germline stem cells (GSCs) and the cyst stem cells (CySCs). These stem cells cluster around the hub, a group of non-dividing cells that constitute the niche. Previous research has indicated that proper communication between and within the hub cells, CySCs, and GSCs is important in maintaining stem cell self-renewal, and allowing proper cellular differentiation to achieve tissue homeostasis. We are investigating the function of a receptor tyrosine kinase (RTK) called PVR (PDGF-VEGF-related receptor) in this niche. We found that the ligand Pvf1 is secreted from hub cells, and its receptor PVR is expressed in both the hub and the cyst stem cells. We hypothesize that PVR signaling may be one mechanism by which the hub maintains expression of proper self-renewal signals during spermatogenesis. In this study we inhibited PVR in the hub cells by hub-restricted expression of either a PVR RNA interference (RNAi) transgene, or a dominant negative transgene. By comparing the experimental group with the control group, we found defects in the germline. Some testes had GSC-like individual germ cells distant from the hub where differentiation is expected. Other testes had transit-amplifying spermatogonia next to the hub. We also noticed that there was a reduction in the number of cyst stem cells surrounding the hub. Our conclusion is that inhibition of PVR in the hub leads to the improper maintenance of both stem cell populations in the testis, thus disrupting the regulation of spermatogenesis.

D1214A *Hrb27C* functionally interacts with ecdysone signaling to maintain the *Drosophila* female germline stem cell fate. *Danielle S. Finger*, Elizabeth T. Ables. East Carolina University, Greenville, NC.

Stem cells maintain an undifferentiated fate while creating new daughters destined for differentiation. Effective use of stem cells as tools for clinical therapy requires a detailed understanding of the molecular mechanisms that control their fate *in vivo*. A variety of molecular signals influence stem cell fate, including local signals from adjacent cells and long-range hormonal signals; however, little is known about how hormones promote the undifferentiated fate. Germline stem cells (GSCs) in the *Drosophila melanogaster* ovary are an ideal model to study the mechanisms of stem cell maintenance on a per-cell basis *in vivo*. GSCs are known to be directly regulated by the steroid hormone ecdysone, which is structurally and functionally similar to human sex hormones. Using a forward genetic screen, we identified *Heterogeneous nuclear ribonucleoprotein at 27C* (*Hrb27C)* as a potential downstream target of ecdysone signaling. *Hrb27C* is a member of the heterogeneous nuclear ribonucleoprotein (hnRNP) family of RNA binding proteins that aid in the localization, maturation, and translation of newly formed RNAs. To investigate whether and how *Hrb27C* regulates GSC maintenance we used *Flippase/Flippase Recognition Target (FLP/FRT)*-mediated recombination to create homozygous *Hrb27C* mutant GSCs, and used molecular markers to track their fate. Our results demonstrated that *Hrb27C* mutants display greater GSC loss than their respective controls, indicating that *Hrb27C* is required for GSC maintenance. This loss is due to deregulation of pMAD, a component of the BMP signaling pathway that is required for repressing differentiation of GSCs. Further, non-allelic non-complementation experiments demonstrated that *Hrb27C* functionally interacts with both ecdysone signaling and BMP signaling to control GSC number. Taken together, these results suggest a model wherein *Hrb27C* mediates the effects of ecdysone signaling in GSCs. Future experiments will be aimed at determining if other hnRNPs work independently or in complex with *Hrb27C* to control GSC maintenance. This will increase our understanding of the function of *Hrb27C* and the hnRNP family in the regulation of stem cell fate, and provide insight into the mechanisms by which steroid hormones maintain stem cell fate in adults *in vivo*.

D1215B Investigating the role of neuropeptides in *Drosophila* ovary. *T. Ma*, D. Drummond-Barbosa. Johns Hopkins University Bloomberg School of Public Health, Baltimore, MD.

Reproduction depends on many factors including mating behavior, feeding behavior, and, crucially, the ability to detect and respond to changes from external stimuli. Neuropeptides are signaling molecules known to be involved in many of these processes in both mammals and other organisms such as insects. For example, neuropeptide Y (NPY) in mammals has been shown to play important roles in feeding, metabolism, reproduction, and stress response, with similar roles shown for neuropeptide F (NPF), the insect ortholog of NPY. Insulin-like peptides (ILPs) are neuropeptides produced by the central nervous system (CNS) and have been shown to directly affect germline stem cell (GSC) proliferation, GSC adhesion to the niche, niche size, cyst growth and follicle cell proliferation, and vitellogenesis in the *Drosophila melanogaster* ovary. Insulin also play crucial roles in mammalian fertility and reproduction. Other neuropeptides such as short NPF (sNPF) and prothoracicotropic hormone (PTTH) have been proposed to play important roles in oogenesis and reproduction in insects. However, much of the connection between neuropeptides and oogenesis has remained unexplored. My project aims to fill this gap by using the well-characterized *Drosophila* ovary to identify and functionally characterize neuropeptides that affect oogenesis, either directly or indirectly. Many neuropeptides and their receptors have been conserved through evolution; therefore, the results will likely have broad relevance and lead to a greater understanding of how the brain and ovary interact in humans and other mammals to control reproduction.

D1216C Cellular mechanisms underlying asymmetric sister chromatid segregation during asymmetric division of Drosophila male germline stem cell. *R. Ranjan*, X. Chen. Johns Hopkins University, Baltimore, MD.

Due to the crucial role that epigenetic mechanisms play in regulating cell identity and function, it has been a long-standing question whether and how stem cells maintain their epigenetic memory through many cell divisions. We found that during asymmetric division of Drosophila male germline stem cell (GSC), histone H3 (H3) becomes asymmetrically segregated — the “old” H3 is retained in the GSC while the “new” H3 is enriched in the differentiating daughter cell (Science, 338: 679-682). Recently, we also found that randomized H3 segregation pattern correlates with both GSC loss and progenitor germline tumor phenotypes, suggesting that asymmetric H3 inheritance is required for both GSC maintenance and proper differentiation (Cell, 163: 792–793). We propose that old and new H3 are asymmetrically deposited to sister chromatids, and mitotic machinery recognizes this asymmetry for differential segregation. To understand this question, we are using live-cell imaging to visualize spatial and temporal regulation of sister chromatids segregation. We have obtained promising data showing asymmetric microtubule activities in GSC, which first interact with the nuclear membrane at the GSC side during G2-phase, and then start “poke-in” and make a hole to interact with chromatin during G2/M phase. Interestingly, during G2 phase, centromeres cluster near the nuclear membrane at the stem cell side, with the “old” Cid (centromeric H3) enriched sister centromeres facing towards the centrosome at stem cell side, which is likely to secure attachment between old H3-enriched sister chromatids and microtubules emanating from the centrosome at the stem cell side. This occurs prior to the attachment of new H3-enriched sister chromatids to microtubules from the centrosome at the differentiating daughter cell side. Coincidentally, we also observed that sister chromatids enriched with old versus new H3 are condensed in a temporally separable manner: the old H3-enriched sister chromatids condense prior to new H3-enriched sister chromatids. We hypothesize that asymmetric microtubule activity, asymmetric centromere and differential condensation of sister chromatids act together to ensure their proper attachment followed by asymmetric segregation. By contrast, such an asymmetry in either the microtubule activity or sister chromatid condensation is not observed in symmetrically dividing progenitor germ cells. Together, we propose that the GSC microtubule has a novel function— it directs the orientation of sister chromatids. This proposed function provides an unappreciated role of the microtubule, namely, in selectively recognizing and segregating sister chromatids based on their differential epigenetic information.

D1217A HES overexpression causes neuroblast hyperplasia by repressing differentiation factors. *S. S. Magadi*[1], Nikolaou Christoforos[2], Christos Delidakis[1]. 1) FoRTH, Heraklion, Crete, GR; 2) UOC Department of Biology, Heraklion, Crete, GR.

Hes genes are immediate targets of Notch and are implicated in maintaining the undifferentiated state in many stem cell-based systems throughout the animal kingdom. Earlier work from our lab showed that larval CNS hyperplasia induced by Notch depends on the integrity of the *E(spl)* locus (harbors 7 Hes genes), although in this context we could detect activation of many other genes by Notch. The CNS defects were due to excessive accumulation of neural stem cells, or neuroblasts (NBs), at the expense of differentiated neurons and glia. In the process of dissecting the genomic networks regulated by Notch in proliferating larval NBs, we sought to discern the part of the signal that is transduced via the Hes proteins. Indeed, we could produce similar CNS hyperplasias by overexpressing only Hes proteins; the most severe defects were obtained by coexpression of E(spl)mγ and deadpan (dpn), another Hes gene that responds to Notch in this tissue. We analyzed transcriptional profiles from hyperplastic CNSs overexpressing Hes proteins individually or in combination. Different Hes overexpressions had nearly identical transcriptomes, which also had 50% overlap with Nicd overexpressing CNSs, suggesting that a large part of the Notch signal is transduced via the Hes proteins. Although Hes proteins are repressors, there is good overlap in both down- and up-regulated genes of Nicd, suggesting an extensive degree of feedforward regulation. For example, the stemness promoting factor grh and the temporal transcription factors svp and cas were amongst the common upregulated genes. We went on to characterize in more detail top downregulated transcription factor genes. Of 6 TFs studied in depth, three are primarily expressed in differentiating neurons, two are expressed in late NBs and one is expressed in intermediate neural precursors of the Type II lineages. Loss of function of most of these genes resulted in no effect suggesting functional redundancy, however overexpression or misexpression of some of these factors led to premature NB loss. At least three of these downregulated targets contain regions that are bound by Dpn by ChIP, suggesting direct regulation. We propose that the Notch-Hes axis maintains NBs in an undifferentiated state by repressing a cohort of TF genes that promote terminal differentiation.

D1218B Eyeless regulates nutrient-insensitive neuroblast proliferation in the central brain. *Conor Sipe*, Sarah Siegrist. University of Virginia, Charlottesville, VA.

The genetically tractable neural stem cell (NSC) population in the *Drosophila* central brain is ideal for investigating how organismal nutritional status affects stem cell proliferation. All neurons in the fly central brain are generated from asymmetric cell divisions of NSCs, known as neuroblasts (NBs). Most NBs enter a period of quiescence at the end of embyrogenesis coincident with declining maternal stores; upon larval feeding and reception of a nutrient-derived cue, these nutrient-sensitive NBs reenter the cell cycle and begin a second round of proliferation that continues until early pupal stages. In contrast, mushroom body (MB) NBs, a subset of central brain NBs, never enter quiescence and divide continuously regardless of developmental stage or systemic nutritional state. Both nutrient-sensitive NBs and nutrient-insensitive MB NBs reside in close proximity to one another, sharing a common brain macroenvironment. This suggests that quiescence versus proliferation decisions may be regulated in a cell-intrinsic manner. Currently, we are investigating whether the *Drosophila* Pax-6 ortholog, Eyeless (Ey) regulates NB quiescence versus proliferation in response to nutrient conditions. Ey, a paired box and homeodomain transcription factor, is expressed specifically in MB NBs and not in other central brain NBs during the embryo to larval transition. When Ey is knocked down in MB NBs, we observe that MB NBs, like other NBs, now enter quiescence when nutrients are limited. Importantly, we find that these quiescent MB NBs reactivate and re-enter the cell cycle once animals are returned to a complete diet. In addition, overexpression of Ey allows nutrient-sensitive non-MB NBs to maintain proliferation when nutrients are limited. This suggests that MB NBs utilize Ey to bypass quiescence during periods of nutrient restriction. Taken together, these results identify a novel genetic program under the control of Ey that promotes neuroblast proliferation independent of systemic nutrient cues.

D1219C Transcriptional regulation of *Drosophila* intestinal stem cells. *David Doupé*[1], Owen Marshall[2], Andrea Brand[2], Norbert Perrimon[1,3]. 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Gurdon Institute and Department of Physiology, Development and Neuroscience, University of Cambridge, Cambridge, UK; 3) Howard Hughes Medical Institute, Boston, MA.

Intestinal stem cells (ISCs) in the *Drosophila* midgut have emerged as an excellent model for the study of epithelial stem cells and homeostasis. The modes of ISC fate, their ability to respond to tissue damage and the signaling pathways involved in their regulation are broadly conserved with mammalian epithelia of the intestine, epidermis and esophagus. While the extrinsic signaling pathways regulating *Drosophila* ISCs have been extensively studied over the last several years, less is known about the intrinsic determinants of stem cell fate. We have used targeted DamID to profile gene expression in undisturbed stem/progenitor cells and the major differentiated cell type (enterocytes). This allowed us to identify 53 transcription factors specifically expressed or enriched in the stem/progenitor population. Characterization of the most highly enriched TFs identified critical regulators of proliferation and differentiation with mammalian orthologs implicated in epithelial homeostasis or cancer. Target profiling by DamID reveals binding to the regulatory regions of cell cycle genes and signaling pathway components, providing possible links between intrinsic and extrinsic regulators of ISC fate.

D1220A Groucho controls proliferation and differentiation of *Drosophila* intestinal stem cells by regulating transcriptional output of multiple signaling pathways. *X. Guo*, R. Xi. National Institute of Biological Sciences, Beijing, CN.

Abstract: Groucho is an evolutionarily conserved transcriptional co-repressor and has been implicated in regulating cell proliferation and cell fate decisions in many developmental processes. But whether it has a role in intestinal stem cell lineages is unknown. From an RNAi genetic screen, we identified Groucho as a critical regulator of cell proliferation and differentiation of intestinal stem cells in Drosophila midgut. We find that depleting Groucho in ISCs leads to rapid accumulation of ISC-like cells and failure of enteroendocrine cell differentiation. It is known that Notch signaling activation is essential for ISC differentiation, but loss of Groucho does not compromise Notch pathway activation. Furthermore, ectopic expression of NiCD or the Notch target E (spl) genes fails to induce differentiation of Groucho-depleted ISCs. Together with the analysis on its role in ISC proliferation, we propose that Groucho acts as a co-repressor to regulate the transcriptional output of multiple signaling pathways: Notch signaling to promote ISC differentiation, and EGFR signaling to inhibit ISC proliferation.

D1221B Sox21a is a critical regulator of adult stem cell proliferation in the *Drosophila* intestine. *F. Meng*, B. Biteau. University of Rochester Medical Center, Rochester, NY.

The precise control of stem cell proliferation is essential to maintain tissue homeostasis. These resident stem cells can adapt their proliferative activity according to tissue demands, allowing normal tissue turnover at homeostasis condition and tissue repair by increasing their proliferation rate under various stress conditions. Although the stress-sensing signaling pathways are shared between stem cells and their differentiated progenies, stress-induced proliferative response is specifically activated in stem cells. The mechanisms underlying this stem cell-specific proliferation control are largely unknown. Here we find that the Sox family transcription factor Sox21a is specifically expressed in progenitor cells in the *Drosophila* intestine. We show that the stem cell-specific Sox21a expression is necessary for their proliferation both at homeostasis and stress conditions. Interestingly, we demonstrate that Sox21a expression level is induced upon stress exposure, which requires Ras, Jun N-terminal Kinase and Fos. Furthermore, we show that the stress-induced Sox21a expression is sufficient to induce stem cell proliferation. Surprisingly, the *Sox21a* mutant flies display no obvious developmental defects besides their shortened lifespan, highlighting a role of Sox21a in regulating stem cell proliferation specifically in adult intestine. In summary, our data show that the stem cell-specific Sox21a as an essential proliferation regulator, suggesting that stem cell-specific mechanisms are utilized to generate a unique proliferative response. We are currently investigating how Sox21a interacts with other known stress-sensing signaling pathways, as well as the mechanism(s) controlling stem cell-specific Sox21a expression. In addition, we are trying to identify Sox21a-interacting factors and transcriptional target genes to fully understand the mechanisms by which Sox21a precisely controls stem cell proliferation.

D1222C The transcription factor Hindsight promotes enterocyte differentiation and is required for the specification of adult intestinal stem cells during the larval/pupal transition. *B. H. Reed*, B. Baechler, C. McKnight, P. Pruchnicki, N. Biro, D. Saghattchi. Univ Waterloo, Waterloo, ON, CA.

The *Drosophila* gene *hindsight* (*hnt*), homologue of mammalian *Ras responsive element binding protein-1* (*RREB-1*), encodes a C_2H_2-type Zinc finger nuclear protein that is required for several developmental processes including germ band retraction, tracheal differentiation, retinal morphogenesis, and proper growth of the follicular epithelium of the ovary. In some processes *hnt* has been identified as a direct target of the Notch signaling pathway. Given the importance of Notch signalling in the regulation of the adult intestinal stem cells (ISCs), we have investigated the regulation and function of *hnt* in this context. We show that *hnt* is expressed throughout the larval and adult midgut, and we further demonstrate that Hnt is required for ISC establishment during the larval/pupal transition. In the adult midgut we find that ISC *hnt* expression does not require Notch signalling, but is dependent on the EGFR/RAS/MAPK signalling pathway. Moreover, we find Hnt overexpression to be a potent effector of ISC loss through enterocyte (EC) differentiation. We also show that EC differentiation via Hnt overexpression can suppress ISC tumour formation associated with either the loss of Notch signalling or the activation of the EGFR/RAS/MAPK signalling pathway.

D1223A *Zfh2*, a conserved *Drosophila melanogaster* transcription factor involved in intestinal stem cell homeostasis. *S. Rojas Villa*[1], B. Biteau[2]. 1) University of Rochester, Rochester, NY; 2) University of Rochester Medical Center, Rochester, NY.

In most adult tissues homeostasis is maintained by tight regulation and crosstalk between pathways controlling self-renewal versus differentiation in adult Somatic Stem cells (SSC). Misregulation of signaling pathways regulating these processes have been linked to several conditions, such as cancer, and other age related diseases. In the last decade SSC in the *Drosophila melanogaster* intestinal epithelium have emerged as a powerful model to study these mechanisms. In this simple tissue the intestinal lineage has been well characterized and markers for every cell population have been defined. Recently our laboratory has identified *zinc-finger homeodomain 2* (*zfh2*), a highly conserved transcription factor, as an important player in the maintenance of intestinal homeostasis. Using immunohistochemistry, I have shown that *zfh2* is expressed in the *Drosophila* intestinal progenitors. Interestingly *zfh2* over-expression leads to a mild hyperproliferation phenotype. Conversely, its knock-down completely blocks stress mediated proliferation. Our preliminary data suggests that *zfh2* knock-down does not affect basal tissue turnover. In conclusion I have shown that proper expression of *zfh2* is necessary to maintain tissue homeostasis in the *Drosophila melanogaster* intestinal epithelium. We are now testing interactions with pathways known to regulate intestinal stem cell proliferation. Interestingly, mutations in *ATBF1*, the *zfh2* mammalian homolog, have been associated with different types of cancers. However nothing is known about any possible role of *ATBF1* in adult tissues under basal conditions. Characterizing *zfh2* in the *Drosophila* adult intestinal epithelium can shed light on the function of its mammalian homolog.

D1224B Injury-stimulated and self-restrained BMP signaling dynamically regulates stem cell pool size during *Drosophila* midgut regeneration. *Ai-Guo Tian*, Bing Wang, Jin Jiang. UT Southwestern Medical Center, Dallas, TX.

Many adult organs rely on resident stem cells to maintain homeostasis. Upon injury, stem cells increase proliferation, followed by lineage differentiation to replenish damaged cells. Whether stem cells also change division mode to transiently increase their population size as part of a regenerative program and if so, what is the underlying mechanism have remained largely unexplored. Here we show that injury stimulates the production of two BMP ligands, Dpp and Gbb, which drive an expansion of intestinal stem cells (ISCs) by promoting their symmetric self-renewing division in *Drosophila* adult midgut. We find that BMP production in enterocyte is inhibited by BMP signaling itself, and that BMP autoinhibition is required for resetting ISC pool size to the homeostatic level after tissue repair. Our study suggests that dynamic BMP signaling controls ISC population size during midgut regeneration and reveals mechanisms that precisely control stem cell number in response to tissue needs.

D1225C Metabolic role of GABA in the blood progenitors. *M. Shin*, J. Shim. Hanyang University, Seoul, KR.

Drosophila hematopoietic organ called Lymph gland is well known for its intrinsic and extrinsic controls in the maintenance of blood progenitors. Previous study has identified GABA as a novel systemic factor that regulates the blood progenitor maintenance through changes in cytosolic calcium concentration. GABA is released from a subset of neuroendocrine cells in the brain of which secretion is mainly controlled by the olfactory receptor neurons (ORNs). When GABA secretion is decreased, blood progenitors are differentiated as cytosolic calcium, a downstream of GABAB receptor in the blood progenitors, is down-regulated. However, whether excessive GABA influences the blood progenitor of *Drosophila* has not been described. Here, we found that constitutive activation of ORNs is enough to release excessive GABA from the brain that also interferes with the blood progenitor maintenance. Excessive systemic GABA increases the level of reactive oxygen species (ROS) in the blood that in turn results in the precocious differentiation of blood cells. Interestingly, this phenotype is rescued by changes in the TCA cycle, indicating a tight link between the systemic GABA and metabolic changes in the blood cells. Overall, our work highlights the novel function of an unconventional TCA-cycle that couples in part with a shunt pathway and its importance in the fine balance of ROS in the blood progenitors.

D1226A Regulation of niche cell plasticity in the Drosophila testis. *Leah Greenspan*, Erika Matunis. Johns Hopkins University, School of Medicine, Baltimore, MD.

Stem cells are necessary to maintain homeostasis within adult tissues. These cells receive signals from their surrounding microenvironment or niche in order to function properly. Precise regulation of stem cells and their niches is vital to prevent depletion or overgrowth of the stem cell pool. Although many mammalian niches have been characterized, the *Drosophila* testis provides a unique and more accessible system to study the regulation of a stem cell niche *in vivo*. This well-defined niche consists of a cluster of non-dividing (or quiescent) somatic hub cells that signal to the attached germline and somatic stem cells. Damaging the testis or overexpressing genes that activate the cell cycle in hub cells induces hub cell divisions, but also leads to the conversion of hub cells to somatic stem cells. This change in cell fate is accompanied by the formation of new niches, characterized by the presence of ectopic hubs each supporting active stem cells. Recently I found that the highly conserved cell cycle inhibitor and tumor suppressor retinoblastoma homolog RBF is a critical regulator of hub cell maintenance. Loss of RBF in the hub is sufficient to cause hub cell proliferation, and lineage tracing reveals that RBF prevents hub cells from converting to somatic stem cells. In addition, extended knockdown of RBF in the hub also leads to ectopic niche formation. Live imaging of hub cells undergoing loss of quiescence in multiple conditions indicates that converting hub cells migrate farther distances than their wild-type counterparts. Knockdown of RBF along with its interacting partner (the cell cycle activator E2F) rescues both the over-proliferation and cell fate conversion phenotypes, suggesting that targets of E2F may drive both the proliferation of hub cells and their conversion to somatic stem cells. However, these two phenotypes may be separable. Loss of the transcription factor escargot from hub cells causes them to convert to somatic stem cells (Voog et al., Cell Reports 2014), and my preliminary data suggest that Escargot does not prevent loss of hub cell quiescence or ectopic niche formation. Thus, RBF works through the canonical cell cycle pathway to actively regulate hub cell quiescence and identity, and likely acts upstream of escargot and additional factors during this process. This work provides a model for understanding the regulation of niche cell quiescence and identity, which could be pertinent in other stem cell niches to prevent over-proliferation and metastases. .

D1227B The Role of PVR in *Drosophila* Testis Stem Cells. *Nastaran SoleimaniBarzi*, Jade Koretko, Kenneth Hammer, Judith Leatherman. University of Northern Colorado, Greeley, CO.

Adult stem cells live in different tissues and they support the tissue they reside in. The stemness behavior is regulated by the environment they reside in, called the stem cell niche. The niche environment in mammals is complex, which makes it hard to study, therefore we use the *Drosophila* testis as a simple model to study adult stem cells in their niche. In the *Drosophila* testis niche there are two populations of stem cells: germline stem cells (GSCs), which will differentiate into sperm, and cyst stem cells (CySCs) that will differentiate into cyst cells. These stem cells are physically in contact with a group of somatic cells known as the hub. As long as they stay in contact to the hub, they will remain stem cells. CySCs and their lineage play a crucial role in self-renewal and differentiation of GSCs. EGFR, a member of Receptor Tyrosine Kinase (RTK) family, is known to promote differentiation in cyst lineage. PVR (PGFG-VEGF-related receptor) is another member of RTK family that is expressed in the cyst lineage. This led us to ask the question whether PVR functions similarly to EGFR, or whether it has a distinct function. Pvf1, the ligand for PVR, is restricted to the hub, suggesting that PVR signaling is only activated in CySCs, not cyst cells. We hypothesize that PVR is one required factor in CySC self-renewal. In order to test our hypothesis we used two strategies, PVR gain of function and PVR loss of function. For gain of function we expressed a constitutive PVR transgene, which caused cyst-lineage cells to divide away from the hub, where they would normally differentiate. For loss of function we expressed PVR RNAi transgenes, a dominant negative PVR transgene, and performed mosaic analysis. Our results show a reduction in CySC number when PVR is ablated in the cyst lineage. In conclusion, PVR is required to maintain the normal cyst stem cell population in *Drosophila* testes. Future work will examine whether PVR is required to maintain normal cell division rates in these stem cells.

D1228C Reactivation of Quiescent Neuroblasts Requires Activation of PI3-kinase Signaling in Cortex Glia. *X. Yuan*, S. Siegrist. University of Virginia, Charlottesville, VA.

Precise timing of stem cell entry into and exit from quiescence is essential for tissue morphogenesis and homeostasis. *Drosophila* neuroblasts (NBs), the stem cells of the Drosophila CNS, provide a model for investigating regulation of stem cell quiescence. At the end of embryogenesis, all NBs in the central brain, except for a subset, exit cell cycle and enter a period of quiescence. NBs exit quiescence and begin proliferating in response to a nutrient-derived cue received soon after larvae consume their first complete meal. NB exit from quiescence fails if larvae consume a meal that lacks amino acids. The current model posits that amino acids are required for the synthesis and secretion of Dilp6 in glia and that local production of Dilp6 in glia is required to reactivate quiescent NBs through activation of the highly conserved PI3-kinase growth signaling pathway in NBs. We are investigating whether amino acids are also required for glia growth, morphology, and subsequent ensheathment of NBs. When animals are fed a diet lacking amino acids, we find that the amount of glial membrane and growth is reduced compared to animals fed a complete diet. This reduction in glial growth is likely caused by a reduction in levels of PI3-kinase activity in glia in response to absence of dietary amino acids. NBs fail to exit from quiescence when dietary amino acids are absent or when PI3-kinase is reduced in glia. Currently, we are investigating whether nutrition first stimulates activation of PI3-kinase signaling in cortex glia, leading to glial growth and ensheathment of NBs, and whether glial ensheathment is required for NB exit from quiescence.

D1229A Destruction of E2f1 is dispensable for stem cell proliferation. *Taylor D. Hinnant*, Elizabeth T. Ables. East Carolina University, Greenville, NC.

Growing evidence suggests that some molecular regulatory pathways dictating cell fate are associated with the cell cycle machinery; however, the molecular connections remain unclear. Because the ability of *Drosophila* ovaries to create mature oocytes depends on a well-characterized population of germline stem cells (GSCs), the proliferative ability of GSCs must be tightly regulated. GSCs therefore serve as an exceptional model for study of cell cycle control in stem cells. The GSC cell cycle has been previously characterized by monitoring the morphology of the fusome, a germline-specific organelle that changes morphology during the cell cycle. To more precisely understand GSC cell cycle regulation, we characterized the Fluorescence Ubiquitin Cell Cycle Indicator (FUCCI) system in GSCs, which utilizes degradable versions of E2f1::GFP and CycB::RFP to fluorescently label cells in each phase of the cell cycle. We found that the FUCCI system faithfully labeled GSC cell cycle phases consistent with somatic cell types, but must be used in combination with fusome morphology for most accurate cell cycle assessment. Importantly, we found that E2f1::GFP expression mirrors that of Cyclin E, previously demonstrated to control GSC fate independently of proliferation. In contrast to *Cyclin E* mutants, however, loss of *E2f1* has only minor effects on maintenance of the GSC fate. Additionally, GSC proliferation and maintenance appear to be largely independent of degradation of E2f1, as stabilizing E2f1 expression throughout the cell cycle results neither in major loss of GSCs nor obvious increases in cell death. Our data suggest that repression of E2f1 activity in GSCs may instead be more highly controlled by Rb and/or the repressor E2f2. We are currently investigating the role of *E2f2* in this context. Our data also further emphasizes that cell cycle-independent roles of Cyclin E regulate maintenance of the GSC fate. These findings provide further insight into the regulation of the balance between maintaining cell fate and proliferation in GSCs, with broad implications on other asymmetrically dividing cells.

D1230B Investigating Histone Inheritance Patterns at Specific Genomic Loci. *E. Kahney*[1], M. Wooten[2], L. Feng[3], X. Chen[4]. 1) Johns Hopkins University, Baltimore, MD; 2) Johns Hopkins University, Baltimore, MD; 3) Johns Hopkins University, Baltimore, MD; 4) Johns Hopkins University, Baltimore, MD.

Stem cells rely on epigenetic mechanisms to regulate cell identity as they undergo **asymmetric cell division (ACD)** to give rise to a daughter that self-renews and another daughter that differentiates, despite each containing identical genomes. Pioneering work from our lab developed a dual-color labeling system to study ACD in *Drosophila* male **germline stem cell (GSCs)** and found that preexisting (old) histones are preferentially retained in the self-renewed GSC while newly synthesized (new) histones are preferentially enriched in the differentiating daughter. Histone modifications play important roles in regulating gene expression and thus stem cells may maintain their identity by selectively inheriting preexisting histones. **Hypothesis:** During ACD, the self-renewing daughter inherits old histones with modifications that maintain active expression at stem cell-promoting genes and repression at differentiation genes. This allows for continuation of the stem cell state by maintaining epigenetic memory. Meanwhile, the differentiating daughter inherits new histones in these regions, erasing the epigenetic stem cell memory and allowing for differentiation to occur.

I will investigate the conservation of asymmetric histone inheritance during ACD in the *Drosophila* female germline and elucidate the epigenetic histone modifications present at genomic loci that undergo gene expression switching during differentiation. Using previously described methods, I have compared the histone inheritance patterns found in actively dividing female GSCs to those found in male GSCs. We know that during ACD in the male germline, old versus new histones are almost completely segregated between the two daughters. In contrast, my new data show that global histone inheritance patterns in actively dividing female GSCs appear symmetric, but correlation mapping can identify significant regions of non-overlapping old and new histone signal. The difference in gene expression programs for male versus female gametogenesis might underlie the global chromatin change seen during male GSC differentiation but local change during female GSC or other cell lineage differentiation, which undergo far fewer expression changes. To explore this possibility, I have created an array of fluorescent probes targeting well-characterized genes associated with promoting the stem-cell state or the differentiation program. To visualize changes in the epigenome that occur during ACD, I will add these fluorescent probes along with antibodies against old versus new histones as well as specific histone modifications in order to perform a proximity ligation assay. This method will reveal how the epigenome signature changes between the renewed stem cell daughter versus the daughter destined to differentiate in ACD.

D1231C Coordinating DNA Replication Initiation to Asymmetrically Segregate Histones H3 in the *Drosophila* Germline. *J. Snedeker*, M. Wooten, R. Ranjan, X. Chen. Department of Biology, Johns Hopkins University, Baltimore, MD 21218, USA.

One of the major mechanisms by which stem cells maintain tissue homeostasis is by the asymmetric division of stem cells such that one daughter cell remains a stem cell and another daughter cell differentiates. The loss of asymmetric stem cell division could contribute to a wide variety of diseases such as cancer, tissue degeneration, and infertility. Despite its critical importance, little is understood about the epigenetic mechanisms underlying asymmetric cell division. Previously, our lab found that preexisting (old) and newly synthesized (new) histones H3, a major carrier of epigenetic information in *Drosophila*, are segregated asymmetrically during the asymmetric division of the *Drosophila* male Germline Stem Cell (GSC), and that the disruption of proper asymmetric histone segregation leads to defects in GSC maintenance and proper spermatogenesis. We recently obtained data suggesting that old and new histones are differentially incorporated during DNA replication, wherein old histones are preferentially incorporated on the leading strand while new histones are incorporated on the lagging strand. However, this explanation alone is not sufficient for creating a global asymmetry old and new histone incorporation on the two sets of sister chromatids. If DNA replication forks fire bidirectionally, it would create a patchwork of old and new histone-enriched chromosomal domains, but not a global asymmetry. We have preliminary data suggesting that the initiation of DNA replication in GSCs is tightly regulated temporally and precisely regulated spatially. We found that GSCs have a unique nuclear architecture and replication initiation pattern: Heterochromatin is localized to a perinucleolar domain where centromeres cluster. DNA replication apparently initiates near this perinucleolar region and

progresses outwards. By contrast, in the differentiating GB daughter cell DNA replication initiates stochastically throughout the nucleus prior to the reformation of the nucleolus. This perinucleolar heterochromatin could potentially serve as a fork block for DNA replication, and thereby coordinate DNA replication fork to progress unidirectionally resulting in the establishment of global asymmetric histone incorporation onto the two sets of sister chromatids, in preparation for their asymmetric segregation during mitosis.

D1232A Histone H3 Threonine Phosphorylation Regulates Asymmetric Histone Inheritance in the Drosophila Male Germline. *Jing Xie*. Johns Hopkins University, BALTIMORE, MD.

A long-standing question concerns how stem cells maintain their identity through multiple divisions. Previously, we reported that pre-existing and newly synthesized histone H3 are asymmetrically distributed during Drosophila male germline stem cell (GSC) asymmetric division. Here,we show that phosphorylation at threonine 3 of H3 (H3T3P) distinguishes pre-existing versus newly synthesized H3. Converting T3 to the unphosphorylatable residue alanine (H3T3A) or to the phosphomimetic aspartate (H3T3D) disrupts asymmetric H3 inheritance. Expression of H3T3A or H3T3D specifically in earlystage
germline also leads to cellular defects, including GSC loss and germline tumors. Finally, compromising the activity of the H3T3 kinase Haspin enhances the H3T3A but suppresses the H3T3D phenotypes. These studies demonstrate that H3T3P distinguishes
sister chromatids enriched with distinct pools of H3 in order to coordinate asymmetric segregation of ''old'' H3 into GSCs and that tight regulation of H3T3 phosphorylation is required for male germline
activity.

D1233B Developmental Toxicity Testing of Cigarette Smoke and E-Cigarette Vapor Using *Drosophila melanogaster* Primary Embryonic Stem Cell Cultures. *T. M. Ubina*, J. Juarez, M. Gallardo, J. Pilotin, N. Bournias-Vardiabasis. California State University, San Bernardino, San Bernardino, CA.

E-cigarettes (EC) are relatively new and many of the effects they have on the body are still unknown. Given this, even less is known about the effects they have on embryonic development. Previously identified as a reliable method for teratogen testing, *Drosophila melanogaster* embryos fully develop and hatch into larvae 24 hours after oviposition which makes them attractive as a fast and reliable method of testing developmental toxicants (Bournias-Vardiabasis, 1983). When primary cultures are taken at the gastrula stage of development, the embryonic stem cells will differentiate into the beginnings of the muscular and neuronal systems *in vitro* within 24 hours and these differentiated cells, called myotubes (MT) and neuronal clusters (NC), can be observed and quantified. In this study, primary cultures of wild type *D. melanogaster* embryos were homogenized and cultured at the gastrula stage and were then exposed to conventional and e-cigarette vapors dissolved into culture media at various concentrations. From conventional cigarettes, mainstream smoke (MS) and sidestream smoke (SS) were both tested. MS smoke is the smoke that the smoker actively inhales and SS smoke is what comes from the burning end of the cigarette and is what we commonly think of as second-hand smoke. The smoke concentrations were measured in Puff Equivalents (PE) which is the amount of smoke from 1 puff of a cigarette that will dissolve into 1 mL of solution. SS smoke, MS smoke were tested at 1.0 PE/mL, 0.1 PE/mL and 0.01PE/mL. EC vapor was tested at 0.1 PE/mL and 0.01 PE/mL. The numbers of neuronal clusters and myotubes were counted 24 hours after exposure and a Student's t-test was performed. If the cell counts of either NCs or MTs were reduced enough to be deemed significant by the t-test, the solution was labeled as a developmental toxicant. MS smoke was toxic at 1.0 and 0.1 PE/ml, SS was toxic at all concentrations, EC vapor was toxic at 0.1PE/mL.

D1234C Polyploidy Associated Hypertrophy: An Alternative to Mitotic Organ Regeneration. *E. Cohen*, D. Fox. Duke University Medical Center, Durham, NC.

In numerous organs, tissue injury is repaired through compensatory proliferation, a regenerative injury response which leads to restoration of tissue morphology and mass. However, numerous tissues have been shown to respond to tissue injury by a distinctly different, non-proliferative process known as hypertrophy. Following injury, hypertrophic tissues increase the size and DNA copy number (ploidy) of remaining cells to restore lost organ mass. While hypertrophy is clearly important to repairing numerous injured organs such as the mammalian liver, this repair process does not always restore tissue morphology and function. Thus, understanding molecular differences between hypertrophy and the more regenerative compensatory proliferation process could improve efforts to regenerate organs. To approach this question, we established that the *Drosophila* pylorus undergoes compensatory proliferation when injured during juvenile (larval) stages, and then switches to a hypertrophic repair program when injury occurs during adulthood. Studying this process, we can now molecularly interrogate the regulation underlying the decision to undergo hypertrophic or proliferative injury responses. We will discuss recent work identifying the time frame in which the switch between proliferation and hypertrophy occurs. This study provides valuable new insights into conserved mechanisms of organ injury repair using a novel model system.

D1235A Chinmo is necessary and sufficient to maintain male fate in somatic cells of the adult Drosophila gonads. *Miriam Akeju*[1], Qing Ma[1], Margaret de Cuevas[1], Justin Fear[2], Brian Oliver[2], Erika Matunis[1]. 1) Johns Hopkins, Baltimore, MD; 2) National Institutes of Health, Bethesda, MD.

Sexual identity is actively maintained in specific differentiated cell types long after sex determination occurs during development. In the adult Drosophila testis, the putative transcription factor Chronologically inappropriate morphogenesis (Chinmo) is required to maintain the male identity of somatic cyst stem cells and their progeny; loss of Chinmo causes these cells to transform into female cells (Ma et al., *Dev Cell,* 2014). Overexpression of the male sex determinant DoublesexM (DsxM) partially rescues this sex transformation, and ectopic expression of the

female sex determinant DsxF enhances it, indicating that Chinmo acts together with the canonical sex determination pathway to maintain the male identity of testis somatic cells. In the adult ovary, ectopic expression of Chinmo is sufficient to induce a male identity in adult ovarian somatic cells; here, however, it acts through a DsxM-independent mechanism (Ma et al., *Development*, 2016). We conclude that Chinmo is necessary and sufficient to promote a male identity in somatic cells of the adult ovary and testis and that the sexual identity of adult somatic cells can be reprogrammed in Drosophila gonads. To gain further insight into how sex identity is maintained, we are using a genome-wide approach to identify the downstream targets of *chinmo* in adult somatic cells. By using a technique called targeted DNA adenine methyltransferase identification (TaDa)(Southall et al., *Dev Cell,* 2013), we will reveal cell type-specific gene expression differences in adult wild-type and chinmo mutant tissues.

D1236B Apoptosis in *Drosophila* hemocytes lead to nitric oxide mediated pro-inflammatory shift in the immune system and developmental function. *M. B. Arefin*[1], L. Kucerova[1], R. Krautz[1], H. Kranenburg[1,2], F. Parvin[1], U. Theopold[1]. 1) Stockholm University, Stockholm, Sweden; 2) University of Münster, Münster, Germany.

Insects have evolved an efficient innate immune system to fight both pathogens and to ensure cellular and organismal homeostasis. *Drosophila* hemocytes perform cellular reactions not only via phagocytosis and encapsulation, but they also release soluble factors (e.g., antimicrobial peptides and cytokines) to induce humoral responses. Furthermore, they engage in coagulation and wounding, and in development. Recent genome wide transcriptome studies identified several immune molecules in humoral and/or cellular pathways involved in nematode infection in *Drosophila.* To shed light on cellular immunity during nematode infection, we eliminated hemocytes by overexpressing the pro-apoptotic genes hid and grim (hml-apo larvae). Surprisingly, we find that although hml-apo larvae contain fewer plasmatocytes and crystal cells (the two hemocyte subtypes present in naïve larvae) they are resistant to nematode infections. Further characterization of hml-apo larvae shows a shift in immune effector pathways including massive lamellocyte differentiation, melanotic nodule formation, induction of Toll as well as repression of imd-signaling. This leads to a pro-inflammatory state. In addition, pupal lethality, and leg defects in adult escapers are found. Most of the phenotypes are alleviated upon administration of antibiotics and changing food source suggesting an involvement of the microbiota. We find that nitric oxide acts as a key regulator in this process. Finally we show that the substrate for nitric oxide synthase L-arginine similarly modulates the response towards an early stage of tumor progression in fly larvae.

D1237C JAK/STAT Signaling in *Drosophila* Muscles Controls the Cellular Immune Response Against Parasitoid infection. *Hairu Yang*, Dan Hultmark. Umeå University, Umeå, SE.

In *Drosophila melanogaster*, several signaling pathways, including the JAK/STAT pathway, are known to mediate blood cell activation and/or to be involved in the defense against parasitoid wasp infection. How these signals control the cellular defense is not understood for any of them. Here we show that parasitoid wasp infection activates JAK/STAT signaling in the *Drosophila* larva, not only in blood cells (hemocytes), but also in somatic muscles. In the muscles, JAK/STAT signaling is activated by the cytokines Upd2 and Upd3, which are secreted from circulating hemocytes. Deletion of the *upd2* or *upd3* genes, but not the related *os* (*upd1*) gene, reduces the cellular immune response. In addition, suppression of the JAK/STAT pathway in muscle cells reduces the encapsulation of wasp eggs and the number of circulating effector cells, called lamellocytes. These results suggest that Upd2 and Upd3 are important cytokines, coordinating the cellular immune response of *Drosophila*. Furthermore, via a JAK/STAT-dependent mechanism, muscles participate in controlling the defense against wasp infection.

D1238A E3 ubiquitin ligase Sherpa mediates Toll innate immune signaling in Drosophila. *T. Kuraishi*[1,2,3], H. Kanoh[1,4], L.-L. Tong[1], S. Kurata[1]. 1) Division of Molecular Genetics, Graduate School of Pharmaceutical Sciences, Tohoku University, Sendai 980-8578, Japan; 2) Precursory Research for Embryonic Science and Technology (PRESTO), Japan Science and Technology Agency, Tokyo 102-0076, Japan; 3) Graduate School of Medical Sciences, Kanazawa University, Kanazawa, Ishikawa 920-1192, Japan; 4) Division of Glycopathology, Institute of Molecular Bio- membrane and Glycobiology, Tohoku Pharmaceutical University, Sendai 981-8558, Japan.

Fruit fly is a sophisticated model animal which possesses an evolutionary conserved innate immune system as represented by the Toll signaling pathway in metazoa. Despite a significant contribution for the identification of mammalian Toll-like receptors, the molecular basis of the intracellular Toll pathway in flies still remains unclear. In this study, we found a suitable cell-line for analyzing the Toll pathway and performed a comparative genome-wide RNAi screening comprised of four distinct screens. Based on the bioinformatic analyses, we identified an E3 ligase gene, Sherpa, as a novel signaling component. Sherpa deficient flies showed susceptibility to bacterial infection as well as the defects in the antimicrobial-peptide production against Gram-positive bacteria and fungi. Cell-based reporter assays indicated that Sherpa functions genetically downstream of Drosophila MyD88 (dMyd88), an adaptor protein for the Toll receptor, and upstream of Tube and Pelle, Drosophila homologues for mammalian IRAK4 and IRAK1/2. Co-immunoprecipitation assays showed that Sherpa interacts with dMyd88 and induces polyubiquitination on dMyd88 and Sherpa itself. Immunofluorescence revealed that Sherpa localizes on the plasma membrane and maintains the proper membrane localization of dMyd88-Tube signaling complex. These results suggested that Sherpa leads adaptor proteins to the plasma membrane around the Toll receptor via polyubiquitinations.

D1239B Seasonal change in *Drosophila melanogaster* innate immunity. *Emily L. Behrman*[1], Virginia M. Howick[2,3], Fabian Staubach[4,5], Alan O. Bergland[5,6], Dmitri A. Petrov[6], Brian P. Lazzaro[2], Paul S. Schmidt[1]. 1) University of Pennsylvania, Philadelphia, PA; 2) Cornell University, Ithaca, NY; 3) Wellcome Trust Sanger Institute, Hixton, UK; 4) Albert-Ludwigs University, Freiburg, Germany; 5) Stanford University, Stanford, CA; 6) University of Virginia, Charlottesville, VA.

The dynamics of adaptive response to abiotic environmental factors is well documented in a variety of systems, but the role of biotic

environment in the adaptive process is less well understood. Ubiquitous microbial communities associated with hosts can be commensal, but some microbiota result in pathogenic infection that challenges the host with consequences ranging from resource reallocation away from other functions to rapid host lethality. The immune system sits at the crucial interface between an organism's external and internal environment and this balance between self and other may be essential in adaptation to environmental heterogeneity. Therefore, immune response may be an important trait to respond to biotic variation along environmental gradients. Here, we investigate innate immunity along spatial and temporal environmental gradients in wild populations of *Drosophila melanogaster*. We find a repeated complete seasonal turnover in the microbial environment associated with wild flies from spring to fall and a corresponding change in the immune response. We simultaneously sampled populations along a latitudinal cline early and late in the season and evaluated the response to infection. Both gram+ (*Enterococcus faecalis*) and gram- (*Providencia rettgeri*) bacteria were used to probe both Toll and IMD immune pathways that are initiated by different pathogen challenges. We find opposing seasonal responses to the gram+ and gram- pathogens, suggesting a seasonal trade-off in defense that is consistent with the frequency dependent selection imposed by the seasonally changes in the bacterial composition in these populations. Whole genome resequencing in these populations identified alleles in immune genes that cycle across seasonal time. We evaluate the function of natural polymorphisms within *Thioester-containing protein 3* (*Tep3*) and among other immune genes and demonstrate non-additive interactions among alleles that contributes to the seasonal differences in immune response in natural populations; these non-additive interactions shape the frequency of the genotypes in the wild across seasonal time. Overall, the data demonstrate that the innate immune response in wild *Drosophila* has a genetic basis that varies with location, season, and pathogen; the trade-offs among innate immunity and other life history traits predict that the biotic environment may be an important underlying selective force in wild populations.

D1240C Zfh2 is an *in vivo* mediator of hypercapnic immune suppression. *J. KWON*. NORTHWESTERN UNIVERSITY, EVANSTON, IL.

Zfh2 is an *in vivo* mediator of hypercapnic immune suppression

James Kwon[1], Ryan Haake[1], Peter H. S. Sporn[2] and Greg J. Beitel[1]
[1]Dept. of Molecular Biosciences, Northwestern University, Evanston, IL
[2]Division of Pulmonary and Critical Care Medicine, Feinberg School of Medicine, Northwestern University, Chicago, IL

Patients with advanced chronic obstructive pulmonary disease (COPD), the third leading cause of death in the U.S., and other severe lung diseases often develop hypercapnia (an elevated level of CO_2 in blood and tissues), which is associated with increased risk of pulmonary infection and mortality. Previously, we reported the results of an S2 cell-based RNAi screen to identify candidate genes that modulate immune suppression by elevated CO_2 levels. Knock down of select genes reversed the suppression of *Diptericin (Dipt)* by CO_2, restoring *Dipt* expression in elevated CO_2 towards levels observed in air. We also reported preliminary results suggesting that the transcription factor Zfh2 is an *in vivo* mediator of hypercapnic immune suppression. We have now confirmed those results by showing that in *S. aureus* infection assays, flies homozygous for the *zfh2[209]* mutation show decreased mortality and decreased bacterial loads compared to *w[1118]* control flies in 13% CO_2, but not in air. Importantly, Western blotting shows that in *zfh2[209]* mutants the level of Zfh2 protein is reduced in the fat body, the major organ of immune response, but not the head or carcass (the body minus the fat body and head). Further evidence that the fat body is a critical site of action for *zfh2* was obtained by knocking down *zfh2* using the shRNA of *zfh2[13305]* and either of the fat body drivers CG-Gal4 or C754, which increased survival and decreased bacterial loads in elevated CO_2 conditions. Using qPCR and a newly developed *ex vivo* fat body culture system, we determined that reducing *zfh2* levels increased expression of the antimicrobial peptide genes *Diptericin*, *Attacin* and *Metchnikowin* in elevated CO_2 conditions, but not in air. Together these results define Zfh2 as the first identified *in vivo* mediator of hypercapnic immune suppression and the fat body as a critical site of action of hypercapnic immune suppression.

D1241A Microbiota-dependent priming of antiviral intestinal immunity in Drosophila. *Christine L. Sansone*, Jonathan Cohen, Jie Xu, Ari Yasunaga, Greg Osborn, Harry Subramanian, Beth Gold, Sara Cherry. University of Pennsylvania, Philadelphia, PA.

Many pathogens, including viruses, are orally acquired and infect cells within the gastrointestinal tract. To counter this, the gastrointestinal tract has evolved as a physical and immunological barrier. Moreover, the microflora within the intestinal tract plays a fundamental role in immunity; however, much remains unknown regarding the molecular mechanisms linking the microbiota to barrier immunity against enteric viruses. Using *Drosophila* as a model insect, we previously found that the ERK pathway controls innate immunity to oral infection within the intestinal epithelium. However, it remains unclear how ERK is activated to restrict infection. Here, we show that two signals are required to activate antiviral ERK signaling in the intestinal epithelium. One signal is dependent on the recognition of peptidoglycan from the commensals, including *Acetobacter pomorum*, which primes the NF-kB-dependent induction of the secreted factor Pvf2. However, the microbiota is not sufficient to induce; a second virus-dependent Cdk9-dependent signal is required for the production of Pvf2. We have screened a panel of transcription factors that are Cdk9-dependent and identified a transcription factor required for Pvf2 induction. These findings demonstrate that sensing of specific commensals primes inflammatory signaling required for epithelial antiviral responsiveness to restrict diverse enteric viral infections. Future studies are directed toward identifying additional antiviral pathways rapidly induced in the gut following oral challenge by performing RNA-seq.

D1242B Translational regulation by Thor drives the innate immune response. *Deepika Vasudevan*[1], Jessica Sam[1], Min-Ji Kang[2], Hyung Don Ryoo[1]. 1) New York University School of Medicine, New York, NY; 2) University of Ulsan College of Medicine, Ulsan, Korea.

The translational inhibitor Thor (*Drosophila* 4E-BP) was first identified in a screen for immune-compromised phenotypes (Bernal et al, 2000). 4E-BP inhibits the initiation factor eIF4E, which is required for the recognition of the m7G cap of transcripts to load ribosomes for translation. Most cellular transcripts are translated via a cap-dependent mechanism requiring eIF4E. However, subsets of transcripts can be translated cap-

independently via special structures in their 5'UTR. While 4E-BP has drawn interest due to its role in lifespan extension, how it is induced during infection and its functional relevance remain unexplained. In this work, we show that 4E-BP is induced by the integrated stress response pathway and is required for the efficient translation of anti-microbial peptides (AMPs) involved in pathogen clearance.

Following pathogen recognition during infection, a signaling cascade is activated culminating in the transcriptional induction and synthesis of AMPs. AMP induction in response to the pathogen Ecc15 was unaltered in 4E-BP$^{-/-}$ suggesting that AMP translation may be affected. To test if AMPs are translated cap-independently in the presence of 4E-BP, we designed a bicistronic assay with the 5'UTR of AMPs sandwiched between GFP and dsRed. Thus dsRed will only be synthesized if the 5'UTR permits cap-independent translation. The 5'UTR of the AMP drosomycin not only scored positively in this assay, but enhanced the synthesis of dsRed when the cells were challenged with Ecc15. These data suggest that while AMPs may be translated cap-independently, their efficient translation during infection requires the inhibition of cap-dependent translation by 4E-BP.

We find that the transcriptional induction of 4E-BP during infection is mediated by the integrated stress response transcription factor, ATF4. ATF4 mutants are immune-compromised similar to 4E-BP$^{-/-}$ and analysis of the 4E-BP genomic region reveals several ATF4 binding sites in an intronic element (4E-BP^{i}). A dsRed reporter driven by 4E-BP^{i} responds specifically to ATF4 but not the canonical 4E-BP transcription factor, FOXO. Mutating the putative ATF4 binding sites in 4E-BP^{i} resulted in loss of reporter activity. Reporter expression is elevated in the gut of larvae orally infected with Ecc15 in accordance with our other data. ATF4 can be activated by one of two upstream kinases, PERK, which responds to stress in the endoplasmic reticulum and GCN2, which responds to amino acid deprivation. Knockdown of GCN2 but not PERK resulted in reduced ability to clear Ecc15 in larvae. These results indicate a role for GCN2/ATF4/4E-BP in mounting an immune response.

D1243C The identification and characterization of immune responsive enhancers. *Z. Wunderlich*. UC Irvine, Irvine, CA.

To produce antimicrobial peptides and up-regulate other genes important for the immune reaction, Drosophila relies on a transcriptional response. In the course of this response, hundreds of genes are differentially regulated, but the loci of only a handful have been examined to find the cis-regulatory elements responsible for these gene expression changes. To identify immune-responsive enhancers genome wide, we infected flies with measured amounts of Gram-positive or Gram-negative bacteria and performed an ATAC-seq experiment on the dissected fat bodies of the animals 4-6 hours after infection. We compared these results to flies that had been injected with a sterile solution. We are analyzing these results to find likely immune-responsive enhancers and will refine this preliminary list with bioinformatics analysis to find regions with a preponderance of binding sites for key transcription factors, Dif, Relish, serpent and Dorsal. In the future, we plan on validating these presumptive enhancers in cell culture assays and studying how natural sequence variation in these enhancers affects the transcriptional reaction in response to infection.

D1244A Insect-*Metarhizium* interactions. *Hsiao-Ling Lu*, Jonathan Wang, Raymond St. Leger. University of Maryland, College Park, MD.

The fungus *Metarhizium anisopliae* is a natural pathogen of fruit flies. We performed a screen of 2,613 mutant *Drosophila* lines to identify host genes affecting susceptibility to *M. anisopliae* 549. In addition, we used *Drosophila* gene disruption mutants and reporter lines such as drosomycin-GFP to examine variation in *Drosophila*'s responses to GFP or RFP tagged *Metarhizium* strains with different infection strategies (e.g., quick kill via toxins vs. slow kill via invasive growth), and different lifestyles (generalist broad host range strains with different degrees of virulence to *Drosophila* and specialists with narrow host ranges that show poor infectivity to *Drosophil*a). To investigate the impact of pathogen and host variation on fungal fitness and host survival we looked at correlations between key life history traits at different steps of the infection process; lethal pathogen dose (LD50), within-host growth (fungal load), host life span (LT50 values), latent period (the lag time between inoculation and sporulation), and sporulation capacity (the total number of spores per *Drosophila* cadaver). By analyzing fungal behavior post infection we identified environmental as well as genetic determinants influencing *Drosophila* pathogen interactions. *Drosophila* mutants disrupted in immune related genes showed increased susceptibility to specialist *Metarhizium*'s adapted to other insects, but mutations had less effect on generalists. Testing isolated components of the *Drosophila* immune response demonstrated that the antifungal peptide Drosomycin did not inhibit *Metarhzium* strains alone nor in combination with cecropin A.

D1245B Investigating the mechanism of declines in male fitness due to chronic infection in *Drosophila melanogaster*. *K. B. Nichols*, S. Tener, K. Staub, M. C. Chambers. Muhlenberg College, Allentown, PA.

Environmental changes can greatly affect animal hosts, impacting both physiology and behavior. Changes that alter the fitness of the organism are most important because they determine which traits continue to subsequent generations. Work across species suggests that organisms have evolved mechanisms to detect the immunological strength of a prospective mate. Using *Drosophila melanogaster* as a model organism, we are investigating the relationship between declines in male fitness and infection with the natural pathogen *Providencia rettgeri*. If a fly survives acute infection with this bacteria, the fly is chronically infected for the remainder of its life. Little was known, however, about how chronic infection impacts male reproduction. We find that chronically infected male flies produce fewer offspring when mated to groups of virgin females. We examined the mechanism behind this reproductive defect by testing the impact of chronic infection on both mate choice and sperm replenishment.

Mate choice is influenced by the composition of a male's cuticular hydrocarbons (CHCs), which are long-chain fatty acids found on the external surface of most insects that mediate a variety of host processes including desiccation resistance, communication, and mate choice. We assessed the ability of chronic infection to influence mate choice by both determining how infection changes the CHC profile of the male fly and how infection influences selection of the infected male fly in a competitive mating assay. In addition, we determined the sperm replenishment capability of chronically infected flies by successively mating the fly with virgin females and scoring viable offspring. Throughout all of these

assays, male flies were also assessed for either pathogen load or survival to allow correlation of phenotypes with severity of infection. We are currently using genetic mutants in various pathways to determine the pathways responsible for modulating the effects during infection. Ultimately, this research will provide a mechanistic example of how sensory detection of infection status impacts male reproduction.

D1246C Functional analysis of *Drosophila* mucins during development. *Z. A. Syed*[1], D. T. Tran[2], K. G. Ten Hagen[1]. 1) Developmental Glycobiology Section, NIDCR/NIH, Bethesda, MD; 2) Biological Chemistry Section, NIDCR/NIH, Bethesda, MD.

The mucosal barrier in the gut, lungs and other vital tubular organs consist primarily of mucins and protects the underlying cells against pathogens, dehydration and physical or chemical injury. Mucins are large, high molecular weight glycoproteins that contain a central polymorphic domain composed of tandem repeats, rich in amino acids serine, threonine and proline. These highly O-glycosylated proteins form densely arrayed structures that provide mutivalency and high stoichiometric power. In *Drosophila*, twenty-three mucins and mucin-related proteins that are expressed dynamically during different stages of the life cycle were identified. To understand the role of *Drosophila* mucins during development, we used the transgenic RNA interference (RNAi) system to systematically knockdown mucins. Ubiquitous knockdown of mucins expressed in the gut resulted in larval and pupal lethality, indicating that they are essential and suggesting their requirement for protective barrier formation in these tissues. Interestingly, tissue-specific knockdown of one mucin (*Muc26B*), which is expressed in the proventriculus, showed 1st instar larva lethality along with a dramatic up-regulation of genes encoding antimicrobial peptides. Additionally, loss of *Muc26B* resulted in activation of conserved signaling pathways. Immunostaining for MUC26B showed that it is expressed in the specialized secretory cells of the proventriculus called the PR cells, which are responsible for the synthesis and secretion of the peritrophic membrane (PM). Indeed, MUC26B staining could be seen in this protective membrane in wild type flies. We therefore hypothesize that MUC26B serves as a crucial component of the PM and we are currently investigating the cellular processes and signaling cascades activated in response to the loss of MUC26B. We are generating transgenic flies that endogenously express *Muc26B*lacking mucin-domains and associated chitin-binding domains to investigate the role of MUC26B in PM formation and barrier function. These transgenic flies will aid in elucidating changes in PM structure and function upon modulation of different MUC26B domains. In addition, we will investigate the role of MUC26B glycosylation in the packaging, secretion and formation of the PM using correlative light and electron microscopy (CLEM). These studies will ultimately advance our understanding of mucins and their role in the protection of epithelial cell surfaces.

D1247A The C-terminal domain of Abelson tyrosine kinase recruits it to axons. *Han Cheong*, Adeel Siddiqui, David Pierce, Mark VanBerkum. Wayne State University, Detroit, MI.

In the embryo, Abelson tyrosine kinase (Abl) is expressed in the central nervous system (CNS), and is localized to the axons of neuronal cells where it acts downstream of axon guidance receptors such as Frazzled and Roundabout. While the Abl N-terminus is highly conserved between Abl proteins of diverse taxa, the sequence of the *Drosophila* Abl C-terminal domain (CTD) of ~1100 amino acids is largely unique, with the exception of a conserved F-actin binding domain at the tail end. Here, we demonstrate that the CTD is essential for the recruitment of Abl to axon tracts. Using the Gal4-UAS system and immunohistochemistry, we confirm that removal of the CTD prevents the remaining N-terminal region from localizing to axons, and demonstrate that the CTD alone is sufficient for localization to axons. Within the CTD, we further define a ~350 amino acid region (amino acids 1117-1492, or the "third quarter") that is sufficient to drive localization of an RFP fusion protein to axons. However, in the context of full-length Abl, removal of the third quarter does not completely prevent axon localization, although stability of the protein is decreased, resulting in overall lower levels of Abl in the axons. Within the third quarter, the two putative EVH1 binding motifs are not required for axonal localization. Surprisingly, adult lethality assays using the expression of Abl transgenes in *Abl* mutant flies indicate that a second region, not involved in axonal localization (amino acids 639-804), is essential for Abl function, and ubiquitous or neuronal expression of the N-terminus fused to this region partially rescues adult lethality despite the protein's inability to localize to axons. Bioinformatic analyses suggest that large regions of the C-terminus are disordered, and these may undergo a disorder-to-order transition during protein-protein interactions. This further suggests that the C-terminus primarily facilitates binding of Abl to target proteins. Work is underway to both identify binding targets of the CTD as well as to assess the ability of our Abl transgenes to rescue axon guidance defects in *Abl* mutant embryos. As a whole, these results identified a region that is sufficient for axonal localization (the third quarter) although in the context of full-length Abl, this region may further co-operate with other regions for localization. Our results also suggest that the C-terminus has additional essential functions besides axonal localization.

D1248B Structural and Functional Analysis of Dunc-115 Using CRISPR. *C. K. Roblodowski*[1], S. Alghambi[2], R. Gomez[2], S. Giordano[2], D. Veyg[2], C. Batista[2], R. Lakha[2], Q. He[2]. 1) Queensborough Community College, 222-05 56th Avenue, Bayside, NY 11364; 2) Brooklyn College, 2900 Bedford Avenue, Brooklyn, NY 11210.

Significant progress has been made toward a better understanding of the axon guidance mechanisms during animal development. Several guidance pathways have been revealed where signaling initiated at the surface receptor level is relayed to the interior of neurons through numerous adaptor proteins. This leads to a reorganization of the cytoskeleton and other responses. We previously showed that the *Drosophila* protein Dunc-115, a homolog of the Unc-115 from the *C. elegans*, is involved in axon projection in the CNS and the visual system. Furthermore, our data also demonstrated that Dunc-115 binds to actin filaments, implying a possible mechanism for actin reorganization via Dunc-115. Dunc-115 is alternatively spliced resulting in the formation of three isoforms, and it has not previously been possible to dissect the functions of individual isoforms. Here, we report that by using the recently available CRISPR, we have generated mutant animals where the actin binding domain (VHD) of the longest isoform is deleted. The deletion of the VHD domain has severe phenotypic defects. The results suggest that the

actin binding domain is essential and that distinct isoforms function differently. The outcome of the structural and functional analysis will be discussed.

D1249C The conserved microtubule-associated protein Mini Spindles regulates dendrite branching and self-avoidance in *Drosophila* class IV dendritic arborization neurons. *Mala Misra*[1], Noor Anvery[1], Claire Kittock[1], Hendia Edmund[2], Elizabeth Gavis[2]. 1) Colgate University, Hamilton, NY; 2) Princeton University, Princeton, NJ.

Neuronal dysgenesis is a common feature of diverse neuropsychiatric and neurodevelopmental disorders, underscoring the need for a more comprehensive understanding of the molecular mechanisms underlying neuronal morphogenesis. The dendrites of *Drosophila* larval class IV dendritic arborization (c4da) neurons provide an excellent model system to study the regulation of dendrite morphogenesis because their complex branching patterns show clear parallels to those seen in vertebrates, and their two-dimensional organization on the surface of the larva allows for easy visualization. We capitalized on these properties in designing a two-tiered genetic screen to identify genes that (1) encode dendrite-localized mRNAs, and (2) regulate dendrite morphogenesis. The goal of the screen was to connect the local regulation of protein synthesis with dynamic morphogenetic events in the dendrites. One positive candidate arising from this effort was the gene *mini spindles* (*msps*), which encodes a microtubule associated protein homologous to XMAP215-family proteins in vertebrates. Previous studies have demonstrated that Msps regulates microtubule nucleation and promotes dynamic instability. We therefore hypothesized that it might play a role in regulating cytoskeletal events important for the growth and/or retraction of dendrite branches in c4da neurons. RNAi-mediated knockdown of *msps* expression in c4da neurons resulted in a modest but significant loss of branching, supporting this initial hypothesis. Strikingly, $msps^{RNAi}$ dendrites also exhibited more than twice as many self-crossings within the receptive field as control *yw* dendrites. Some previously characterized instances of aberrant c4da self-crossing have been linked to the enclosure of dendrites by overlying epidermal cells and a consequent loss of the characteristic two-dimensional array; immunostaining for Coracle, a marker of enclosure, confirmed that self-crossing dendrites in $msps^{RNAi}$ neurons also exhibit this behavior. The localization of *msps* mRNA to dendrites and the disorganization of dendrite branching in the absence of Msps protein suggest a preliminary model in which local control of Msps expression could regulate cytoskeletal dynamics and dendrite morphogenesis in response to local signaling between the neuron and the external environment.

D1250A *Drosophila* tissue inhibitor of matrix metalloproteinases regulates synaptic development through trans-synaptic signaling. *Jarrod Shilts*, Kendal Broadie. Vanderbilt University, Nashville, TN.

The activity of extracellular matrix metalloproteinases (MMPs) can shape synaptic structure and functional neurotransmission during neural development. Dysregulation of MMPs has been causally implicated in neurodevelopmental disorders such as Fragile X syndrome (FXS). *In vivo*, MMP regulation includes the secretion of endogenous tissue inhibitors of MMPs (TIMPs). However, the general roles of MMP regulation by TIMPs at the synapse remain elusive, due both to the redundancy of the mammalian MMP/TIMP system and the nesting of TIMP genes within synapsin genes. *Drosophila* has only two MMPs regulated by a single TIMP, making it possible to dissect the entire matrix metalloproteome in a tractable genetic model. Using CRISPR/Cas9 genome editing, we have created the first precise disruption of TIMP in order to study its neurological phenotypes. We discovered that loss of TIMP results in significant overelaboration of neuromuscular synapses, resembling the synaptic abnormalities seen in FXS disease models. Using cell-targeted RNAi, we have found bidirectional contributions of TIMP for maintaining synaptic morphology. Analysis of multiple *trans*-synaptic signals has revealed a mechanism where TIMP selectively tunes BMP signaling to control synaptic expansion. We are now extending these results using engineered TIMP alleles that will allow us to visualize its expression and differentiate its functional domains. To link our genetic results with biochemical data, we have optimized and begun testing a protocol for measuring MMP activity at individual synapses. Together, these genetic, biochemical, and neurobiological approaches demonstrate an important role for TIMP in regulating synaptic development, with potential applications to neurodevelopmental disease states.

D1251B Tenectin recruits integrin at synaptic terminals and stabilizes bouton architecture at the *Drosophila* neuromuscular junction. *Qi Wang*, Tae Hee Han, Peter Nguyen, Mihaela Serpe. NICHD/NIH, Bethesda, MD.

Extracellular matrix (ECM) proteins and their receptors have important roles during synapse assembly, development and plasticity, but very little is known about the underlying molecular mechanisms. In a genetic lethality screen for candidates interacting with *neto*, an obligatory auxiliary protein at the *Drosophila* NMJ, we found *tenectin* (*tnc*). Tnc is a mucin-like ECM protein expressed in motor neurons and striated muscles in 3rd instar larvae. *tnc* mutants are partially lethal and the escapers have severe climbing and locomotor defects, suggesting that Tnc is required for NMJ development. Using genetics, histology, super-resolution imaging, electron microscopy and electrophysiology approaches, we found that *tnc* mutants have collapsed synaptic boutons, but normal synaptic contacts and postsynaptic densities. Instead, Tnc is secreted into the synaptic cleft, and binds to pre- and postsynaptic βPS-containing integrin receptors. These Tnc-βPS bridges appear to stabilize the bouton shape partly by recruiting the membrane skeleton locally. Indeed, the distribution of membrane skeleton components such as α-Spectrin, Adducin, Ank2L are disrupted at Tnc-deprived NMJs. Furthermore, Tnc-coated beads recruit βPS and α-Spectrin to specific membrane domains in S2R+ cells.

Tnc is also involved in the regulation of synaptic vesicle release. Electrophysiology recordings show that *tnc* mutants NMJs have reduced mEJPs frequency, EJPs amplitude and quantal content, and exhibit higher paired-pulse ratio (PPR). Expression of Tnc in motor neurons, but not in muscles, can rescue the synaptic accumulation of βPS integrin,α-Spectrin and Adducin and partially rescue the behavior defects of *tnc* mutants. Together, our data demonstrate that pre- and postsynaptic secreted Tnc recruits integrin receptors at NMJs, and anchors the synaptic

membrane skeleton to the ECM to ensure synaptic boutons architecture and function. Our findings extend the knowledge on how ECM proteins organize the synaptic membrane skeleton to regulate synaptic structure and function. .

D1252C Notch-mediated lateral inhibition regulates proneural wave propagation when combined with EGF-mediated reaction diffusion. *M. Sato*[1], Y. Minami[2], T. Miura[3], M. Nagayama[2]. 1) Kanazawa University, Kanazawa, Ishikawa, JP; 2) Hokkaido University, Sapporo, Hokkaido, JP; 3) Kyushu University, Fukuoka-shi, Fukuoka, JP.

Notch-mediated lateral inhibition regulates binary cell-fate choice, resulting in salt-and-pepper patterns during various developmental processes. However, how Notch signaling behaves in combination with other signaling systems remains elusive. The wave of differentiation in the *Drosophila* visual center or 'proneural wave' accompanies Notch activity that is propagated without the formation of a salt-and-pepper pattern, implying that Notch does not form a feedback loop of lateral inhibition during this process. However, mathematical modeling and genetic analysis clearly demonstrated that Notch-mediated lateral inhibition is implemented within the proneural wave. Moreover, the combination of Notch-mediated lateral inhibition and EGF-mediated reaction diffusion enables a novel function of Notch signaling that regulates propagation of the wave of differentiation.

D1253A Wnt signaling specifies progenitor zone identity in the *Drosophila* visual center. *O. I. Trush*[1], T. Suzuki[2], T. Yasugi[3], R. Takayama[3,4], M. Sato[1,2,3,4]. 1) Grad. School of Med. Sciences, Kanazawa University, Kanazawa, Ishikawa, JP; 2) Laboratory of Developmental Neurobiology, Brain/Liver Interface Med.Research Center, JP; 3) Math.Neuroscience Unit,Institute for Frontier Science Initiative, JP; 4) CREST, JST, Saitama, JP.

Neuronal diversity is essential for the formation of complex and correct neuronal circuits. During brain development, various types of neuronal populations are produced from different progenitor pools to produce neuronal diversity that is sufficient to establish functional neuronal circuits. Thus, multiple progenitor pools produce different subsets of neuronal populations to contribute to the neuronal diversity. However, the molecular mechanisms that specify the identity of each progenitor pool remain obscure. Here, we show that Wnt signaling is essential for the specification of the identity of progenitor pools in the Drosophila visual center. In the medulla, the largest component of the visual center, different types of neurons are produced from two progenitor pools: the outer proliferation center (OPC) and glial precursor cells (GPC). However, we found that OPC-neurons are produced in the GPC at the expense of GPC-neurons when Wnt signaling is suppressed in the GPC. In contrast, GPCs are ectopically formed when Wnt signaling is ectopically activated; consequently, GPC-neurons are ectopically produced in the OPC. These results suggest that Wnt signaling is necessary and sufficient for the specification of identity of the progenitor pools. We also found that Homothorax (Hth), which is temporally expressed in the OPC, is ectopically induced in the GPC by suppression of Wnt signaling and that ectopic induction of Hth phenocopies the suppression of Wnt signaling in the GPC. Since β-catenin signaling specifies progenitor pool identity in the developing mammalian thalamus, evolutionarily conserved Wnt signaling may specify the identity of progenitor pools in mammalian and fly brains. .

D1254B The large and small SPEN family proteins stimulate axon outgrowth during neurosecretory cell remodeling in *Drosophila*. *T. Gu*, T. Zhao, R. Hewes. Univ Oklahoma, Norman, OK.

Nervous system remodeling in *Drosophila* occurs during metamorphosis to support the transition from larval to adult-specific behaviors. The process of neuronal remodeling involves the pruning back of old dendritic and axonal connections followed by outgrowth of adult-specific arbors. Similar remodeling processes are seen throughout the animal kingdom in different developmental contexts, but the mechanisms underlying this morphological plasticity in each case remain unclear. Here, we found Split ends (SPEN) and its homolog, Spenito (NITO), are required for metamorphic remodeling of the CCAP/bursicon neurosecretory cells. SPEN and NITO belong to a well-conserved family of nuclear proteins with critical functions in transcriptional regulation and the post-transcriptional processing and nuclear export of transcripts. Cell-targeted overexpression of SPEN in CCAP/bursicon cells had no effect on the larval morphology or the pruning back of the CCAP/bursicon cell axons at the onset of metamorphosis. During the subsequent outgrowth phase of metamorphic remodeling, overexpression of either SPEN or NITO strongly inhibited axon extension, axon branching, peripheral neuropeptide accumulation, and soma growth. Cell-targeted loss-of-function manipulations for both *spen* and *nito* caused reductions in axon outgrowth, indicating that the absolute levels of SPEN and NITO activity are critical to support developmental plasticity in these neurons. Loss of *spen* also caused defects in central neurite pathfinding and development of boutons in peripheral axons. Although *nito* RNAi did not affect SPEN protein levels, the phenotypes produced by SPEN overexpression were suppressed by *nito* RNAi. These results suggest that SPEN and NITO function additively or synergistically in the CCAP/bursicon neurons to regulate multiple aspects of neurite outgrowth during metamorphic remodeling.

D1255C Replacement of the glial architecture in *Drosophila* central brain during metamorphosis. *T. Awasaki*, K. Kato. Kyorin University School of Medicine, Mitaka, Tokyo, JP.

Glial cells are one of the major components of the central nervous system. In the *Drosophila* central brain, different subtypes of glial cells form specific architectures. Neural networks of holometabolous insects such as *Drosophila* remodel during metamorphosis. How do the glial architectures change in response to the neural remodeling? Here we report that the larval glial architecture associating with neuropil in the brain is replaced with newly formed architecture during metamorphosis. Two subtypes of neuropil-associated glia, ensheathing glia and astrocyte-like glia, are found in both larval and adult brains. Neuropils of both larval and adult brains are wrapped by ensheathing glia and filled with astrocyte-like glia. However, we found that the larval and adult neuropil-associated glial architectures are composed of different cell population. Larval neuropil-associated glial cells change their molecular and morphological features in the early pupal stage. On the other hand, immature glial cells appear at the interface between cell-body region and neuropil in the late larval stage. As the number of immature glial cells

increases, they spread over in the interface. When these immature glial cells were genetically labeled in larval stage, labels were specifically found in both subtypes of neuropil-associated glial cells in the adult brains, indicating that these immature glial cells are precursors of adult neuropil-associated glia.

In order to understand how the new neuropil-associated glial architecture is formed over the old one, we analyzed development of the glial precursors and their lineage in detail. Using the cell tracing system combined with the cell cycle marker, FUCCI, and cell death marker, PARP::VENUS, cell proliferation and apoptosis were analyzed in the glial precursor lineage, respectively. We found that these glial precursors generate immature glial cells excessively by cell proliferation and the immature cells are distributed confluently at the interface. Then, excess cells are removed by apoptosis. Finally, survived cells differentiate into two glial subtypes and form adult neuropil-associated glial architecture. These results suggest that the adult glial architecture is established through the overproduction and elimination of immature glial cells. We would like to discuss the potential molecular mechanism regulating the adjustment of the glial precursor lineage.

D1256A Regulation of Neuron-Glia Interactions in the Developing Eye. *Victoria Hans*, Asma Patel, Jennifer Jemc. Loyola University Chicago, Chicago, IL.

Glial cells in vertebrates have numerous functions, including myelination of neuronal axons. While *Drosophila* don't have myelination to increase the efficiency of action potential transmission, a subpopulation of glia wrap around neurons to support neuron function. Previous studies have shown that when *raw* expression is reduced in glia, the result is lethality during pupal stages, leading us to ask what the role of *raw* is in glia during development. The developing eye of *Drosophila* provides an excellent system for studying the role of *raw* in glia due to its well-characterized glial subtypes and well-described development. Perineurial glia start in the brain and optic stalk, then migrate into the developing eye imaginal disc during the third larval instar, where they make contact with photoreceptor cells. Following contact with neurons, perineurial glia differentiate into wrapping glia and ensheath photoreceptor axons. Axons then extend along glia to the optic lobe of the brain. Our studies using immunohistochemistry have revealed a reduction in the number of glia in the third instar eye imaginal disc when *raw* levels are reduced in glial cells using the Gal4/UAS system to produce *raw* RNAi. While we observe a reduction in the number of glia, it is unclear if the reduction of glia is due to cell death, reduced proliferation, or defects in specification. Preliminary studies in the embryo suggest that glia are properly specified early in development in *raw* mutants, making it unlikely that glia specification is the origin of the *raw* mutant phenotype. To determine if the reduction arises from an increase in cell death we have performed immunostaining for activated Caspase, as well as acridine orange and do not observe an increase in cell death. Currently, we are using an antibody for phospho-histone H3 to determine if glial proliferation is reduced in *raw* RNAi samples relative to controls. Finally, it is possible that the reduction in glia in the eye disc arises from defects in glial migration. In order to examine this possibility, a live imaging approach is being developed to examine glial migration in cells with reduced *raw* levels. Images will be taken every 10-15 minutes over the course of a few hours to observe the glial migration process, allowing us to track the path of specific glial cells and to examine the rate at which glia are migrating. Finally, glia are important for proper axon targeting to the optic lobe of the brain. In larvae with reduced *raw* levels in glia, we observe axon mis-targeting in the brain, suggesting that Raw functions indirectly to regulate axon targeting as well. Thus, we have identified a new regulatory protein that functions in cell autonomously in glia cell non-autonomously in neurons during development.

D1257B Identification of a Novel Regulator of Glial Development . *D. Luong*, M. Davis, J. Jemc. Loyola University Chicago, Chicago, IL.

Glial cells perform numerous functions to support neuron development and function, from regulation of axon pathfinding and synapse formation to ensheathment of neurons and maintenance of ionic homeostasis. In vertebrates defective glial cells have been linked to neurological diseases such as neuropathies and schizophrenia. Our lab is interested in genes that regulate glia-neuron interactions during development. Specifically, we have found the *raw* gene to be required in glia, as reducing *raw* levels in glial cells by RNAi results in lethality. Due to the lethality observed when *raw* is removed from glia we examined how glia were being affected in the developing central and peripheral nervous system. We have observed a decrease in the size of the brain and an elongated ventral nerve cord within the central nervous system. In the peripheral nervous system, reduced levels of *raw* affect the number of glia along the nerve extension region (NER) of the peripheral nerves. Further examination of peripheral nerve structure by transmission electron microscopy reveals significant changes in nerve morphology when *raw* levels are reduced. These phenotypes suggest a defect in glial specification, proliferation or survival. While glia appear to be specified normally in *raw* mutants, we are currently examining the levels of glial proliferation and death when *raw* levels are reduced. Finally, we are interested in how impaired glial function affects neuronal output. Results of a larval crawling assay reveal that larvae exhibit reduced locomotion when Raw levels are reduced in glia as compared to controls. These studies have resulted in the identification of a novel regulator of glial development, and are likely to yield novel molecular mechanisms underlying the establishment of neuron-glia interactions during development.

D1258C Glial cell remodeling during peripheral nerve reorganization in *Drosophila*. *Aswati Subramanian*[1], Matthew Siefert[2], Soumya Banerjee[3], Kumar Vishal[4], Kayla Bergmann[1], Clay Curts[1], Meredith Dorr[5], Meredith Rataiczack[6]. 1) Miami University, Oxford, OH; 2) Children's hospital, Cincinnati, OH; 3) EPFL, Lausanne, Switzerland; 4) Kansas State University, Manhattan, Kansas; 5) University of Toledo, Toledo, OH; 6) Midwestern University, Glendale, AZ.

During development, remodeling of the larval nervous system is necessary for establishing adult specific behaviors in the fruit-fly *Drosophila melanogaster*. During metamorphosis, five pairs of abdominal nerves fuse together to form a terminal nerve trunk (TNT) as they exit the CNS. Segmental nerves defasciculate from the TNT at appropriate segmental levels to innervate the body wall. Glial cells are likely to play a significant role in nerve fusion and we are interested in examining layer specific remodeling of the nerve during metamorphosis. The most

external layer, the non cellular layer of extracellular matrix called the neural lamella, disappears during the first quarter of pupal development and appears again during the last quarter of pupal development. However, the two glial layers- the perineural glia (PG) and the sub-perineural glia (SPG) persist during this process. The innermost layer-the wrapping glia retracts its processes during early pupal development and after the third day of metamorphosis, extends its processes. Glial cell numbers across all cellular glial layers change during pupal development. Confocal microscopy analyses have been substantiated by transmission electron microscopy (TEM) to study the ultrastructural changes that take place during peripheral nerve reorganization. The present study focuses on the role of the most external layer, the PG in TNT formation. A three-fold increase in the glial population was observed during the first day of metamorphosis (25% of development), when 75% of the cells comprises of perineural glia. Induction of perineural glial cell death by targeting the cell death gene *reaper* and the Diphtheria Toxin (DT), results in eclosion defects (28% emergence and 3% emergence respectively). TNT branching pattern was defective in 100% of the experimental animals analyzed at the pharate adult stage (n=15). TEM studies are currently underway to identify the nature of ultrastructural changes in these mutants. The study of glial remodeling in *Drosophila* will lay the groundwork for future studies on the role of glia- neuron communication during TNT formation, and could lead to the establishment of a model system to study gliopathies.

D1259A Border formation between medulla and lobula-complex in the optic lobe. *C. Liu*[1], T. Suzuki[2], M. Kaido[3], R. Takayama[4], M. Sato[5]. 1) Development of neurobiology; 2) Graduate School of medical,; 3) Kanazawa university; 4) Kanazawa; 5) JP.

The fly optic lobe is composed of four ganglia; lamina, medulla, lobula, and lobula plate. Neurons in these ganglia derive from two distinct progenitor pools, the outer proliferation center (OPC) and inner proliferation center (IPC). OPC produces lamina and medulla neurons, whereas IPC generates lobula and lobula plate neurons. These neurons in each ganglion are located at specific regions to form compartments, and are never intermingled with each other at the interfaces between ganglia. However, mechanisms that inhibit cell-mixing at the borders between each ganglion have been unclear. Previously we and other group showed that cell-cell interaction through Slit-Robo signaling, an axon guidance signaling, is involved in the inhibition of cell mixing between lamina and IPC (Tayler et al., 2004) and that between medulla and IPC during larval development (Suzuki et al., in press). Since cell-mixing occurs only partially in sli or its receptors mutant larvae, additional signalings may also participate in the border formation.

Here, we show that Netrin signaling, another axon guidance signaling, regulates the border formation between medulla and IPC. The NetA and NetB ligands are expressed in IPC while their receptors Fra and Unc5 are expressed in lamina glial cells. In NetAB or fra mutants, IPC cells intruded into the medulla cortex. unc5 RNAi also caused similar phenotype. Since Fra and Unc5 are expressed in the lamina glial cells, we examined glia specific loss-of-function of Fra and Unc5, which also caused cell mixing, suggesting that glial cells play essential roles in the border formation between medulla and lobula through Netrin signaling.

D1260B Dynamic requirement for Polycomb group genes in neuroepithelial stem cell proliferation and differentiation in the *Drosophila* optic lobe. *H. Luo*[1], X. Chen[2]. 1) Hunan University, Changsha, Hunan, China; 2) Tsinghua University, Beijing, China.

The Polycomb group (PcG) genes encode conserved proteins that are required for establishing a repressive state of Hox gene expression. Emerging evidence implicates these proteins in stem cell maintenance and differentiation. Here, we examine the roles of PcG genes in *Drosophila* optic lobe development. Using loss-of-function mutant assays, we show that PcG genes have a dual requirement for neuroepithelial stem cell proliferation and differentiation. The Hox gene *Abdominal-B* is derepressed in PcG mutant cells, and ectopic *Abd-B* expression inhibits neuroepithelial cell proliferation. Also associated with the functional loss of PcG genes, JAK/STAT is ectopically activated, but Notch is inactivated; these conflicting signaling activities may account for the defects in neuroepithelial cell proliferation and differentiation. Our results demonstrate a temporal requirement for PcG genes in the proliferation and differentiation of neuroepithelial stem cells in *Drosophila* brain development.

D1261C Investigating the role of *Sox Neuro* in the development of adult nervous system. *Shweta Singh*, Ken Dawson-Scully, John R. Nambu. Florida Atlantic University, Biological Sciences, 5353 Parkside Drive, Jupiter FL-33458.

Many aspects of development are controlled through the actions of specific transcription factors that regulate gene expression patterns. The mammalian *Sry* gene, a sex determining Y chromosome was discovered in 1990 and encodes a transcription factor with single high mobility group DNA binding domain. More than 20 transcription factors in humans and 8 in *Drosophila* share a related HMG domain with at least 50% identity to that of *Sry*. These Sox (Sry box) proteins bind to the minor groove of DNA and induce 70° to 90° bends to regulate chromatin structure and transcription initiation. *Drosophila* possesses 4 highly related Group B Sox genes *SoxNeuro, Dichaete*, *Sox21a* and *Sox21b*. Previous study has shown that Dichaete has a strong role in development, affecting processes that include differentiation of specific neuronal and glial cells, segmentation, hindgut development, differentiation of imaginal discs. Dichaete is expressed in several clusters of neurons in the brain, including intermingled olfactory LNs and central complex neurons and important for the elaboration of the adult olfactory system. SoxN function is important for the formation of neural progenitor cells in *Drosophila* and evidence suggests that loss of SoxN function results in defects in the neuroblast formation. Interestingly, both *SoxN* and *Dichaete* have region-specific functions in CNS development as they both regulate dorsal/ventral partitioning of the embryonic neuroectoderm into specific columns. Evidence also suggests that SoxN and Dichaete function in a redundant manner in neuroblast formation and other developmental processes including neuroectoderm formation, central nervous system development, and sensory trichome formation. However, little is known about the expression and function of SoxN in the adult brain. This study focuses on identifying the expression patterns and function of SoxN in the development of the adult nervous system. Our data shows SoxN is expressed both in neurons and glia of the adult central brain. Interestingly, SoxN expressing neurons are both cholinergic and GABAergic neurons. Our data also suggests role of SoxN in the development of olfactory circuit formation. The result of this study will lead to a

better understanding of Sox gene functions in both conserved and specific aspects of development. Sox proteins have essential developmental functions in many species, including key roles in sex determination, segmentation, neural patterning, differentiation of neurons and glia, and formation of eyes, bone, cartilage, heart, and craniofacial structures. Furthermore, Sox gene mutations are associated with a wide array of human congenital disorders and cancer. Thus, these studies on *Drosophila* Sox genes may illuminate conserved developmental functions in mammals and are relevant for human health.

D1262A New insights into Gene Regulatory Network evolution: Neofunctionalization of the *Drosophila* midline CNS gene regulatory network in the Zika vector mosquito *Aedes aegypti* . *K. Suryamohan*[1,2], C. Hanson[3], E. Andrews[4], S. Sinha[3], M. Duman Scheel[4,5], M. Halfon[1,2,6]. 1) University at Buffalo-State University of New York, Buffalo, NY; 2) NY State Center of Excellence in Bioinformatics and Life Sciences, Buffalo, NY; 3) University of Illinois Urbana-Champaign, Champaign, IL; 4) Indiana University School of Medicine, South Bend, IN; 5) University of Notre Dame, South Bend, IN; 6) Roswell Park Cancer Institute, Buffalo, NY.

Gene regulatory networks (GRNs) ensure precise spatio-temporal control of gene expression during development. Changes in GRNs underlie the evolution of morphological novelty. We have investigated the mechanisms of GRN evolution using the dengue fever and Zika vector mosquito *A. aegypti* and the fruitfly *Drosophila melanogaster* CNS developmental paradigms. Despite substantially similar nervous system morphology, the two species show significant divergence in a set of genes coexpressed in the *Drosophila* ventral midline, including the master midline regulator *single minded* (*sim*) and downstream genes including *short gastrulation* (*sog*), *Star*, and *NetrinA* (*NetA*). In contrast to *Drosophila*, we find that in *A. aegypti* midline expression of these genes is absent or severely diminished, and instead they are co-expressed laterally in the nervous system. This suggests that in *A. aegypti* this "midline GRN" has been redeployed to a new location while being simultaneously lost from its previous site of activity, with a new GRN acquiring the original role. In order to characterize the GRNs, we employed SCRMshaw—a computational method we previously developed for supervised motif-blind and sequence alignment-free CRM prediction—to identify 6 novel CRMs from *A. aegypti* and 6 CRMs for *D. melanogaster* genes and validated them *in vivo* in transgenic *D. melanogaster*. Analysis of these validations and results from genetic perturbation experiments suggest that these changes are due to a trans-dependent redeployment of the GRN, potentially stemming from *cis*-mediated changes in the expression of *sim* in combination with one or more transcription factors in *A. aegypti*. We are continuing to identify additional relevant CRMs as well as undertaking an in-depth analysis of the expression patterns of multiple genes in this network in both species. Our results illustrate a novel "repeal, replace, and redeploy" mode of GRN evolution in which a conserved GRN undergoes neofunctionalization at a new site while its original function is co-opted by a different GRN without causing substantial changes in overall morphology and function.

D1263B Identification of developmental determinants of olfactory sensory neuron identity and connectivity. *Phing Chian Chai*, Steeve Cruchet, Richard Benton. Center for Integrative Genomics, University of Lausanne, Switzerland.

Two important features that characterize nervous system development are the generation of distinct neuronal subtypes and the establishment of precise connections between them. Previous studies in *Drosophila* and vertebrates have shown that the acquisition of specific neuronal identity requires concerted actions of multiple transcription factors during animal development. However, elucidating the molecular mechanisms that are governed by these transcription factors has been difficult, partly due to the lack of definitive molecular markers that allow unambiguous identification of neuronal fates. The olfactory system of *Drosophila* offers an excellent model to address this problem, as it is comprised of ~60 olfactory sensory neuron (OSN) subtypes; almost all of these are defined by the expression of a single, distinct ligand-specific olfactory receptor gene. These diverse OSNs arise from a seemingly homogenous population of progenitor cells located at distinct regions in the antennal imaginal disc. These properties allow us to assay for the spatial and temporal contributions of the developmental determinants that are involved in specifying and diversifying OSN fate. Using a transgenic RNAi approach, we have tested the role of 808 genes in antennal OSN specification, encoding putative transcription factors, chromatin regulators and embryonic patterning determinants. To circumvent the detrimental effects of ubiquitous gene knock-down, we induced RNAi specifically in the eye-antennal discs from the second instar larval stage onwards using a combination of an *actin-flip out-GAL4* driver and *eyeless-Flippase*. Correct OSN specification entails both the expression of a particular olfactory receptor gene and targeting of its axon to a specific glomerulus in the antennal lobe. We therefore screened for phenotypic defects upon gene knock-down by examining the expression of olfactory receptor reporters and axon projections in two different populations of OSNs, as well as the global structural integrity of antennal lobe glomeruli. Our primary screen has revealed that ~15% of the tested genes might play a role in OSN specification and/or development. In an attempt to elucidate the processes that are regulated by these genes during olfactory system development, these genes were further classified into different categories based on their RNAi phenotype (eye-antennal defects, antennal lobe malformation, ectopic structures, reduced axon density, axonal mistargeting and other defects). The majority of genes (>82%) exhibit multiple phenotypic defects upon RNAi, suggesting that these factors could regulate different functions, depending on their spatial and temporal contexts. We will present the results of this screen and our follow-up work on individual determinants of OSN identity and wiring.

D1264C The functional impact of Synaptojanin phosphorylation by the Minibrain kinase during synaptic vesicle recycling in *Drosophila*. *Karen Chang*, Liping Wang, Junhua Geng, Jooyeun Lee. University of Southern California, Los Angeles, CA.

Impaired synaptic transmission is a pathological alteration commonly found in various neurological disorders. The rapid recycling of synaptic vesicles during stimulation is essential for the sustained function of the nervous system, and clathrin-mediated endocytosis is one prominent molecular pathway in synaptic vesicle recycling. Synaptojanin (Synj), a phosphoinositide phosphatase, plays an important role in endocytosis and is responsible for the uncoating of clathrin during the process. Previously, we identified that minibrain (Mnb), homolog of the mammalian

dual-specificity tyrosine phosphorylation-regulated kinase 1A (DYRK1A), is a serine/threonine kinase required for normal synaptic growth and rapid synaptic vesicle endocytosis at the *Drosophila* neuromuscular junction. We also found that Synj is a substrate of Mnb. However, site on Synj phosphorylated by Mnb has not been identified and functional consequences underlying Mnb-dependent phosphorylation of Synj are also not well understood. Here, we show that Mnb phosphorylates Synj at Serine1029 *in vivo*. Phosphorylation of Synj at S1029 is required to maintain normal synaptic vesicle recycling *in vivo,* but is not required to sustain neurotransmission during high frequency stimulation. It is interesting to note that both Mnb and Synj are upregulated in Down syndrome (DS) and Synj is mutated in Parkinson's disease. An understanding of mechanisms that modulate Synj function will thus provide valuable insights into basic mechanisms affecting neuronal communication and lead to strategies to treat these neurological disorders.

D1265A *Drosophila* SLC22A transporter is a memory suppressor gene that influences cholinergic neurotransmission to the mushroom bodies. *Yunchao GAI*, Ze Liu, Isaac Sandoval, Ronald Davis. The Scripps Research Institue, Jupiter, FL.

The mechanisms that constrain memory formation are of special interest because they provide insights into the brain's memory management systems and potential avenues for correcting cognitive disorders. RNAi knockdown in the *Drosophila* mushroom body neurons (MBn) of a newly discovered memory suppressor gene, Solute Carrier DmSLC22A, a member of the organic cation transporter family, enhances olfactory memory expression, while overexpression inhibits it. The protein localizes to the dendrites of the MBn, surrounding the presynaptic terminals of cholinergic afferent fibers from projection neurons (Pn). Cell-based expression assays show that this plasma membrane protein transports cholinergic compounds with the highest affinity among several *in vitro* substrates. Feeding flies choline or inhibiting acetylcholinesterase in Pn enhances memory; an effect blocked by overexpression of the transporter in the MBn. The data show that DmSLC22A is a memory suppressor protein that limits memory formation by helping to terminate cholinergic neurotransmission at the Pn/MBn synapse.

D1266B Mutations in the Vesicular Acetylcholine Transporter Cause Impaired Locomotion in *Drosophila*. *Andrew Blake*, Mika Heredia, Hakeem Lawal. Delaware State University, Dover, DE.

Acetylcholinergic dysfunction is a key underlying feature in the cognitive decline associated with aging. The machinery required for presynaptic acetylcholine (ACh) release and post-synaptic signaling have been described in detail, yet the precise relationship between alterations in ACh neurotransmission and downstream changes in behavior in the nervous system remain poorly understood. The vesicular acetylcholine transporter (VAChT) is a critical element of cholinergic signaling, mediating the transport of ACh from the cytoplasm into synaptic vesicles for exocytotic release. A complete loss of *Vacht* is lethal in flies, worms and mammals. Here we hypothesize that subtle changes in *Vacht* will uncover important roles of ACh release in behavior. Using point mutations, recovered in an ethyl methanesulfonate screen, to disrupt VAChT function, we report that a series of *Vacht* mutations impair two locomotion circuits, baseline and touch response locomotion. In particular, *Vacht* mutants display a deficit in the timing of the response to touch stimulus in a manner corresponding to severity of the mutant alleles studied. We categorized the resulting allelic series as mild, moderate and severe with respect to acetylcholine release. We further report the genetic rescue of *Vacht* mutant deficits using wildtype VAChT. In addition, we conducted a pharmacological rescue study using agonists of the dopaminergic and cholinergic pathways, and found that both drugs partly rescued the locomotion deficits in the mutants. Together, this report supports a key role for acetylcholine signaling in regulating the timing of the response to a mechanical stimulus and underscores the utility of point mutations that compromise VAChT activity in vivo as tools to elucidate the complex relationship between altered ACh release and behavioral deficits.

D1267C Activation of octopaminergic neurons innervating the oviduct. *Sonali Deshpande*, Daniel Suto, David Krantz. University of California, Los Angeles, Los Angeles, CA.

Oviposition (egg-laying) in *Drosophila* requires passage of the egg from the ovary to the uterus via the oviduct, and activation of octopamine receptors in the oviduct. Additional glutamatergic and peptidergic inputs work in concert with octopaminergic signals to promote movement of the egg through the oviduct, but the mechanisms by which these pathways interact remain unclear. Studies in larger insects suggest that glutamate and proctolin cause contraction of the oviduct, whereas octopamine may promote relaxation. The opposing effects of glutamate and octopamine on contraction suggest that the descending, presynaptic neurons mediating each effect might be activated in a reciprocal pattern. To test this possibility, and more precisely determine the mechanism by which glutmatergic and octopaminergic components of this circuit interact, we have developed a preparation for live imaging of both neuronal firing in the thoracic ganglia, and muscle contractions in the oviduct. Using a genetically encoded calcium indicator, we observe activation of a single octopaminergic neuron the thoracic ganglion lasting up to 100seconds and an unexpected localization of calcium signals to muscle to defined subdomains in the oviduct musculature. Further experiments using application of exogenous octopamine and calcium imaging in glutamatergic neuron will be used to establish the precise relationship between the activity of glutamatergic neurons, octopaminergic neurons and regulation of contractions in the oviduct.

D1268A Identification of novel genes that regulate dopamine dynamics through forward genetic screens in *Drosophila*. *S. Yamamoto*[1,2], S. Deal[1], J. L. Salazar[1], M. Lagarde[1], S. Saurabh[1], E. S. Seto[2]. 1) Baylor College of Medicine, Houston, TX; 2) Texas Children's Hospital, Houston, TX.

Dysregulation of dopamine (DA) dynamics (synthesis, secretion, and metabolism) and signaling underlies a number of symptoms seen in various neurological and psychiatric diseases. Core components of DA dynamics and signaling are being extensively characterized in diverse model systems. In contrast, very little is known about the genes and cellular pathways that fine-tune the activity of this neuromodulator in vivo.

To identify novel factors that regulate DA dynamics, we have been performing a forward genetic screen in *Drosophila melanogaster*. We first screened for novel genes that affect cuticle pigmentation (a DA dependent phenotype) in adult flies using chemical mutagenesis/clonal analysis

and tissue specific RNAi. Through this primary screen, we identified 123 genes, ~85% of which are evolutionarily conserved between flies and human. We then performed a Drosophila Activity Monitor (DAM) based secondary screen to determine whether these genes exhibit a defect in basal activity upon dopaminergic neuronal knockdown. Genes that exhibit strong hypo- or hyperactivity are being prioritized for a tertiary analysis to determine whether dopaminergic neuron specific knockdown of these genes directly affect brain DA levels.

We are currently focusing on genes whose human homologs have been linked to Autism Spectrum Disorders (ASD). Interestingly, 20 of the 123 genes we isolated in our primary screen have human homologs that have been strongly linked to ASD including *gigas* (*TSC2*), *Prosap* (*SHANK1-3*), *slp1* (*FOXG1*), and *Usp7* (*USP7*). By studying the molecular function of these genes in the context of dopamine dynamics and signaling, we hope to understand how defects in these genes may contribute to some of the symptoms found in ASD patients.

D1269B Receptor-based Mapping Reveals the Architecture of a Neural Circuit that Governs a Behavioral Sequence in Drosophila. *F. Diao*, Amicia Elliott, Fengqiu Diao, Sarav Shah, Benjamin White. national institute of mental health, Bethesda, MD.

Studies in both vertebrates and invertebrates have shown that neuromodulators can reconfigure the output of multifunctional neural networks to generate multiple motor patterns. However, very few such networks have been characterized in detail and knowledge of how modulators act at different levels within a network remains poorly understood. Progress has been impeded both by the lack of complete maps of most neural networks and by incomplete knowledge of how network-wide activity translates into behavior in intact animals. Here we address these issues, using the pupal ecdysis sequence of *Drosophila* as a model, taking advantage of its essential dependence on neuromodulatory inputs and its well-defined behavioral components. Pupal ecdysis consists of three, sequentially executed motor rhythms and is governed by multiple neuroactive factors, among which Ecdysis Triggering Hormone (ETH), CCAP, and Bursicon have well-characterized roles. By manipulating neurons that express the receptors of these factors, we have succeeded in mapping the hierarchical organization of the ecdysis network. We find that three distinct subsets of ETH receptor-expressing neurons comprise individual input modules, each one essential for a different behavioral phase. Bursicon receptor-expressing interneurons form a multi-functional central pattern generator (CPG) targeted by the ETHR-expressing modules. Downstream of this CPG are CCAP receptor-expressing motor neurons, which are responsible for generating the ecdysis motor rhythms. The expression patterns of the receptors of key modulators governing the ecdysis sequence thus define the hierarchical architecture of the ecdysis network. Our results provide an example of how receptor mapping can be used to identify functional nodes in a neural circuit and characterize their organization. In addition, our work serves as an entry point to investigating the mechanisms underlying multi-level control of behavioral state by neuromodulators in a neuronal circuit.

D1270C Decision-making neurons direct downstream signaling based on input specificity in male *Drosophila melanogaster*. *J. Schweizer*, L. Eaton, L. Boisvert, A. Auge, W. J. Kim. University of Ottawa, Ottawa, Ontario, CA.

Elucidating neural networks underlying behaviors is an essential task of neuroscience. Fruit fly, Drosophila melanogaster, offer significant advantages for this purpose since they exhibit easily quantifiable, robust and genetically traceable behaviors. We previously reported two consistent, context dependent mating behaviors, called longer- and shorter-mating duration (LMD and SMD). LMD is a rival-induced, prolonged mating duration and SMD a sexual experience-mediated shortened mating. We identified specific components of the underlying neural circuits and found that neuropeptide signaling plays a key role in regulating both behaviors.

We identified four SIFamide (SIFa) producing neurons located in the pars intercerebralis, which are critical to induce both behaviors. To identify how SIFamide signaling bridges between two distinct neuronal pathways, we hypothesized that SIFa neurons act as input-specific decision makers in the context of output, which is mating duration. We first screened neurotransmitter (NT) systems to test this theory since NTs are expressed in large but discrete populations of neurons, which allows for large-scale circuit mapping studies of SIFa signaling in the context of mating duration. We also tested sexually dimorphic neuronal populations in the context of SIFa signaling because LMD and SMD are male-specific behaviors.

To test the impact of SIFa signaling on mating duration, NT-GAL4 lines were crossed with UAS-SIFaR-RNAi to knock-down (KD) SIFaR protein expression in GAL4-labeled neurons. To minimize the developmental impact of SIFaR knockdown, crosses are kept at 18°C until adults eclose, then moved to 25°C. We identified that KD of SIFaR in GAD+ (GABAergic) and Tdc2+ (octopaminergic) neurons affects SMD while a SIFaR KD in Cha+ (cholinergic) and DDC+ (dopaminergic/serotonergic) neurons induced a loss of affects both LMD and SMD. These data suggest that SIFaR signaling in GABAergic/octopaminergic neurons is specifically involved with the SMD pathway while signaling in cholinergic and dopaminergic/serotonergic neurons affects both pathways of LMD/SMD. Inactivation of SIFaR+/fru+ neurons (intersectional method) disrupts only LMD not SMD. This data suggests that fru+ neurons are specifically involved with LMD.

All these data suggest that different groups of neurons are targeted by SIFa signaling depending on the social context (input), leading to distinct behavioral outputs. We suggest that SIFaR signaling pathways could be a good model to improve our understating of how neural computations decide different behavioral outputs depending on different input signals. The study of how this decision-making is achieved can provide new models for neuronal computation and a new insight on neural network architecture.

D1271A Postsynaptic function of DEG/ENaC PPK29 at the *Drosophila* Larval NMJ. *A. Hill*[1], X. Zheng[1], X. Li[2], R. McKinney[1], D. Dickman[2], Y. Ben-Shahar[1]. 1) Washington University, St. Louis, MO; 2) University of Southern California, Los Angeles, CA.

Degenerin/Epithelial Sodium Channels (DEG/ENaCs) represent a diverse family of animal-specific ion channels that play an important role in regulating ionic gradients across epithelial barriers. Members of the family are also enriched in neural tissues. However, in contrast to epithelial tissues, their neurophysiological functions are still mostly unknown. The *Drosophila* genome encodes an exceptionally large number of DEG/ENaC subunits termed *pickpocket 1-31* (*ppk*) family. By using genetic, neurophysiological, and behavioral approaches, we demonstrate that the DEG/ENaC channel subunit PPK29 contributes specifically to postsynaptic modulation of excitatory synaptic transmission at the larval neuromuscular junction (NMJ). We show that *ppk29* is necessary in the muscle for normal response to spontaneous, but not stimulus-evoked, neurotransmitter release, without an apparent impact on gross synaptic development or morphology. In addition, mutations in *ppk29* lead to impaired coordinated movement required for stereotypic larval rolling behavior. Together, our data indicate a novel postsynaptic function for members of the DEG/ENaC family of ion channels.

D1272B Neuronal insulin signaling negatively regulates synaptic vesicle exocytosis via a FOXO-dependent mechanism. *Rebekah Mahoney*[1,2], Jorge Azpurua[1], Benjamin Eaton[1,2]. 1) UTHSCSA, San Antonio, TX; 2) Barshop Institute for Aging and Longevity, San Antonio, TX.

Altered insulin signaling within the brain has been linked to cognitive dysfunction and neurodegenerative disease. Appropriate signaling downstream of the insulin/IGF-1 receptor has been linked to a number of cell processes that could contribute to the effects of insulin signaling on brain function including maintenance of neuronal health, reduced cell stress, neuron development, and synapse function. However, a role for insulin signaling during the regulation of neurotransmission has not been demonstrated. Using a novel synaptic preparation in adult Drosophila, we have found that cell autonomous insulin signaling negatively regulates the presynaptic release of neurotransmitter via the activity of the eif-4e binding protein (4eBP), a negative regulator of protein translation. In this context, the activity of 4eBP is regulated transcriptionally by the forkhead transcription factor Foxo and not the mammalian target of rapamycin (mTOR). Furthermore, the regulation of neurotransmission by insulin signaling requires the mRNA binding protein Staufen, which is known to localize mRNAs to distinct compartments within neurons, and is blocked by the protein synthesis inhibitor cycloheximide. Our data supports the model that cell autonomous insulin signaling regulates the presynaptic release of neurotransmitter via the local translation of negative regulators of synaptic vesicle exocytosis. Analysis of candidate molecules required for the effect of insulin signaling on synaptic vesicle exocytosis will be presented.

D1273C Sleep facilitates memory by blocking dopamine neuron mediated forgetting. *Jacob Berry*, Isaac Cervantes-Sandoval, Molee Chakraborty, Ronald Davis. Scripps Research Institute, Jupiter, FL.

Early studies from psychology suggest that sleep facilitates memory retention by stopping ongoing retroactive interference caused by mental activity or external sensory stimuli. Neuroscience research with animal models, on the other hand, suggests that sleep facilitates retention by enhancing memory consolidation. Recently in *Drosophila*, the ongoing activity of specific dopamine neurons was shown to regulate the forgetting of olfactory memories. Here we show this ongoing dopaminergic activity is modulated with behavioral state, increasing robustly with locomotor activity and decreasing with rest. Increasing sleep-drive, with either the sleep-promoting agent Gaboxadol or by genetic stimulation of the neural circuit for sleep, decreases ongoing dopaminergic activity, while enhancing memory retention. Conversely, increasing arousal stimulates ongoing dopaminergic activity and accelerates dopaminergic based forgetting. Therefore, forgetting is regulated by the behavioral state modulation of dopaminergic-based plasticity. Our findings integrate psychological and neuroscience research on sleep and forgetting.

D1274A Dopamine-mediated plasticity across the mushroom body. *T. Boto*, S. Tomchik. The Scripps Research Institute, Jupiter, FL.

Dopaminergic neurons innervate multiple brain regions, including the mushroom body (MB), where they modulate learning. During olfactory classical conditioning, large subsets of dopaminergic neurons are activated, releasing dopamine across broad sets of postsynaptic neurons. These dopaminergic neurons respond strongly to the US and their activity can be sufficient as reinforcement when paired with odor delivery. However, the specific way in which dopamine alters the physiology of the MB neurons is not well understood.

Using *in vivo* calcium imaging, we studied the effect of manipulation of different subsets of dopaminergic neurons in the odor response of several mushroom body regions. Odor presentation was paired with activation of different populations of neurons with the application of an odor and odor-evoked calcium responses were compared before and after the treatment.

We previously reported that pairing the activation of dopaminergic neurons labeled by TH-Gal4 with odor exposure leads to calcium plasticity specifically in the gamma lobes of the MB (*Boto et al., 2014*), whereas activation of the neurons of the PAM cluster leads to a broader pattern of facilitation. In order to understand how dopamine affects the MB responses during differential conditioning, we paired an odor (CS+) with dopaminergic neuron activation, followed by a second odor (CS-) not associated with dopamine released**.** Our results show that pairing odor with dopaminergic stimulation generates positive change in the ratio of CS+/CS- responses: either an increase of the response to the CS+ and no change/decrease on the CS- response, or no change in the CS+ response, but a decrease in the CS- response. The specifics of this plasticity depend on the odors used for the CS+/CS-.

Using more specific drivers to study different dopaminergic cluster subdivisions, we saw that subdivisions of the TH-GAL4 driver produce distinct spatial effects on neuronal plasticity.

D1275B Scabrous mediates acute ethanol response in the *Drosophila* brain through the Notch pathway. *M. Feyder*, R. Muster, A. Ray, N. Mei, A. Mathur, E. Petruccelli, K. Kaun. Brown University, Providence, RI.

Alcohol use disorders (AUDs) take a significant social and medical toll on the world's population. *Drosophila* have proven to be a useful genetically tractable model in which to investigate the molecular and behavioral effects of alcohol. We have previously shown that flies form long-lasting memories for the intoxicating properties of ethanol and identified the Notch pathway regulator *scabrous (sca)* as a potential molecular component of ethanol reward memory. Despite evidence that *sca* mutants exhibit several Notch-dependent developmental phenotypes, the general role of Notch signaling in the adult brain as well as in response to ethanol exposure remains poorly understood. Although Sca is known to bidirectionally regulate the Notch pathway in a context- and tissue-dependent manner, the exact mechanisms by which Notch and Sca interact in the adult fly brain is unclear. We predict that Sca mediates ethanol response in the mushroom body by promoting the cleavage of the Notch intracellular domain resulting in its activation. To test this, we used western blotting to characterize Sca effects on cleavage and processing of the Notch intracellular domain in adult fly heads. Compared to wild-type flies, *sca* mutants have increased levels of membrane-associated Notch and decreased levels of cleaved Notch, suggesting that Sca acts as a positive regulator of Notch pathway activity in this context. We also found that repeated exposure to intoxicating amounts of ethanol induces differential activation of the Notch pathway in wild-type and *sca* mutant flies, using both western blotting and a GFP reporter for Notch activation, suggesting that Sca affects the acute ethanol response of *Drosophila* by altering Notch cleavage and subsequent activation. Further work will investigate downstream targets of Notch, potentially illuminating its function in long-term memory formation and alcohol reward behavior.

D1276C Effect of sound as context on appetitive and aversive conditioning in Drosophila. *F. L. Hannan*[1], E. Dautaj[1], S. J. Gjeci[1], N. Narayanan[2], P. Meade[1], E. B. McGough[1]. 1) New York Med Col, Valhalla, NY; 2) Touro College, Manhattan, NY.

Associative learning and memory tasks critically depend on the simultaneous activation of multiple sensory pathways. Such tasks are very sensitive to context, including location, color, time of day and temperature. In humans it is well known that sound can trigger recall of past events, and it has been shown that sound can enhance or interfere with word recall tasks and working memory (Balch et al., 1992; Sorqvist, 2010), and that ultrasound can affect cortical activity (Legon et al., 2014). The fruit fly, Drosophila melanogaster, has been employed extensively for studies of learning and memory, using classical and operant conditioning tasks (Brembs 2011; Davis 2011). Sound is also an important environmental stimulus in flies. Male flies "serenade" females during courtship by flapping one wing (Shorey, 1962). Males also "yell" at each other with dual wing flicks during fights (Jonsson et al., 2011). We have observed that both pleasant and agonistic sounds can interfere with a reward based olfactory association task that pairs sucrose with odors inwild type flies as well as learning and memory mutants including Nf1, amnesiac and dunce. The same sounds, however, do not affect an aversive olfactory association task that pairs electric shock with odors, nor do they affect deaf flies (mer mutants). It is well known that different circuitry and neurotransmitters are involved in aversive versus appetitive conditioning, however there are also operational differences in the learning protocols that may interfere with exposure to sound. Future studies include developing an aversive conditioning protocol using bitter tastants, to better simulate the appetitive task, and to assay the effect of sounds on appetitive long term memory. Ultimately we would like to Identify the neural circuits and biochemical pathways involved in the integration of sound context into learning and memory, using the powerful genetic tools available in Drosophila.

D1277A From image to behavior: use of MiMICs to identify a novel protein kinase required for memory formation . *P. Lee*[1,5], G. Lin[1,5], Z. Zuo[1,5], K. Schulze[5,6], F. Diao[7], B. White[7], H. Bellen[1,2,3,4,5,6]. 1) Department of molecular and Human Genetics; 2) Program in Development Biology; 3) Department of Neuroscience; 4) Jan and Dan Duncan Neurological Research Institute, Texas Children's Hospital, Houston, TX, United States; 5) Baylor College of Medicine, Houston, TX, United States; 6) Howard Hughes Medical Institute; 7) Laboratory of Molecular Biology, National Institute of Mental Health, National Institutes of Health, Bethesda, MD, United StatesUSA.

We are interested in providing a better understanding of the molecular mechanism underling memory formation. Fly biologists have uncovered the role of genes required for learning and memory formation and many of these affect the cAMP-PKA-Creb pathway, including *dnc*, *rutabaga*, *amnesiac*, *DC0*, and *creb2*. These genes are often expressed in mushroom bodies (MB) which is the seat of learning and memory formation. However, it is likely that other players are involved in learning and memory.

To identify new genes required for learning and memory in the adult fly we screened a collection of MiMIC,insertions (Venken et al., 2011; Nagarkar-Jaiswal et al., 2015) MiMICs that are inserted in coding introns were modified through recombination mediated cassette exchange (RMCE) to generate flies with an additional exon that encodes GFP. We stained adult brains of 500 MiMICs that were tagged with GFP to identify genes expressed in MB. Unfortunately, only about 15% of the stocks express detectable levels of GFP in adult brains whereas GFP expression was observed in 90% of the third insaar larval brains (Nagarkar-Jaiswal et al., 2015). We therefore also converted the MiMICs with the T2A-Gal4 "Trojan exon" casette (Diao et al., 2015). This leads to the production of the Gal4 protein in the proper spatial and temporal pattern and permits the detection of GFP (via UAS-mCD8-GFP) for nearly 100% of the Gal4 tagged genes. Using this approach, we characterized the expression pattern of 30 genes encoding protein kinases and observed that 12 were expressed in MB. To identify whether or not these protein kinases are required for learning and memory we performed the olfactory aversive conditioning assay. We removed the GFP tagged kinase in adult flies using the Degrad-FP system in MBs and restored the protein in the same flies. By this approach, we identified a novel kinase required for memory. Interestingly, the loss of function of this gene leads to a complete loss of anesthesia-sensitive and long-term memory but does not affect anesthesia-resistant memory and learning. Our preliminary data indicate that this novel kinase regulates some of the substrates that are phosphorylated by protein kinase A (PKA).

In summary, we show that the MiMIC system, coupled to the Trojan exon and DegradFP technologies, is a powerful platform to screen for genes that are required for memory formation and probably many other behavioral functions.

D1278B Differences in the cyclic-AMP-induced plasticity of the odor responses among the Kenyon cell subpopulations: a single-cell imaging study. *T. Louis*, S. Tomchik. The Scripps Research Institute, JUPITER, FL.

In *Drosophila*, the mushroom bodies (MB), a critical structure for olfactory learning and memory, are formed by three different types of Kenyon cells (KC), α/β, α'/β' and γ. They all received information from the olfactory pathway and are modulated by extrinsic dopaminergic neurons also known for their role in associative learning and memory. Recently, our lab demonstrated that the modulation of cAMP levels in KCs induced by simultaneous odor presentation and artificial activation of TH-GAL4+ dopaminergic neurons or by using an adenylate cyclase activator, forskolin, lead to an increased of odor-evoked calcium response only in the γ lobes of MB. Nevertheless, it was still unknown if the learning-related plasticity seen in the g lobes relies on an enhancement of the response in cells that responded before training or on the recruitment of new responding cells. To answer this question, we designed an *in vivo* Ca^{2+}-imaging experiment for which we recorded the odor response in the soma of each KC subtype before and after forskolin exposure. Our work shows that, at the single-cell level, forskolin exposure produces diverse effects on the odor-evoked calcium responses in individual neurons, both across KC subpopulations and within a given subpopulation.

D1279C Effect of the spontaneous mutation *agn^{X1}* in *limk1* gene on formation of medium-term memory in *Drosophila melanogaster*. *E. A. Nikitina*[1,2], O. P. Yashanova[2], E. V. Savvateeva-Popova[1]. 1) Pavlov Institute of Physiology RAS, St-Petersburg, Russia; 2) Herzen State Pedagogical University, St-Petersburg, Russia.

The field of synaptic plasticity, long-term potentiation (LTP) and long-term depression (LTD) presumed to comprise a fine cellular basis for learning and memory is connected with such genetics processes as neuron-specific transcription, epigenetic chromatin remodeling, trafficking of mRNAs from soma to the remote sites of their local translation in axons and dendrites. All these processes are result from a multilevel organization of the genetic material in the nucleus of a nerve cell. *Drosophila* is a helpful model organism to determine the sequence of events in this system of hierarchical relationships. *Drosophila* LIMK1 gene (*agnostic*) with a specific chromosome architecture around the gene capable of generating miRNAs, recapitulates many features both of Williams syndrome and of neurodegenerative disorders. LIMK1 being the key enzyme of actin remodeling. This signal cascade involving receptors of neurotransmitters – small Rho GTPases (RhoA, Cdc42 and Rac1) –LIM kinase 1 (LIMK1) - cofilin – actin – is believed to play the main role in dendrite- and synaptogenesis. Conditioned courtship suppression paradigm was used to asses learning acquisition and medium-term memory formation in *Drosophila* mutant *agn^{X1}* characterized by existence of the spontaneous mutation *agn^{X1}* in *limk1* gene harbored by the *agnostic* locus. Learning acquisition appeared to be normal in intact control. However, a failure of 3-h memory formation was observed in *Drosophila* mutant *agn^{X1}* in normal conditions. We used heat shock (HS) as a stress factor. HS led to restoration of medium-term memory in this mutant. Thus stress influences for *agn^{X1}* mutant are necessary and sufficient for restoration of ability to memory formation.

This work was supported by the grant of the Russian Foundation for Basic Research (No 15-04-07738).

D1280A The role of octopamine beta-like adrenergic receptor Octβ1R in olfactory learning and memory. *J. Sabandal*, A. Clark, K.-A. Han. The University of Texas at El Paso, El Paso, TX.

Associative learning is a fundamental form of behavioral plasticity. It is indispensable for many organisms to appropriately respond to external cues predicting danger or reward for survival. The major monoamine octopamine plays a vital role in various types of learning and memory processes. Previous studies have shown that dopamine and octopamine are key mediators of olfactory learning. While dopamine regulates both aversive and appetitive learning, octopamine is known to mediate appetitive but not aversive learning. In order to clarify whether octopamine is also important for aversive learning, we employed negatively reinforced olfactory Pavlovian conditioning. Wild-type *Canton-S* flies showed robust learning and normal short-term memory. However, the flies deficient in the octopamine receptor Octβ1R exhibited poor learning but normal short-term memory. This suggests that the octopamine's signal through the Octβ1R receptor is critical for aversive learning. Studies are in progress to identify the key neural site where Ocβ1R regulates aversive learning.

D1281B A Circuit Screen for Song Production Neurons in *Drosophila melanogaster*. *A. Hammons*, D. Pacheco, M. Murthy. Princeton University, Princeton, NJ.

The courtship song production circuit in the fruit fly *Drosophila melanogaster* provides an excellent animal model for studying decision-making and motor pattern generation that are important for mate selection in a number of species. With the small and genetically tractable nervous system of *Drosophila*, identification of the specific neurons involved in courtship song production allows interrogation of the principles underlying the transformation of complex patterns in the nervous system to a motor output. Though five neuronal classes capable of producing courtship song have been identified, previous screens for song production neurons only targeted neurons expressing the male-specific transcription factor *fruitless*. The functional properties and connectivity of these five neuronal classes also remains uncharacterized. To uncover more of the neural circuits underlying song production, we performed a neural activation screen for ventral nerve cord neurons that drive song production in headless males by expressing the temperature-sensitive ion channel TrpA1 in small subsets of neurons (labeled by the Janelia GAL4 collection). We identified seven GAL4 lines capable of song production when artificially activated. An intersectional approach where TrpA1 was restricted to neurons expressing either the *fruitless* or *doublesex* gene revealed that five of these GAL4 lines contain song production neurons that do not express either of these two genes. Chronic inactivation (using tetanus toxin light-chain (TNT), a genetically encoded protein that blocks synaptic transmission) of these candidate neurons during a courtship pair assay that measures both male and female movement while also recording song, allowed us to characterize these neurons' effect on song patterning and female responses to song. Using *in vivo* calcium imaging of candidate song neurons from this screen combined with optogenetic activation of the song

command neuron P1, we are currently examining whether or not the newly identified song neurons lie within an interconnected song circuit with those neurons previously identified.

D1282C Selection for starvation resistance impairs copulation and provides a context-dependent courtship advantage. *Pavel Masek*[1], Lauren Reynolds[3], Thomas L. Turner[4], Allen G. Gibbs[5], Alex C. Keene[2]. 1) Binghamton University, NY; 2) FAU, FL; 3) Florida State University, FL; 4) UNLV, NV; 5) UCSB, CA.

Although courtship and starvation resistance are under stringent evolutionary pressure, the relationship between these traits has been difficult to investigate experimentally. Interactions between fitness and courtship have been documented in diverse species where both male and female flies display preference for mates with improved fitness characteristics that include body size, ornamental displays and pheromonal profiles. We have generated three replicated lines of starvation resistant flies by selecting for survival on a non-caloric agar diet and were then compared to three replicated populations of fed control flies. S flies live up to 18 days without food compared to the ~4 days for F flies. Starvation resistant flies display a number of behavioral and physiological changes including reduced fecundity, suggesting a trade-off between starvation resistance and reproduction. Here we characterize the courtship behaviors of male and female flies selected for starvation resistance. While courtship duration, courtship latency, song quality and quantity does not differ between starvation resistant flies and controls, the starvation resistant flies displayed dramatically reduced copulation success. Analysis of courtship in mixed pairings revealed both male and female contributions to reduced copulation in starvation resistant flies, raising the possibility of a functional trade-off between starvation resistance and copulation efficiency. While non-selected control flies outperform starvation resistant flies in competition assays under fed conditions, the result is reversed when flies are fasted prior testing. Taken together, these findings indicate that selection for starvation resistance results in genetic changes that impair copulation without affecting courtship duration and provide an adaptive copulation advantage in the absence of food.

D1283A Postmating gene expression in the parovaria (female accessory reproductive glands) of *Drosophila melanogaster* . *C. McDonough*, S. Pitnick, S. Dorus. Syracuse University, Syracuse, NY.

Female reproductive tract secretions are putatively involved in a diverse array of reproductive events, including sperm storage and survival, ejaculate-female interactions, ovulation, postmating immune response, lubrication for egg-laying, and the production of protective egg coating. However, little is known about the source, contents or function of these secretions. We characterized mating-induced gene expression in the parovaria, a secretory gland of the female reproductive tract, using RNAseq analysis at 3 time points (premating, 6hrs, and 24hrs postmating). Genes significantly upregulated postmating included proteases, peptidases and anti-microbial genes, thereby supporting established functions of female secretions in seminal fluid processing and postmating immune response. Many of these genes have similar postmating expression patterns in other female reproductive structures, indicating a suite of redundant functions spatially distributed throughout the female reproductive tract. We also identified genes with distinct expression patterns in the parovaria, suggesting unique functions of these glands. In particular, we found an enrichment of highly expressed genes on the X chromosome, including several novel genes created through gene duplication occurring during the radiation of the *melanogaster* subgroup. Contributions of these genes to postmating changes in female physiology and fertility are currently being assessed using an RNAi knockdown approach.

D1284B Sex differences in the translatome of *Drosophila melanogaster fru P1*- expressing neurons. *N. R. Newell*[1], C. M. Palmateer[1], F. N. New[2], J. E. Dalton[1], L. M. McIntyre[2], M. N. Arbeitman[1]. 1) Florida State University, Tallahassee, FL; 2) University of Florida., Gainesville, FL.

Male and female reproductive behaviors in *Drosophila melanogaster* are vastly different, but the neurons that express sex-specifically spliced *fruitless* transcripts (*fru P1*) underlie these behaviors in both sexes. How a similar set of neurons can drive such different behaviors is an unresolved question in neurogenetics. A particular challenge is that *fru P1*-expressing neurons comprise only 2-5% of the adult nervous system, and so inferences made in studies of adult head tissue or even the whole brain are limited. To assess gene expression in the *fru P1*- expressing cells we used Translating Ribosome Affinity Purification (TRAP). This technique allows us to conduct a sensitive, cell-specific assay of gene expression by identifying the actively translated pool of mRNAs from *fru P1*-expressing neurons. Additionally, to examine the changes in gene expression across development we assay three different time-points in the fly life cycle—48hr pupae, 0-24hr adult, and 10 day adults. Here, we present results on the 0-24hr adults and find that the male and female *fru P1*-expressing neurons have a shared set of 7,967 genes identified by TRAP that form a distinct repertoire relative to those identified from TRAP analyses of all neurons in the adult head. Further, there are genes that have sex-biased TRAP abundance in *fru P1*-expressing neurons, with the majority of these genes having male-biased TRAP abundance. This suggests an underlying mechanism to generate dimorphism in behavior, with a transcript repertoire that specifies male and female behaviors present in both sexes and a large additional set of genes with expression in the male. Thus, these additional genes could invoke the male-specific behaviors by establishing cell fate in a similar context of gene expression observed in females. These results suggest a possible global mechanism for how distinct behaviors can arise in different environments from a shared set of neurons.

D1285C Comparison of mate choice in *Drosophila melanogaster* exposed to a mutagen. *Y. Trujillo Varela*[1], P. Ramos-Morales[1], SM. Villagrán[2], AJJ. Espinosa[3], C. Macías[4]. 1) Laboratorio de Genética y Toxicología Ambiental Facultad de Ciencias UNAM; 2) Departamento de Biología Comparada, Facultad de Ciencias UNAM; 3) Instituto de Investigaciones Biomédicas, UNAM; 4) Instituto de Ecología, UNAM. CdMx 04510, México.

Organisms are continually exposed to a wide variety of substances which can be harmful and may put at risk the integrity of organisms and the health of future generations. Even sublethal concentrations can alter competitive, fundamental skills for reproduction and transmission of

genetic material to subsequent generations. In this work, we use Drosophila melanogaster to determine whether exposure to the mutagen Sodium Azide modifies the possibility that males could be chosen as breeding pair, comparing male performance in massive and individual crosses. Wild type (Canton –S), third instar larvae, were fed semichronically with sodium azide (SA) [0.125- 1.13E-13], a mutagen that induces repair by recombination in Drosophila melanogaster (Gonzalez-Ramos, 1997). For the rest of the assays we used SA [3.86 E -6] because this concentration does not affect the survival of the adults. For all matings, ywf homozygous untreated females were crossed with wild-type treated males mixed with mutant no treated males for any combination of the y w f markers (X-linked). A massive crossing with a ratio of operating sexes (OSP) 1:1 was performed. Two days later, females were placed individually in vials to produce progeny. The type of the progeny obtained was used as an indicator of how many couples have the parental female and the male phenotype chosen by the female. Females take part in three matings (average). It was found that the wild-type phenotype predominates in the offspring of treated and untreated males, although it is possible that the same kind of male participates in more than one copula. The experiment was repeated but now only one male of each kind of mutant marker and the treated wild-type male were put with 8 ywf females. On these matings, the female take part in two copulas and when exposed males were used, mutant progeny was more abundant than the wild-type. Acknowledgments: To Master in Biological Sciences, UNAM-CONACyT (Grant 262619) and to Drosophila Stock Center Mexico, UNAM to provide the biological material.

D1286A A Novel Gene Controlling the Timing of Courtship Initiation in *Drosophila melanogaster*. *S. A. Zaki*[1], P. Luu[1], D. H. Tran[1,2], R. L. French[1]. 1) San José State University, San José, CA; 2) Counsyl, Inc., South San Francisco, CA.

Drosophila melanogaster is an ideal model organism to study genetic regulation of innate behaviors. Male *Drosophila* carry out a complex courtship ritual involving a specific sequence of steps, which depend on the processing of sensory cues by the CNS. *fruitless* (*fru*) is the master regulatory gene that controls sex-specific behaviors; this gene is both necessary and sufficient for all aspects of the courtship routine. We have identified a gene, *Trapped in endoderm 1* (*Tre1*), that is essential for normal courtship behavior in male flies. *Tre1* encodes an orphan G-protein-coupled receptor that is required for both cell migration and establishment of cell polarity, but has not previously been implicated in courtship. The goal of this research is to characterize the role of *Tre1* in *Drosophila* mating behavior. We found that male flies in which *Tre1*-expressing cells are feminized through expression of the female specific isoform of the splicing factor Transformer (Tra^F), display unusually rapid courtship initiation. Additionally, partial loss-of-function mutants in *Tre1* show an aberrant courtship behavior, including rapid courtship initiation. To establish whether this phenotype resulted in increased reproductive fitness, we performed fertility assays and found that male flies with feminized *Tre1*-expressing cells were at a competitive reproductive advantage, while the *Tre1* hypomorphs were at a competitive reproductive disadvantage, indicating a complex requirement for *Tre1* in courtship success. Finally, we found that *Tre1-GAL4* is expressed in a sexually dimorphic pattern in the olfactory organs and olfactory centers of the CNS: the antennae, antennal lobe, and lateral horn, suggesting a role for Tre1 in the processing and integration of sensory signals during courtship. Future experiments will involve characterization of the Tre1 signal transduction pathway, specifically, determination of the Tre1 receptor ligand and downstream targets. This will further implicate Tre1's role in *Drosophila* courtship. Additionally, to determine whether feminization of *Tre1-GAL4* expressing cells leads to a gain-of-function or loss-of-function effect, we will perform experiments driving the expression of a temperature-sensitive allele of *shibire*, and the heat-sensitive TrpA1 channel in *Tre1-GAL4* neurons. We will present the results of feminization of *Tre1-GAL4* expressing neurons, as well as the effects of mutations of *Tre1* on courtship behavior. We will also describe how feminization and mutation of *Tre1* affect the fertility of male *Drosophila*. Furthermore, we will show confocal images of the sexually dimorphic expression pattern of *Tre1-GAL4* in the CNS.

D1287B Disruption of circadian rhythm through misexpression of a frontotemporal dementia-associated mutation in circadian pacemaker neurons in *Drosophila*. *S. T. Ahmad*, C. S. Krasniak, P. J. Kavaler. Colby College, Waterville, ME.

Frontotemporal dementia (FTD) is the second most common early-onset neurodegenerative disease. One subtype of FTD causes the production of $CHMP2B^{Intorn5}$, a mutant isoform of an ESCRT-III subunit. This causes disruptions in the autosomal-lysosomal and autophagy pathways. FTD patients show a variety of neurological symptoms, including disinhibition, apathy, aggressive behavior, and circadian rhythm deficits. To investigate these circadian rhythm deficits we ectopically expressed human $CHMP2B^{Intron5}$ using the GAL4-UAS system with the driver lines *cry*-GAL4 and *pdf*-GAL4 in *Drosophila*. These drivers are specific to an important subset of circadian pacemaker neurons in the brain. Using activity monitoring, we observed moderately disrupted circadian behavior. We did not observe any cellular death phenotype through whole brain imaging. To investigate the circadian deficits we are currently examining *timeless* and *period* transcript levels to investigate possible disruption of the molecular clock. This will allow us to further describe the circadian deficits caused by $CHMP2B^{Intorn5}$ misexpression.

D1288C A large-scale forward genetic screen to understand the role of glia in locomotion, arousal, and sleep. *V. Ahmad*[1], C. King[1], M. K. Gronauer[1], B. Kottler[2], R. Faville[1], B. Zhang[1]. 1) Division of Biological Sciences, University of Missouri, Columbia, MO; 2) Department of Basic and Clinical Neuroscience, Institute of Psychiatry, Psychology & Neuroscience, King's College London.

In order to decipher the contribution of glial cells in motor behavior and sleep regulation and to gain insight into glia-neural interaction, we used a "cell-centric" forward genetic screen approach to identify glia subset involved in these mechanisms. We hypothesize that specific glial cells are crucial for various key endpoints related to locomotor activity, arousal and sleep by modulating the functionality of specific neuronal subsections. We conducted an unbiased genetic screen by genetically manipulating subset of glia cells within a broad glial-specific *repo*-Gal4 expression pattern using the FINGR (Flippase-induced Intersectional Gal80/Gal4 Repression) method. We perturbed the function of specific glia subsets by expressing a UAS-effector (polyglutamine, polyQ) to determine its effect on behavior, and mapped glial morphology and location by labeling the relevant subset with GFP. We assayed locomotion, arousal and sleep in flies by using a video-based platform, and the DART (Drosophila Arousal Tracking) system in a 12:12 L:D cycle. An ongoing study has screened 122 lines (male and female) and identified 27 lines

with a defect in sleep impacting daytime or nighttime sleep or both. We believe that the characterization of these sleep phenotypes should help identify specific and novel roles of subset glia modulating neurons in the regulatory mechanisms of sleep and its functional consequences.

D1289A Circadian master regulator CLOCK in the central complex of *Drosophila* mediates sexual development. *Vinodh ILANGOVAN*[1], Zeynep Orhan[2], Ramanathan Narayanan[3], Halyna Shcherbata[1], Gregor Eichele[1]. 1) Max Planck Institute for Biophysical Chemistry, Goettingen, DE; 2) Bilkent University, Ankara, TR; 3) International Max Planck Research School- Neurosciences, Goettingen, DE.

Circadian locomotor activity patterns in *Drosophila* exhibit distinct sexual dimorphism in the phase of the rhythm. Since central complex is involved in integration of visual inputs and acts as higher order centre for locomotion, we investigated the presence of peripheral circadian clocks in the central complex and the possible substrate for sexually dimorphic locomotor activity patterns. Misexpression of positive regulators of circadian clock i.e., CLOCK and CYCLE in the central complex led to an altered locomotor pattern under periodic conditions but did not change the overt rhythmicity in the absence of time cues. Evening activity peak was abolished and a reduction in total activity was observed upon inducing dominant negative version of CLOCK in the central complex. Interestingly, we found that females failed to develop when a dominant negative version of CLOCK is expressed using one of the central complex drivers. Our study identified the involvement of central complex at cellular network level and the circadian activator CLOCK at the molecular level in mediating sexually dimorphic development and locomotor behavior of male flies.

D1290B Courtship, sleep and circadian rhythm of *Drosophila melanogaster* are greatly impacted by loss of the Dα1 nicotinic acetylcholine receptor subunit. *Hang Luong*, Jason Somers, Trent Perry, Philip Batterham. Bio21 Institute, School of BioSciences, University of Melbourne, Parkville, Australia.

Nicotinic acetylcholine receptors are a major class of ligand-gated ion channels in insect nervous system. Despite being well studied as insecticide targets, their roles in insect behaviours are still poorly understood. This study identified one of the ten receptor subunits, Dα1, as a modulator of sleep and circadian rhythm in Drosophila melanogaster as well as courtship behaviour. Using ends-out gene targeting, a genomic deletion of Dα1 was generated. Null mutant flies showed decreased night sleep which was due to shorter sleep episodes. Without a cycling light-dark condition, a severe loss of both sleep and circadian rhythm was observed. Additionally, courtship behaviour was also greatly affected in mutant flies. Unsurprisingly, their lifespan was significiant reduced to almost half that of control flies. Pan-neuronal GAL4 driven expression of the wildtype allele in the null background was sufficient to revert most, but not all, of these phenotypic changes. Even though mutations in Dα1 clearly confer a high level of resistance to neonicotinoids, a main class of commercial insecticides, fitness costs associated with a complete loss of Dα1 might explain the low observed frequency of such mutations in the targeted pest specieis.

D1291C A wing damage screen identifies novel genes affecting *Drosophila* aggression. *S. Davis*, A. Thomas, L. Liu, I. Campbell, H. Dierick. Baylor College of Medicine, Houston, TX.

Aggressive behavior is widespread throughout the animal kingdom as a means to compete for territory, food, and mates. Fighting animals can benefit from these encounters but also run the risk to lose resources, and they may incur physical damage and even risk death. While aggression is part of the normal repertoire of complex behaviors for many animals, excessive aggression also occurs in many human neurological and psychiatric disorders. The molecular and neuronal mechanisms underlying this trait in health and disease remain largely unknown. The identification of novel genes that regulate aggression through a forward genetic screen has so far never been attempted in any organism because the complex nature of the behavior makes screening prohibitively time consuming. We circumvented this challenge when we discovered a positive correlation between aggression and physical wing damage in male flies that were group-housed. Using this easy-to-screen wing damage phenotype we performed the first chemical mutagenesis screen to isolate mutants with increased aggression. After screening ~1,400 EMS induced X-chromosome mutants for increased wing damage, we found 5 lines that also had increased aggression. Using whole-genome sequencing, meiotic mapping, and genomic duplication rescues, we identified the causal mutation in 2 of these strains. These novel mutants likely affect neuronal excitability and gene regulation, although the mechanisms through which they function remain unknown.. This aggression-induced wing damage screening approach can also be applied to other chromosomes to further identify novel genes regulating this behavior in flies and may also provide insight into human aggression.

D1292A Male aggression requires the function of both octopamine and glutamate in dual neurotransmitting neurons. *H. R. Morgan*[1], H. M. McKinney[2], S. J. Certel[1], R. S. Stowers[2]. 1) University of Montana, Missoula, MT; 2) Montana State University, Bozeman, MT.

How information is encoded, transformed, and processed as it is transmitted between neurons is a fundamental question in neuroscience. In the last 15 years, dual transmission, or the ability of a neuron to release *multiple* transmitters has become firmly established, yet the functional significance has been difficult to dissect. Here we demonstrate through antibody labeling and new intersectional genetic tools that a subset of octopamine (OA) neurons within the adult brain also utilizes the neurotransmitter glutamate (Glut). Eliminating OA in these neurons has previously revealed aberrant male social behaviors including a delay in the initiation of aggression and a reduction in aggressive lunge number. OA has also previously been shown to mediate the choice between reproduction and aggression as males without OA display increased levels of male-male courtship and intermix aggression and courtship behavioral patterns. With this foundation, we are investigating if both OA and glutamate signaling from OA-Glut neurons is required for male aggression and reproductive behavior using two approaches. First, we examined the behavior of males deficient for glutamate in OA neurons through RNAi interference *(tdc2-Gal4/UAS-vGlut-IR).* Preliminary results indicate males lacking glutamate in the OA-Glut dual neurotransmission neurons exhibit a reduction in lunge number similar to the loss of OA yet do not display an increase in male-male courtship as compared to transgenic controls. Second, we will use the new intersectional genetic method to

eliminate only glutamate in the OA neurons by creating a vGlut complete loss-of-function allele within the OA neuronal population and quantify the subsequent changes on male behavior. Finally, males deficient in both OA and glutamate transmission will be assessed for the same behaviors. Taken together, our results demonstrate glutamate function within OA neurons is required for sex-specific, sensory-invoked behavior and provide a platform to understand the behavioral relevance of dual transmission in any system.

D1293B Molybdenum cofactor synthase 1 (Mocs1) regulates aggressive behavior in *Drosophila melanogaster*. *M. Ramin*, Y. Li, Y. Rao. Centre for Research in Neuroscience, McGill Uni., Montreal, Quebec, CA.

Aggression is an overt behavior that can be adaptive for individual survival. It occurs when two or more individuals have a conflicting common interest for food, mating partner and territory, with the dominant animals having more access to these resources. Both genetic and epigenetic factors have been shown to play important roles in regulating the levels of aggressiveness. In this study, we utilize *Drosophila melanogaster* as a model system to study the molecular mechanisms underlying the control of aggression.

In a search for genes that are involved in modulating aggressive behavior, we found that mutations in the *Mocs1* gene encoding Molybdenum cofactor synthase 1 (Mocs1), cause a significant decrease in the levels of fly aggressiveness. Cell-type-specific knockdown shows that Mocs1 is required in neurons for the control of aggression. While *Mocs1* mutants display severe defects in aggression, they show normal pattern of sexual discrimination, male-male and male-female mating behaviors. Other behaviors such as olfactory sensation and locomotor activity also remain normal in *Mocs1* mutants. These results suggest that Mocs1 plays a specific role in regulating fly aggression. To determine the exact mechanism by which Mocs1 is involved in the control of aggression, we are taking a combination of molecular and genetic approaches to investigate the molecular networks in which Mocs1 functions, and identify the Mocs1-dependent neuronal circuits that directly control aggressive behavior. The results will be presented at the meeting.

D1294C Analysis of pruritogen induced grooming behavior in *Drosophila melanogaster*. *Ciny John*, Rodney Murphey, Ken Dawson-Scully, John Nambu. Florida Atlantic University, Jupiter, FL.

Pruritus, or itch, is an unpleasant sensation that evokes a desire to scratch. Itch can be classified as either an acute or a chronic condition. Acute itch typically results from a bite or sting and can serve as a protective mechanism against tissue damage caused by parasites. However, chronic itch can result from the dysfunction of the immune and/or nervous systems. In mammals, pruritogens, or itch inducing agents, stimulate peripheral unmyelinated c-fiber pruriceptors, which are pruritogen detecting primary sensory neurons in the skin, causing transmission of sensory input to interneurons and projection neurons of the brainstem via the spinothalamic tract. This induces the itch sensation in the brain and the subsequent scratching behavior. Itch is a primary symptom in patients with broad range of illnesses, including skin diseases and systemic and metabolic disorders like liver and kidney diseases, HIV/AIDS and brain cancer. It is also seen in psychiatric disorders such as anxiety, depression, schizophrenia and delusions of parasitosis, leading to self-injurious behavior. The current understanding of pruritus in systemic diseases is limited due to the lack of sufficient animal models that mimic clinical chronic itch conditions. Furthermore, the antihistamines that are currently available for treatment of itch are typically ineffective in treating most cases of pruritus. *Drosophila* possess the homologs of many of the genes known to be involved in the mammalian pruritic pathway. Therefore, in current study, we are developing *Drosophila* as a model organism in order to investigate pruritus and identify key mediators of this condition in an established genetic model. To analyze the effects of pruritogens on *Drosophila*, we administer pruritogens to the fly and measure changes in their grooming behavior. Our preliminary results indicate that Histamine and Compound 48/80, which induces the natural release of histamine, both evoke longer grooming bout duration, compared to the control flies. Interestingly, two other pruritic mediators, Chloroquine and cowhage, do not have a significant effect on the flies' grooming behavior, leading us to believe that Histamine and Compound 48/80 evoked a pruritic response. Histamine is one of the best studied pruritogens in mammals and *Drosophila* are known to have two Histamine receptors, Histamine-Gated chloride channel 1 (HisCl1) and Ora transientless (Ort). Both receptors have been studied for their role in photoreception and visual transduction, however, additional functions of these receptors have not been investigated. Therefore, we also set out to identify the receptor(s) responsible for the change in grooming behavior we observed, using Histamine receptor mutants. Based on our findings, we conclude that *Drosophila* can indeed be used as a model organism for investigating pruritus.

D1295A Regulation of meal size by sucrose and sweet taste. *Margaux R. Ehrlich*, Keith R. Murphy, William W. Ja. The Scripps Research Institute, Jupiter, FL.

Ingestive behavior is composed of parameters such as meal frequency and meal size. Previous studies suggest that increased meal size plays a large role in the propensity for obesity. Thus, understanding how meal size is regulated could lead to interventions to treat obesity, diabetes, and general eating disorders. The advent of novel methods for measuring *Drosophila* feeding behavior has increased its use as a model for understanding the mechanisms underlying the regulation of hunger and satiety. Meal size is thought to be dictated by oral and post-ingestive signaling; however, the interaction between the two remains unclear. We found that feeding flies increasing sucrose concentrations resulted in decreased average meal size. In contrast, increasing concentrations of sucralose, a non-nutritive but sweet tasting substance, increased meal size. Interestingly, following starvation, meal size had a non-monotonic relationship with sucrose concentration, revealing state-dependent positive regulation by sucrose. These data suggest that accumulating hunger may unequally modulate taste and post-ingestive signaling to determine meal size. Furthermore, we have identified a subset of neurons that are necessary for the regulation of meal size; when these neurons are silenced, animals are unable to regulate feeding and meal size is increased. Future studies will determine whether these neurons regulate oral or post-ingestive signaling and will further elucidate the mechanisms underlying meal size regulation.

D1296B Ir76b conductance is gated by other Ir proteins to mediate amino acid taste. *Anindya Ganguly*, Anupama Dahanukar. University of California, Riverside, Riverside, CA.

Amino acid taste has remained largely unexplored in flies. Although there is evidence that flies exhibit enhanced behavioral sensitivity to amino acids when deprived of dietary amino acids, the cellular and molecular basis for amino acid taste is not understood. Our objective was to systematically study amino acid taste and investigate mechanisms underlying their detection.Yeast is the chief source of dietary proteins and free amino acids. We found that amino acids serve as the key cues for yeast feeding preference. Flies showed a strong feeding preference for yeast extract, which was lost when amino acids were depleted from it. Individual L-amino acids were able to evoke feeding preference to varying extents in binary choice assays with sucrose, which was not observed for D-amino acids. As found previously for yeast, feeding preference for amino acids showed sexual dimorphism and dependence on mating state – mated females showed higher preference as compared to males or virgin females.We conducted an RNAi screen targeting ionotropic receptors (Irs) and identified *Ir76b*, which is widely expressed in taste neurons, to be necessary for yeast preference. *Ir76b* mutants lose their preference for yeast extract and amino acids, which was restored by expressing *Ir76b* in the mutant background using the *UAS-Gal4* system. *Ir76b* is highly conserved in insects and we found that its *Anopheles gambiae* ortholog (*AgIr76b*) could rescue behavioral defects in yeast and amino acid preference in *Drosophila Ir76b* mutants, suggesting functional conservation of this receptor across evolution.By expressing GCaMP3 and imaging amino acid-evoked changes in fluorescence, we found that a subset of tarsal *Ir76b*+ neurons responded to amino acids. Interestingly, we found a functional overlap between amino acid and sucrose-sensing neurons, but not with those that detect water, salt, bitter or acid tastants. This was surprising because Ir76b has been shown to function as an ungated salt channel. We therefore examined the role of other *Ir* genes as potential co-receptors that gate Ir76b conductance in response to amino acids. One other candidate that emerged from the RNAi screen was *Ir20a*. We tested the hypothesis that Ir20a blocks salt response of Ir76b by co-expressing the two receptors in sweet taste neurons. We found that Ir76b was sufficient to confer salt response when expressed alone, but the response was greatly reduced in the presence of Ir20a. Conversely, Ir76b alone was not capable of conferring response to a mixture of amino acids, but a response was observed when Ir76b is expressed together with Ir20a.Overall, our results suggest that Ir20a, and possibly other Irs, combine with Ir76b to form amino acid-gated receptors, and offer a simple explanation for mutually exclusive roles of Ir76b in salt and amino acid sensing taste neurons.

D1297C Contribution of altered feeding to caffeine-mediated sleep suppression. *Chenchen Su*, Erin S. Keebaugh, Mounika Vattigunta, William W. Ja. The Scripps Research Institute, Jupiter, FL.

Caffeine promotes wakefulness and reduces sleep in many organisms, including *Drosophila*. Given that taste likely affects ingestion and that caffeine is also popularly studied as a bitter tastant, aversion to caffeine might influence fly food intake. Since it is known that reduced nutrient intake also reduces sleep—an effect known as starvation-mediated sleep suppression—we hypothesized that reduced feeding might contribute to caffeine-mediated effects on sleep. We quantified the individual and combined effects of starvation and caffeine supplementation on sleep in Canton-S males using the *Drosophila* Activity Monitor system. Our results may reveal the extent to which altered food intake and pharmacology influence caffeine-mediated sleep suppression in the fly.

D1298A Evidence of pleiotropic effects in some mutants of *Drosophila melanogaster*. *T. Alonso Vásquez*, P. Ramos Morales, Y. Trujillo Varela. Facultad de Ciencias UNAM, Cuidad de México, Delegacion Tlalpan, MX.

As in other organisms, in Drosophila, the mutant genes are named and characterized in regard to the change or obvious changes that cause with respect to wild-type flies, leaving aside other issues that could be affected by the presence of this mutation, i. e., although many genes could be pleiotropic, they are considered single acting and used under this concept in tools for studying genetic terminal events and mutagenesis studies. The aim of this study is to compare the displacement (negative geotropism) of mutant and wild-type flies. We used flies showing mutations that could affect locomotion and other affecting color eyes and body color which is assumed, they are not related with locomotion activity: protruding wings (nub: nubbin), miniature wings (m: miniature); dark body color (e: ebony), white eyes (w: white); and interactions among these mutations: protruded wings-dark body (nub-e), white eyes-miniature wings (w-m), white eyes-dark body (w-e), and the wild-type flies (Canton-S, CS), (Lindsley & Grell, 1972). The flies were placed in graduate plastic tubes (pipettes), it was tapped so the fly stay at the base and the traveled distance at 5 min was recorded. Both of them, CS and nub flies traveled the same distance, the rest of the mutants showed a greater displacement ($p < 0.05$), being the displacement of e and w mutants higher than all others ($p < 0.05$). The order of the registered average displacement is: e = w> w-e> nub-e = m = w-m> CS = nub. To confirm the response, the experiment was repeated at noon and afternoon. The average distance traveled by all mutants and wild type flies, were significantly different ($p<0.05$). In addition, the average of distance traveled was different among the mutants used. At noon, the order of average distance traveled was w = e = CS> nub = m = w-e = nub-e = w-m. At afternoon, the order of average distance traveled was w> e = CS = m = w-e = nub-e > w-m = nub. The results show that some of the mutations used can affect seemingly unrelated activities, such as body or eye color and locomotion. Of all the mutants, w travels farther than wild flies regardless of the schedule of tests ($p < 0.05$). It is interesting to explore further to understand why this mutant offers an apparent advantage to the carrier flies under laboratory conditions, but not necessarily in field conditions. Acknowledges: To Banco de Moscas (Drosophila Stock Center Mexico) to provide the biological material.

D1299B An optogenetic and quantitative dissection of descending neuron control of behavioral in *Drosophila*. *J. Cande*[1], G. Berman[2], S. Namiki[1], W. Korff[1], G. Card[1], J. Shaevitz[3], D. Stern[1]. 1) Janelia Research Campus, Ashburn, VA; 2) Emory University, Atlanta, GA; 3) Princeton University, Princeton, NJ.

In most animals, the brain sends signals to local neural circuitry in the nerve chord to produce behaviors. Despite the central importance of these signals as an informational and anatomical bottleneck, little is known about how these signals are encoded at the neuronal level or how they control aspects of behavior. In insects, signals from the brain to the ventral nerve chord are carried by an estimated 350 pairs of bilaterally symmetric descending neurons (DNs). To date, only a handful of these descending neurons have known functions. In order to understand how DNs can control insect behaviors, we developed a method to identify descending interneuron function in an unbiased and systematic fashion in the model insect *D. melanogaster*. Using the red-shifted channelrhodopsin *CsChrimson*, we activated neurons in a collection of ~200 lines, most of which target single neurons out of a collection of DNs that fall into 60 distinct neuro-anatomical classes. Using a PCA and frequency analysis based technique described in *Berman et al.* (2014) we created a two-dimensional behavioral space based on the underlying postural dynamics of freely moving flies with and without red light activation. In this map, stereotyped behaviors are represented by local probability density maxima, and distinct behavioral motifs are easily distinguished. We then looked for map regions that were upregulated in *CsChrimson* activated animals. Using this technique, we were able to assign phenotypes to 90% of the DNs in our collection. We find that (1) DN control of stereotyped behaviors appears to be modular, (2) much DN function can be correlated with neuro-anatomy, and (3) the nature of this correlation hints at centralized control of locomotory activities. These findings, which are only apparent in a dataset of this size, have wide-ranging implications for how complex signals from the brain are encoded by descending neurons.

D1300C Sensing, processing, and response to heating and cooling in the *Drosophila* larva. *M. Klein*[1], A. J. Ferrer[1], B. Kaminski[1], L. Ni[2], P. A. Garrity[2], M. Berck[4], A. D. T. Samuel[4], S. V. Krivov[3], M. Karplus[4]. 1) Univ. of Miami, Coral Gables, FL; 2) Brandeis Univ., Waltham, MA; 3) Univ. of Leeds, Leeds, UK; 4) Harvard Univ., Cambridge, MA.

The ability to sense and respond to temperature is universally important for the wellbeing of motile animals. Navigation in environments with variable temperature (thermotaxis) is built from signal generation in sensory neurons, signal processing in the brain, and signal conversion to physical muscle action. Working in the *Drosophila* larva model system, we explore the response to temperature at the scales of populations, individual animals, neuronal circuitry, and molecules. We find that response to heating is independent of response to cooling at all these levels, as the two distinct sensorimotor transformations operate in parallel. Modeling and Monte Carlo simulations using empirically-derived rules for behavioral mode transitions demonstrate that realistic movement can be recovered with a small number of parameters, and show the benefit of randomness in navigation decisions. Behavioral tracking of individual larvae establishes navigation patterns and shows that thermotaxis is specifically an aversive rather than attractive response to both heating and cooling. We employ an improved device for generating rapid changes in temperature to subject larvae to random noise stimuli, then generate mathematical filters that can probabilistically predict the larvae's responses at high and low temperatures. At the cellular level, we measure *in vivo* the activity of separate cool-sensing and heat-sensing neurons and identify downstream connectivity that points towards a more complete understanding of complex brain circuits. Finally, by using the above behavioral and neurophysiological methods, we uncovered the mechanism of cooling sensation, showing that two ionotropic receptors (IRs) are required for navigation and detection in adult flies and larvae, and also identifying candidates for heat sensation in the larva. The quantitative approaches used here should also be applicable to work in other sensory modalities and other model systems seeking to characterize sensory and circuit-level steps that lead to behavior.

D1301A *D. melanogaster* flies that survive environmental insults modify some crucial behaviors for later survival. *Karla I. Martínez-Ledezma*, Patricia Ramos-Morales. Laboratorio de Genética y Toxicología Ambiental, Departamento de Biología Celular, Facultad de Ciencias, UNAM, Coyoacán, México City.*.

Sodium azide (SA) (NaN3) is well known as a potent mutagen in bacteria. In eukaryotes is a metabolic poison that traps oxygen excited, interfering with the activity of various enzymes. In Drosophila melanogaster, causes mitotic recombination in somatic cells, in response to chromosomal breakage. In addition, it has been observed that the treatment itself causes an apparent delay in the development of the larvae exposed. In this study, we evaluated whether the exposure to sublethal concentrations of NaN3 affects the development cycle (10 days at 25 °C) and tropisms such as the negative geotaxis of adult flies recovered. Wild-type, third instar larvae, were fed semichronically with serial dilutions of SA, from 0.125 mM to 1.8E-13mM. Each day, adult flies recovered were counted and separated, until all flies had emerged. Two groups were formed according to the time of hatching: 10-12 days and 13 or more days. The effect on treatment in the behavior of flies from two periods of hatching (10-12 and 13 or more days) was compared. Groups of 20 flies were put into a vial (15 ml of volume) connected through a channel of 6 mm with other vial (same volume). The frequency of flies that cross in one minute to the second vial was determined. 20 families per concentration were used. Sodium Azide treatment changes the frequency with which the flies went through the second tube. Although the response was not linear, a higher frequently of crossing to the second tube was found in flies that hatched among 10-12 days and were treated with 1.8E-12 1.5E-11 2.4E-7 of SA; In contrast, flies in group 13 or more showed a higher frequency of crossing only if was previously fed with 1.5E-11. When comparing the frequency of passage between groups (10-12 and 13 or more), differences in all concentrations were confirmed, except in the highest proven, 1.25E-1. Both of them, the treatment with SA, and the emergency period, determine the behavior of crossing on Drosophila melanogaster. These results show that exposure to genotoxins should be evaluated on several types of responses, which may be relevant to determine the real effect induced on organisms surviving to toxic exposures.

D1302B Gut bacterial modulation of locomotion in *Drosophila melanogaster*. *C. Schretter*[1], S. Keremane[2], J. Vielmetter[2], I. Bartos[3], Z. Márka[3], S. Márka[3], S. Hess[4], S. Mazmanian[1]. 1) Division of Biology & Biological Engineering, California Institute of Technology, Pasadena, CA, USA; 2) Protein Expression Center, Beckman Institute, California Institute of Technology, Pasadena, CA, USA; 3) Department of Physics, Columbia University, New York, USA; 4) Proteome Exploration Laboratory, Beckman Institute, California Institute of Technology, Pasadena, CA, USA.

Trillions of microbes inhabit the human gastrointestinal tract and are known to influence metabolism and immunity. However, relatively little is known about how these organisms influence the behavior of their host. As gut bacteria participate in digestion, they alter the levels of macromolecules, such as carbohydrates, within the gut and produce neuromodulators as byproducts. Due to their participation in energy-availability within the host, we hypothesized that gut bacteria play a role in locomotion. We have found significant differences between the locomotive behavior of adult flies without a microbiota (axenic) and those with a full microbiota (conventional). Mono-colonization studies have revealed that specific bacteria and, in particular, a bacterially-derived molecule influences a fly's gait, speed, and activity levels. Through administering antibiotics and performing later colonization time points, we have also found that these effects are not due to changes during development. Neither mass, glucose, nor the IMD (Immune Deficiency) pathway has been found to mediate these effects on locomotion.

Our results reveal that the bacterial composition of the gut and its metabolic products are an important modulator of host locomotion. Locomotion is a behavior critical for the survival of an organism and is part of the progression of certain disease states. When combined with our results, this suggests that the gut microbiota is an important factor to consider in a variety of neural pathways and their behavioral outputs.

D1303C Ion pumps in the generation of scolopidial receptor lymph. *D. F. Eberl*, B. Zora, E. Sivan-Loukianova, M. Roy. Univ Iowa, Iowa City, IA.

Chordotonal mechanoreception in insect hearing relies on ciliated sensory neurons that express TRPN and TRPV ion channels. Under high frequency auditory stimulation, these channels may only open for short times, minimizing receptor current. This is counteracted by an elevated electrochemical gradient across the ciliary membrane, achieved by a specialized receptor lymph in the scolopale space enclosed by the scolopale cell. The receptor lymph is thought to be rich in K^+ and if it resembles the endolymph of mammalian cochlea, it may also be electro-positive. To test the roles of ion pumps and transporters in generating the receptor lymph in the *Drosophila* Johnston's organ, we expressed RNAi constructs that target a panel of ion pump and transporter genes specifically in the scolopale cells, using the *nompA*-Gal4 driver. We found that subunits of the Na/K-ATPase and the V-ATPase, primary ion pumps, are essential in the scolopale cell for hearing. Furthermore, we found evidence that some secondary transport mechanisms, such as in the cation chloride co-transporter family, which rely on the gradients generated by the primary transport mechanisms, also play a role in this cell. Our results establish a model for receptor lymph generation and help to understand the fundamental mechanisms of mechanotransduction.

D1304A Subfunctionalization and Neofunctionalization of Drosophila Odorant Binding Proteins. *J. A. Johnstun*[1,2], F. S. Haire[1,2], T. F. C. Mackay[1,2], R. R. H. Anholt[1,2]. 1) North Carolina State University, Raleigh, NC; 2) W. M. Keck Center for Behavioral Biology.

The functions of most Drosophila odorant binding proteins (Obps) remain unexplored, and many exist in tandem arrays throughout the genome. As these genes most likely arose through recent duplication, genes within a cluster likely have partially redundant or pleiotropic functions. Here, we used the CRISPR-Cas9 system to generate two knock-out lines, the first lacking the four paralogs of the *Obp56a-d* cluster, and the second lacking the single *Obp56h* gene, another possible paralog of the *Obp56* cluster. Various phenotypic tests on these knockout lines demonstrate significant functional overlap and novel pleiotropic functions. Both lines shared decreased viability in early development and development time, while the *Obp56a-d* KO line uniquely showed decreased height of pupation. The *Obp56h* KO line showed increased copulation duration and decreased aversion to 2-heptanone. Reinserting the *Obp56a-d* genes one-by-one and in various combinations in a PhiC31 integration site engineered in their original location during CRISPR-Cas9 excision will enable reconstruction of their functional evolutionary history. Supported by NIH grant GM059469.

D1305B Metabolite exchange within the microbiome influences *Drosophila* behavior. *C. N. Fischer*[1], E. Trautman[2], J. M. Crawford[2], E. V. Stabb[3], N. A. Broderick[4], J. Handelsman[1]. 1) Department of Molecular, Cellular and Developmental Biology, Yale University, New Haven, CT, USA; 2) Department of Chemistry, Yale University, New Haven, CT, USA; 3) Department of Microbiology, University of Georgia, Athens, GA, USA; 4) Department of Molecular and Cell Biology, University of Connecticut, Storrs, CT, USA.

Our understanding of the molecular mechanisms by which microorganisms affect animal behavior rests on single-microorganism studies. Yeasts affect *Drosophila melanogaster* olfactory behavior, yet it is unclear how bacteria or microbe-microbe interactions affect *Drosophila* behavior. The *Drosophila* microbiome consists of yeasts, acetic acid bacteria (AAB), and lactic acid bacteria (LAB), which co-occur in fruit and in the *Drosophila* intestinal tract. *Drosophila* appears to augment its resident microbiome through feeding, implicating *Drosophila* behavior in microbiome selection. Beneficial AAB and LAB emit acetic acid and lactic acid, respectively, yet acidity repels *Drosophila* via a dedicated olfactory circuit. One answer to this paradox is that *Drosophila* acquires bacterial microbiome members through a passive mechanism, whereas another posits that bacterial microbiome members actively attract *Drosophila* despite their acidity, either alone or in the context of communities. To distinguish these possibilities, we adapted a behavioral assay and measured *Drosophila* olfactory preference toward microbiome members grown individually and in communities. *Drosophila* prefers cultures of microbiome members grown in communities relative to cultures of the same microorganisms grown individually and then mixed, suggesting that *Drosophila* olfactory behavior is tuned to emergent microbe-microbe interactions. The conserved olfactory receptor *Or42b* partially mediated *Drosophila* preference for the two microorganisms grown together (yeast-AAB co-culture) to the same microorganisms grown individually and then mixed. *Drosophila* co-culture

preference correlated with three emergent properties: ethanol catabolism, a unique volatile profile, and yeast population decline. *Acetobacter* conversion of *Saccharomyces*-derived ethanol was necessary and acetic acid and its metabolic derivatives were sufficient for *Drosophila* co-culture preference, supporting the hypothesis that AAB actively attracts *Drosophila* as part of a microbial community. Additional chemical and behavioral analyses identified acetaldehyde metabolic derivatives as emergent microbial community metabolites that attract *Drosophila*. In sum, we discovered a molecular mechanism by which a multispecies community affects animal behavior. Our data support a model whereby emergent microbial metabolism cues *Drosophila* to associate with a diverse, metabolically beneficial microbiome.

D1306C ORN activity patterns in *Drosophila* larvae elicited by ecologically relevant odorants. *R. Kellermeyer*, D. Mathew. University of Nevada, Reno, Reno, NV.

Most insects locate their food source primarily through olfaction. In *Drosophila* larvae, attraction and repulsion to environmental odorants are based on the activity of only 21 olfactory receptor neurons (ORNs). While a considerable amount of information has been generated regarding the ORN responses of worms, flies, and mammals to odorants, much less is known about their role in driving behavioral output. This gap in knowledge prevents development of reliable odor coding models that can elucidate general principles of information processing, as well as instruct effective solutions for insect control. In this study, we examined the hypothesis that ecologically relevant attractive or repulsive odorants elicit specific patterns of ORN activity in the *Drosophila* larva. To measure this, a simple two-choice behavioral paradigm was used to test the behavioral response of wild type *Drosophila melanogaster* larvae to 54 odorants selected from its ecological habitat. Using this behavioral screen, a panel of 10 odorants that elicited the strongest attractive or repulsive responses in larvae was identified. This panel of odorants was then used to assess the response patterns among the 21 larval ORNs. For this, we expressed each larval odorant receptor in an in vivo expression system, the "empty neuron" system, and measured neural responses using single unit electrical recordings. At the test concentration, the panel of strong behavioral determinants elicit both excitatory and inhibitory responses from a variety of larval odor receptors expressed in the empty neuron system. Further, many of these receptor-odorant combinations exhibit varying response dynamics. Overall, our preliminary evidence suggests that ecologically relevant odorants elicit specific patterns of ORN activity. This study is significant because conserved patterns of sensory neuron activity may instruct downstream olfactory coding of behavioral valence. By comparing amplitude, temporal dynamics, and distribution of all 21 ORN responses, we aim to identify conserved patterns among sensory neuron activity elicited by attractants and repellents. The results from this study have the potential to impact development of more reliable odor coding models as well as to transform existing methods of insect control.

D1307A Receptor Basis of Serotonergic Modulation in an Olfactory Circuit. *T. R. Sizemore*, A. M. Dacks. West Virginia University, Morgantown, WV.

Animals must efficiently detect and process stimuli, then tune behavioral output according to dynamic physiological demands. To achieve this, the nervous system uses neuromodulators, such as serotonin (5-HT), to modify the excitability and synaptic efficacy of individual neurons based on the animal's current state. Neuromodulation, therefore, can result in changes in lateral interactions within the network and shape the direct output from the network. For instance, 5-HT enhances odor-evoked responses of projection neurons (PNs) and enhances pre-synaptic inhibition of olfactory receptor neurons (ORNs) by local interneurons (LNs) within the antennal lobe (AL) of *D. melanogaster*. However, the effect of a neuromodulator on an individual neuron is dictated by the cognate receptor-type expressed by that neuron. Therefore, to understand the mechanistic basis for neuromodulation, the functional identity of the neurons that express each neuromodulator receptor within a network must be determined. This will allow the separation of the effects of a neuromodulator on a single neuron from the consequences of modulating the input that a neuron receives. Therefore, we have used immunocytochemistry and T2A-GAL4 transgenic animals driving the expression of GFP to determine the neuron type within the AL of *D. melanogaster* that express the five 5-HT receptors (5-HTRs). The T2A-GAL4 lines act as a direct reporter for 5-HTR translation ("protein-trap") by decoupling GAL4 from the nascent 5-HTR mRNA during translation. Using immunocytochemistry, we determined the cell type (i.e. ORN, PN, LN, etc.) and transmitter content of each 5-HTR producing cell in the AL. Each 5-HT receptor are expressed by distinct functional populations of neurons suggesting that 5-HT targets distinct features of olfactory processing within the AL. In general, the inhibitory 5-HT receptors are expressed by inhibitory neurons including distinct subpopulations of LNs and GABAergic PNs, while the excitatory 5-HT receptors were expressed by ORNs and cholinergic PNs. This suggests that within the AL, the effects of 5-HT on olfactory processing are mediated by a combination of network-wide disinhibition and glomerulus specific enhancement. .

D1308B Mapping Chromatic Visual Pathways in *Drosophila*. *TY. Lin*[1,2], J. Luo[2], K. Shinomiya[3], CY. Ting[2], Z. Lu[3], I. Meinertzhagen[3], CH. Lee[2]. 1) National Defense Medical Center, Taipei, Taiwan; 2) NICHD, Bethesda, MD, USA; 3) Dalhousie University, Halifax, Canada.

In *Drosophila*, color vision and wavelength-selective behaviors are mediated by the compound eye's narrowspectrum photoreceptors R7 and R8 and their downstream medulla projection (Tm) neurons Tm5a, Tm5b, Tm5c, and Tm20 in the second optic neuropil or medulla. These chromatic Tm neurons project axons to a deeper optic neuropil, the lobula, which in insects has been implicated in processing and relaying color information to the central brain. The synaptic targets of the chromatic Tm neurons in the lobula are not known, however. Using a modified GFP reconstitution across synaptic partners (GRASP) method to probe connections between the chromatic Tm neurons and 28 known and novel types of lobula neurons, we identify anatomically the visual projection neurons LT11 and LC14 and the lobula intrinsic neurons Li3 and Li4 as synaptic targets of the chromatic Tm neurons. Single-cell GRASP analyses reveal that Li4 receives synaptic contacts from over 90% of all four types of chromatic Tm neurons, whereas LT11 is postsynaptic to the chromatic Tm neurons, with only modest selectivity and at a lower frequency and density. To visualize synaptic contacts at the ultrastructural level, we develop and apply a

"two-tag" double-labeling method to label LT11's dendrites and the mitochondria in Tm5c's presynaptic terminals. Serial electron microscopic reconstruction confirms that LT11 receives direct contacts from Tm5c. This method would be generally applicable to map the connections of large complex neurons in *Drosophila* and other animals.

D1309C Virtual Fly Brain 2.0 - The data integration hub for Drosophila neurobiology. *D. J. Osumi-Sutherland*[1], R. Court[2], M. Costa[3], N. Staudt[3], H. Parkinson[1], J. D. Armstrong[2], G. S. X. E. Jefferis[4], C. J. O'Kane[3]. 1) EMBL-EBI, Cambridge, UK; 2) University of Edinburgh, Edinburgh, UK; 3) University of Cambridge, Cambridge, UK; 4) MRC Laboratory of Molecular Biology (LMB), Cambridge, UK.

Advances in genetic techniques allow ever more accurate targeting of specific neurons with reagents that modulate or detect their activity. At the same time, advances in imaging technology and image processing are producing detailed maps of neuroanatomy down to the level of individual synaptic connections. As a result, there are now unprecedented opportunities to use the power of model organism genetics to functionally dissect neural circuits: inhibiting, activating or otherwise modulating the activity specific neurons and observing the effects on phenotype and circuit function. To take full advantage of these opportunities, researchers need simple, intuitive tools to search and visualize data integrated from multiple bulk datasets, identify candidate circuit elements, and find reagents to target specific neurons. These tools need to be integrated with systems for combining and viewing 3D images.

Virtual Fly Brain (VFB) fulfils this role, integrating data curated from the literature and from many bulk sources. Its search system allows users to search for neurons and neuro-anatomical structures using almost any name found in the literature. Its sophisticated query system allows users to identify neurons innervating any specified neuropil or fasciculating with any specified tract. It also allows users to query for genes, transgenes and phenotypes expressed in any brain region or neuron. Search and query results combine referenced textual descriptions with links to related structures and 3D images. VFB features tens of thousands of 3D images of neurons, clones and expression patterns, registered to a standard adult brain. Any combination of these images can be viewed together on our stack browser. A BLAST-type query system (NBLAST) allows users to find similar neurons and drivers starting from a registered neuron tracing.

We will present a new version of VFB featuring a 3D image browser and a new adult ventral nerve cord template with registered image data. We will also outline plans for the release of VFB 2.0 later this year. This will feature a fully interactive 3D browser, a new query interface with full integration of NBLAST and a standard larval brain. Drosophila neurobiologists have generated a particularly rich set of shared neuroanatomical data and genetic driver lines; our experiences with VFB should be very relevant for other model organism resources focussing on the nervous system.

D1310A Mechanism underlying inhibitory control. *E. Saldes*, Paul Sabandal, Youngcho Kim, John Sabandal, Kyung-An Han. The University of Texas at El Paso, El Paso, TX.

Mechanism underlying inhibitory control

Erick Saldes, Paul Sabandal, Youngcho Kim, John M. Sabandal, and Kyung-An Han

Department of Biological Sciences, BBRC Neuroscience/Metabolic Disorders, University of Texas at El Paso, El Paso, TX USA

The ability to suppress ongoing motor actions that are no longer appropriate is a fundamental feature of executive function supporting flexible and goal-oriented behaviors. This inhibitory control is known as response inhibition and has been studied in mammals but not in non-mammalian species. We have identified that the fruit fly *Drosophila* displays response inhibition. A go/no-go test is typically used to measure response inhibition in human subjects and requires subjects to produce a motor response when cued to do so (go) or otherwise withhold it (no-go). To study response inhibition in *Drosophila*, we developed a fly version of the go/no-go test and found dopamine as an important neuromodulator for inhibitory control. When subjected to a go/no-go test, the *fmn* mutants lacking dopamine transporter initially withheld movement upon exposure to salient stimuli but, within a minute, exhibited flying behavior. The *fmn* mutants have impaired sleep thus we examined additional sleep mutants Sh and HK. Similar to *fmn*, they also displayed impaired response inhibition. Studies are in progress to clarify the role of sleep in response inhibition and underlying mechanisms. Anomalous response inhibition is associated with numerous brain disorders but its underlying mechanisms are largely unknown. Our study may help fill the knowledge gap.

D1311B RNA-processing genes control sensory neuron function in *Drosophila melanogaster*. *A. D. Dyson*, C. Kawada, R. Stewart, M. Gaglianese-Woody, A. Bellemer. Appalachian State University, Boone, NC.

Chronic pain affects approximately 100 million Americans and generates costs of up to $600 billion per year, according to the Institute of Medicine. Characterization of molecular signaling pathways in sensory neurons is an important step toward development of more effective clinical interventions. The goal of this study is to identify genes involved in regulating the function of class IV multidendritic neurons, which are nociceptors integral to the detection of noxious thermal, mechanical, and photic stimuli. We are using Drosophila melanogaster larvae as a model system, which exhibit a distinct and quantifiable response to noxious stimuli termed nocifensive escape locomotion (NEL). Recent research has found that the transcripts of key genes necessary for nociceptor function are alternatively spliced. We have systematically knocked down putative RNA-processing genes with a previously identified role in dendrite development and/or alternative splicing by crossing a *ppk-GAL4;UAS-dicer2* fly strain with RNAi lines targeting genes of interest. Using *ppk-GAL4* as our driver limits expression to nociceptors and *dicer2* expression promotes increased efficacy of RNAi knockdown. We then tested progeny for changes in NEL latency relative to wild-type larvae using a thermal nociception assay. Nineteen genes were identified for which knockdown resulted in either a significant increase or decrease in response latency, indicating a potential defect. Follow-up assays for defects in mechanical nociception have demonstrated that select genes are required for both thermal and mechanical nociception. Additionally, our results suggest that behavioral defects do not always

correlate with defects in dendrite morphology. This study has also revealed a complex role for translation initiation factors, which will be investigated further using genetic and functional assays of multidendritic neuron structure and function.

D1312C Cellular and molecular dissection of noxious cold nociception in *Drosophila*. *A. A. Patel*[1], H. N. Turner[2], K. Armengol[3], N. J. Himmel[1], M. J. Galko[2], D. N. Cox[1]. 1) Georgia State University, Atlanta, GA; 2) University of Texas, MD Anderson Cancer Center, Houston, TX; 3) University of Maryland, College Park, MD.

Diverse organisms utilize thermoreceptors to detect and respond to noxious thermal stimuli, however the basic cellular and molecular mechanisms underlying noxious cold perception are not well understood. We developed novel global and local behavioral assays for genetic and cellular dissection of noxious cold responses in *Drosophila*. Larvae respond to near-freezing temperatures via a mutually exclusive set of singular behaviors– in particular full body contraction (CT). Class III (CIII) multidendritic (md) sensory neurons are specifically activated by cold and optogenetic activation of these neurons elicits cold-evoked behavior. Moreover, blocking synaptic transmission in CIII neurons inhibits CT behavior. Genetically, the transient receptor potential (TRP) channels Trpm*,* NompC*,* and Polycystic kidney disease 2 (Pkd2) are expressed in CIII neurons where each is required for CT behavior. We further demonstrate that these TRP channels are not generally required in the propagation of a cold signal, but rather likely play important roles in the initial cold sensing. In support of this, we show that overexpression of Pkd2 in normally cold-insensitive class IV md neurons confers cold sensitivity measured by *in vivo* cold evoked calcium responses. Thus CIII neurons are multimodal with roles in noxious cold detection and gentle touch mechanosensation. To clarify how these cell may distinguish between cold and gentle touch, we developed and implemented an optogenetic dose response assay revealing that gentle touch mediated head withdrawal behavior responses are due to low threshold activation of CIII neurons, whereas noxious cold evoked CT responses are due to high threshold CIII activation. To investigate how diverse nociceptive thermosensory stimuli are processed, we optogenetically co-activated CIII (cold) and CIV (heat) md sensory neurons. Interestingly, these studies revealed a dominant CT behavioral response with simultaneous activation of CIII and CIV neurons. Moreover, expression of the warm-activated TRPA1 channel in CIII neurons confers heat sensitivity, however, heat-mediated activation of these neurons leads to a majority of larvae exhibiting CT behavior and a dramatic declination in typical heat-induced rolling behavior. To initiate an investigation into cold nociceptive neural circuitry, we have conducted live, *in vivo* imaging of cold-evoked calcium responses throughout the larval ventral nerve cord (VNC) via GCaMP6 and CaMPARI imaging. These analyses reveal that noxious cold stimuli are transmitted down CIII axons and progress from a posterior-to-anterior direction within the VNC. Collectively, we demonstrate that *Drosophila* larvae utilize distinct cells and channels to respond to noxious cold temperatures via complex thermosensory and nociceptive circuits.

D1313A Extreme Quantitative Trait Locus Mapping for Ethanol Consumption in *Drosophila melanogaster*. *S. Fochler*[1,2], T. V. Morozova[1], T. F. C. Mackay[1], R. R. H. Anholt[1]. 1) Program in Genetics, W. M. Keck Center for Behavioral Biology, and Department of Biological Sciences North Carolina State University, Raleigh, NC, USA; 2) School of Biosciences and Medicine, Faculty of Health and Medical Sciences, University of Surrey, Guildford, UK.

Excessive alcohol consumption and alcoholism incur substantial socio-economic and health costs in our society. Identifying and disentangling the genetic and environmental factors that underlie alcohol consumption in human populations is challenging, due to genetic heterogeneity, uncontrolled environments and difficulty in precisely quantifying alcohol related phenotypes, as well as comorbidity with other addictive behaviors and psychiatric disorders. *Drosophila melanogaster* presents a powerful genetic model for exploring the genetic underpinnings of alcohol consumption because both the environment and genetic background can be controlled, alcohol consumption can be quantified precisely, and pathways associated with alcohol metabolism are evolutionarily conserved. We used an outbred Drosophila population which was generated by an advanced intercross of 37 sequenced lines of the *Drosophila melanogaster* Genetic Reference Panel, which are free of inversions, free of *Wolbachia* infection, are maximally homozygous and maximally unrelated. This advanced outbred population generates virtually unlimited numbers of unique individuals, which provides excellent statistical power for extreme QTL mapping (xQTL). We measured voluntary intake of 4% ethanol in an 8% sucrose solution using the Capillary Feeding (CAFÉ) assay. We scored 6000 males and 6000 females for alcohol consumption and obtained a distribution of ethanol intake, ranging from 0 to 3 ul per fly. We pooled three replicates of the 10% lowest and highest drinkers along with random control flies, sexes separately, for extreme QTL mapping, totaling 100 males and 100 females for each pool. We performed DNA sequencing on the extreme pools to identify differentially segregating alleles between the contrasting phenotypes. Construction of genetic networks of candidate genes and superposition of human orthologs on these networks will provide insights in the genetic architecture that underlies variation in alcohol consumption. .

D1314B Dynamics of ethanol preference in Drosophila. *A. Park*, N. Atkinson. University of Texas in Austin, Austin, TX.

Alcohol use disorder (AUD) imposes adaptations that perturb psychological and physiological characteristics of an individual that can contribute to the addicted state. Drosophila are favorably used to study alcohol-related behaviors due to their well-developed genetic toolkit, and shorter lifespans. However, previous researchers have struggled to quantify alcohol consumption in Drosophila due to their small size. In addition, the assays available currently cannot measure consumption in a temporally robust way, and rely on starvation to motivate the animals. We have developed a novel assay that measures the amount of consumed ethanol and can accurately track alcohol preference in a starvation independent paradigm. This new assay is temporally precise and better emulates natural feeding behaviors. Using this assay we have found male Canton S Drosophila naïve to ethanol are innately aversive to it as a food source (>5% ABV), however this aversion disappears when the flies are pretreated with ethanol. In addition, female Drosophila have innate attraction to ethanol (<15% ABV). Now, we are measuring ethanol preference in mutants that were selected through identifying genes that were epigenetically regulated during tolerance acquisition.

These mutants are not able to acquire functional tolerance to alcohol and testing their ethanol preference will determine if tolerance to alcohol exacerbates preference for drinking.

D1315C Aged Parents Have Less Social Offspring. *D. Brenman*, S. Long, A. Simon. University of Western Ontario, London, ON, CA.

Parental and grandparental age can alter the fitness of the progeny. For example, studies have found reduced fecundity, longevity, and memory in *Drosophila melanogaster* when parents were aged. These trans-generational effects can also be sex-biased, as aged female *Drosophila* appear to have a stronger negative influence on the longevity of their daughters, whereas aged males have some influence on the longevity of their sons.

Here we studied the effect of aging on neurodevelopment in the progeny in terms of changes to basic social behaviors such the social spacing between individuals and social avoidance of stressed flies. We also investigate the trans-generational effect on social behavior on progeny whose parents have been aged.

We have found that at older ages (30 days old, 90% survival and 50 days old, 50% survival) the distance between neighboring *Drosophila* increases, indicating that they are less social. Similarly, the social spacing between the progeny of aged *Drosophila* is also increased as compared to those with young parents. This suggests that the aging process contributes heritable change to the developing brain and therefore changes to social spacing. This also may indicate different aging mechanisms in germ cells versus somatic tissues resulting in a stronger effect in the progeny of aged parents than in the parents. Interestingly, the ability of individuals to avoid aversive stimuli is maintained throughout age and does not change the parents are aged, displaying maintenance of some social behaviors with age. We also show that it is enough to have an old father for the sons to be less social. We are currently investigating the effect of aged mothers as well.

We recapitulate the effect of old age of the parents on social spacing of their progeny by accelerating the aging process though increased metabolism (aging flies at 29C instead of the usual 25C) or via reactive oxygen species exposure (paraquat). In contrast, with delayed aging of the parents through caloric restriction, the progeny appeared more social.

Understanding the impact of aging is especially important as recently individuals with neuropsychiatric disorders like autism and schizophrenia have been linked to fathers over the age of 45. And although it is still unclear how exactly the aging process affects gametes leading to changes in neurodevelopment and thus specific social behaviors, the powerful model system *Drosophila* and its underused ability to display simple social interactions will allow us to identify the underlying mechanisms.

D1316A Elevation of Dube3a in glia, but not neurons, produces synaptic changes and susceptibility to seizure. *K. Hope*, L. Reiter. UTHSC, Memphis, TN.

Duplications of chromosomal region 15q11.2-q13.1 cause Duplication 15q (Dup15q) syndrome, characterized by a high incidence of autism spectrum disorder (ASD), seizures, and cognitive impairment. This duplication includes the *UBE3A* gene, and elevated levels of UBE3A in neurons are thought to be the primary cause of Dup15q syndrome. *UBE3A* overexpression in other cell types has been largely unexplored. Evidence from mouse models indicates that *UBE3A* is bi-allelically expressed in glial cells and maternally expressed in neurons. Duplications of the *UBE3A* locus should cause elevated UBE3A in glia as well as neurons. Here we elevated the fly homolog (*Dube3a*) in glial cells and evaluated Dup15q related phenotypes. We found that elevated *Dube3a* levels in glia results in a robust seizure susceptibility phenotype absent in animals overexpressing *Dube3a* in neurons. To identify changes in gene expression, we performed RNAseq and identified 497 differentially expressed transcripts in *elav>Dube3a* animals (neuronal expression) and 1,222 differentially expressed transcripts in *Repo>Dube3a* animals (glial expression). 854 transcripts were differentially expressed in glia compared to neurons and showed significant enrichment in synaptic transmission, substrate specific channels, and neurotransmitter synthesis. Transcript expression of the presynaptic active zone protein *bruchpilot* was reduced by 2-fold in glial versus neuronal overexpression of *Dube3a*, and a similar reduction was observed at the protein level. Interestingly we saw no change in the neuronal marker elav in the brain, indicating that the reduced expression of presynaptic proteins is not due to a loss of neurons. Furthermore, a reduction of on/off transients was observed in electroretinograms of flies overexpressing *Dube3a* in glia, indicating impaired synaptic transmission. These results demonstrate that elevated levels of Dube3a in glial cells drive changes in key neuronal functions that may underlie Dup15q seizure phenotypes. We observe a similar seizure susceptibility phenotype when human *UBE3A* is overexpressed in fly glial cells, potentially indicating a conserved mechanism between fly and human *UBE3A* in seizure production. Currently we are working to identify the causal genes mis-regulated in glia and the nature of impairment between glia and neurons that result in seizure susceptibility due to glial *Dube3a* overexpression. These studies may lead to the identification of new genes and pathways for novel epilepsy treatments in Dup15q syndrome..

D1317B Social Isolation Induced Depressive Like Behavior in *Drosophila Melanogaster*. *D. Hu*, L. Liu. Peking University, Beijing, China.

Major Depressive Disorder (MDD) is an idiopathic neuropsychiatric disorder that is highly prevalent. The exact cause and mechanism of the illness are still unclear. To help investigate MDD, we proposed utilizing *Drosophila Melanogaster* as the model organism. In order to induce depressive like behavior, a chronic stress has to be used. When social isolation was used as a stressor, wild type fruit flies exhibited locomotor hyperactivity when compared with control. Similar behavior was observed when mice was given chronic unpredictable mild stress (CUMS). The locomotor hyperactivity was found to be dependent on physical interaction among the flies. It was also found that social isolation reduced the brain serotonin content in the flies, which is concurrent with the monoamine hypothesis. To confirm this possibility, we fed the flies with serotonin or monoamine based antidepressants and found these drugs could reverse the social isolation induced locomotor hyperactivity. Since neurogenesis is theorized to be the mechanism behind MDD, we tested this possibility by performing real time PCR on related genes, such as CREB. It turned out that socially isolated flies had lower CREB expression in the brain versus socially housed flies. Epigenetics were

theorized as a possible mechanism that suppressed CREB expression. To test this, we fed several HDACi and DNMTi drugs to the flies. Certain epigenetic inhibitors were indeed capable of reversing the locomotor hyperactivity. These data suggest that Drosophila Melanogaster can be utilized in the research of MDD, and that epigenetics is causatively related to MDD. Further research into this model shows promise in the hope of procuring a treatment for MDD.

D1318C Identifying new modulators of blood cell development using *Drosophila* as a low complexity model of human myeloproliferative neoplasms. *Alessandro Bailetti*, Abigail Anderson, Elizabeth Rodkin, Erika Bach. New York University School of Medicine, New York, NY.

Myeloproliferative neoplasms (MPNs) are clonal hematopoietic disorders that cause over-proliferation of specific myeloid lineages. More than 95% of patients with polycythemia vera, one type of MPN, have a point mutation in the *JAK2* gene ($JAK2^{V617F}$), which generates a constitutively-active JAK2 that hyperactives the JAK/STAT pathway. In *Drosophila,* JAK/STAT signaling is conserved but simplified, with a single JAK Hopscotch (Hop) and a single STAT (Stat92E). $hop^{Tum\text{-}l}$ is a dominant, temperature-sensitive allele of *hop* that hyperactivates the JAK/STAT pathway. Similar to $JAK2^{V617F}$-bearing MPN patients, $hop^{Tum\text{-}l}$ mutants have dramatically increased number of myeloid-like cells, which leads to melanotic tumors. The $hop^{Tum\text{-}l}$ tumor phenotype is dependent on JAK/STAT signaling, and reducing one copy of *Stat92E* in $hop^{Tum\text{-}l}$ flies strongly suppresses the tumor burden. Based on this dominant modification of the tumor burden by reduction in *Stat92E*, we hypothesize that reducing the dose of genes involved in JAK/STAT signaling or in hematopoiesis will enhance or suppress the tumor incidence or burden in $hop^{Tum\text{-}l}$ flies. Given the conservation of the pathway, our screen may identify genes that modify the $hop^{Tum\text{-}l}$ phenotype and that have human homologs which may be involved in MPNs.

We conducted a dominant deficiency screen of the right arm of the second chromosome. We tested 90 deficiencies in the Bloomington kit, which together uncovers 98.5% of 2R euchromatin. We have identified 11 enhancer and 8 suppresser deficiencies. A deficiency that uncovers *Enhancer of Polycomb [E(Pc)]* significantly enhances melanotic tumor burden and larval/pupal lethality in $hop^{Tum\text{-}l}$ animals. This enhancement was recapitulated by heterozygosity for *E(Pc)* alleles. To test if *E(Pc)* has a role in blood development, we depleted *E(Pc)* from hematopoeitic tissue. *E(Pc)* depletion promoted differentiation of lamellocytes, which are absent in control animals. Additionally, larval hemolymph bleeds of *E(Pc)* depleted animals revealed microtumors and small melanotic tumors, that are not present in in control larvae. E(Pc) is a highly conserved protein and regulates transcription through the Polycomb Group (PcG) factors. Recently, E(Pc) also was shown to function as part of the Tip60 complex, a chromatin remodeling complex. To further characterize the *E(Pc)* phenotype, we are first assessing if heterozygosity for PcG and Tip60 complex genes also enhance the tumor burden in $hop^{Tum\text{-}l}$ animals. Second, we are hematopoietically depleting PcG or Tip60 complex genes in control larvae to assess if their depletion also leads to blood cell abnormalities. Our current data support the model that E(Pc) represses genes necessary for lamellocyte differentiation.

D1319A Genetic analysis of invasive pathways engaged by the EcR-coactivator protein Taiman. *P. K. Byun*, K. H. Moberg. Emory University, Atlanta, GA.

The transformation of non-motile epithelial cells to a migratory state plays a significant role in normal development and diseases such as cancer. During *Drosophila* oogenesis, a specialized group of cells termed border cells (BCs) acquire the ability to detach from their host epithelium and migrate through surrounding cells to the posterior end of the oocyte. The steroid receptor transcriptional co-activator *taiman* (*tai*) plays an important role in promoting this motility process, but its downstream transcriptional targets remain poorly defined. Here we introduce a novel, pathogenic model of Tai-driven tissue invasion that allows for rapid genetic screening for elements of the Tai-induced transcriptional program. Overexpression of *tai* in non-motile pupal wing cells causes these cells to invade through adjacent thoracic cuticle and into internal tissues, leading to a high-penetrance adult phenotype of wing tips embedded into the thorax. Using this phenotype as the basis for a dominant-modifier screen led to identification of alleles of genes in the Hippo pathway as modulators of Tai-driven tissue invasion. Our published work shows that Tai and Yki (the downstream effector of the Hippo pathway) bind together and co-regulate target genes (Zhang et al, 2015). In support of this model, a version of Tai that cannot bind to Yki also cannot efficiently drive invasion of wing cells into the thorax. Genetic and transcriptomic analysis has identified candidate Tai-target genes involved in promoting wing cell invasiveness, including the extracellular serine protease *gastrulation defective* (*gd*) and the actin-remodeling complex protein *Arpc3B*. Data on *gd* and *Arpc3B* as putative transcriptional targets of Tai and Yki, and the roles of the Gd and Arpc3B proteins in driving the invasive process will be presented.

D1320B Understanding the mechanism of RIOK2 function in Glioblastoma. *A. S. Chen*, R. D. Read. Emory University, Atlanta, GA.

Glioblastoma multiforme (GBM), a tumor derived from glia and glial progenitor cells, is the most aggressive and prevalent form of primary brain cancer and is incurable. Amplification, mutation, and/or overexpression of the EGFR receptor tyrosine kinase and activating mutations in components of the PI3K pathway are common in GBM tumors, although the pathways that act downstream of EGFR and PI3K to drive tumorigenesis remain poorly understood. To better understand the underlying biology of tumorigenesis, we use a *Drosophila melanogaster* GBM model in which malignant neoplastic tumors arise from glial progenitor cells overexpressing activated oncogenic versions of EGFR and PI3K. This *Drosophila* model was used in kinome-wide genetic screens that identified Right-Open-Reading-Frame-2 (RIOK2), an atypical serine-threonine kinase, as a possible driver of EGFR-PI3K-dependent GBM. Subsequent studies in patient-derived GBM cell cultures suggest that RIOK2 promotes GBM cell proliferation and survival in response to oncogenic EGFR and PI3K signaling, and that, interestingly, these effects are dependent on RIOK2 catalytic kinase activity. Our data strongly implicate RIOK2 in driving tumorgenesis; however, little is understood about RIOK2 function or downstream targets. Preliminary immunoprecipitation experiments of RIOK2 from patient-derived GBM cell cultures coupled with proteomics identified several RIOK2 binding proteins and potential substrates. We conducted subsequent experiments in *Drosophila* since *Drosophila* possess orthologs for all of the RIOK2 binding proteins, and the functions of *Drosophila* orthologs of many of these proteins are

evolutionary conserved. Using our *Drosophila* GBM model, we conducted a blind screen of all of our candidate RIOK2 substrates, and we discovered that RNAi against several mRNA-binding proteins drastically reduced aberrant glial cell proliferation and invasion similar to RIOK2 knock-down. These RNA binding proteins are involved in stabilizing and promoting the translation of their target mRNAs, several of which are known drivers of GBM that are overexpressed in response to oncogenic EGFR and PI3K signaling. Preliminary analysis of human GBM cells showed that, upon RIOK2 knockdown, protein levels were reduced for several of these target mRNAs. Based on our preliminary results all together, we hypothesize that RIOK2 drives tumorigenesis by modulating the activity of RNA-binding proteins involved in stabilizing and promoting the translation of their target mRNAs, and that this promotes the translation of target mRNAs that drive tumor cell proliferation and survival. Our study uses *Drosophila* as a model organism to better understand the mechanisms of GBM tumorigenesis and to gain insight into the biology of novel pathways that drive GBM.

D1321C An RNAi-mediated genetic screen identifies genes that promote tumour progression in a living epithelium. *Z. Cornhill*, A. Couto, N. Mack, B. Canales Coutino, U. Nagarajan, M. Georgiou. University of Nottingham, Nottingham, GB.

The complex process by which cancer cells invade local tissue and metastasise is responsible for approximately 90% of cancer related deaths. The cell biological events that underlie this transition to malignancy are driven by invariable alterations within the genome, however relatively little is known about the genetic determinants involved. If identified, novel genes which perturb the rate of tumour progression could become potential targets for future therapeutic intervention.

Using a novel in vivo system, it is possible to characterise the behaviour of transformed cells during the early stages of tumour development and follow these cells in real time, thus improving our understanding of the critical events that initiate cell proliferation, tumour cell invasion and metastasis. Using *Drosophila* as a model organism it is possible to generate neoplastic tumours within the dorsal thorax whereby clones of transformed cells are homozygous mutant for a specific tumour suppressor gene. By specifically labelling these transformed cells with GFP, their behaviour can be observed in high temporal and spatial resolution within the living epithelium. RNAi technology can also be employed to simultaneously knock-down expression of an additional gene specifically within the mutant tissue. This forms the basis of a large-scale screen for novel genes that may promote tumour progression in this epithelium.

So far we have screened through more than 400 genes, the majority of which have previously been implicated in cancer but remain uncharacterised. We have observed a wide range of phenotypes, with genes affecting cell proliferation, invasion, cell shape, actin organisation, junction integrity and epithelial multilayering. By setting 'thresholds' for particular phenotypes 'hits' have been identified which drastically enhance tumour progression, and these genes are in the process of being fully characterised to further our understanding of their role in tumour progression.

D1322A Genetic and mathematical dissection of tumor heterogeneity that triggers cancer progression. *M. Enomoto*[1], H. Naoki[2], D. Takemoto[1], T. Igaki[1,3]. 1) Lab. of Genet., Grad. Sch. of Bio., Kyoto Univ., Kyoto, Japan; 2) Imaging Plat. for Spat.-Temp. Info., Grad. Sch. of Med., Kyoto Univ., Kyoto, Japan; 3) PRESTO, JST.

Tumor heterogeneity plays an important role in cancer progression. However, the mechanisms of how clonal diversity is generated within the tissue and how such diversity causes tumor progression are poorly understood. Here, we found in *Drosophila* eye imaginal disc that oncogenic cell clones expressing Ras^{V12} or Src normally result in benign tumors but both develop into metastatic tumors when interact with each other. We found that Notch is upregulated in Src-activated clones while the Notch ligand Delta is upregulated in Ras-activated clones, leading to trans-activation of Notch signaling in Src-activated cells nearby Ras clones. Elevated Notch signaling in Src-activated cells causes tumor invasion cell-autonomously, while at the same time induces metastatic invasion of neighboring Ras-activated cells *via* upregulation of secreted growth factor Upd. Furthermore, we developed a mathematical model for cell population dynamics in the epithelium, in which Ras- and Src-activated clones exhibit proliferation and apoptosis depending on intercellular signaling between them. Through the simulation, we found that inter-clonal cooperation of Ras- and Src-activated tumors leads to expansion and persist activation of Notch and JAK-STAT signaling throughout the tissue, which generates highly heterogeneous cell populations with distinct oncogenic activities. This heterogeneity could cause symbiotic malignant tumors observed in the *Drosophila* imaginal discs.

D1323B Modeling the effects of the *Helicobacter pylori* virulence protein CagA on induced pathogenesis in *Drosophila*. *Tiffani A. Jones*, Karen Guillemin. University of Oregon, Eugene, OR.

Healthy gut microbiota, the complex consortia of resident microbes colonizing the human GI tract, influence aspects of health and normal development. An altered, or dysbiotic, microbial community can promote pathologic inflammation or hyperplasia, which can lead to a variety of diseases including cancer. Cancer-causing pathogens, such as *Helicobacter pylori,* can be associated with dysbiotic microbiota; however, whether dysbiotic communities contribute to *H. pylori* pathogenesis is unknown. Currently, many aspects of *H. pylori*-associated pathology are thought to be due to the action of the virulence protein CagA. CagA is translocated into host epithelial cells where it mimics a mammalian scaffold protein, alters cellular polarity, and manipulates host-signaling pathways that promote cell proliferation. We hypothesize that CagA also contributes to *H. pylori* pathogenesis by inducing microbial dysbiosis that contributes to cell proliferation and altered immune signaling.

Current animal models of *H. pylori* pathogenesis rely on infection with CagA positive strains to investigate the effects of CagA on host cell proliferation and disease progression. These models are limited because they cannot accurately disentangle the effects of the virulence protein from that of *H. pylori* or other microbes in the community. Using a transgenic *Drosophila* model of CagA expression within the gut epithelium we can genetically dissect the effects of CagA on the host epithelium from that of the pathogen or other microbial contributions. We have found that expression of CagA within host intestinal stem cells causes high rates of cell proliferation in the midgut epithelium. Our transgenic

model also revealed that the gut microbiota promotes some of the pathological proliferation, as flies derived germ free have lower levels of cell proliferation than conventionally reared flies. Notably, the gut microbiota in CagA transgenic flies differs from that of wild-type flies, such that the microbiota is sufficient to induce both overexpression of an anti-microbial peptide and cell proliferation in wild-type flies. This demonstrates the pro-proliferative capacity of the CagA transgenic fly microbiota.

This model of CagA expression establishes that a bacterial virulence factor alters the gut microbial community, which exacerbates cell proliferation and immune phenotypes previously associated with *H. pylori* infection. This reveals a previously unrecognized role for the surrounding gut microbes in *H. pylori* pathogenesis, which provides valuable new insights into the mechanisms by which interactions between a pathogen, its host, and the microbiota contribute to disease.

D1324C Novel inhibitor of cdk5 signaling axis suppresses self-renewal properties of glioblastoma stem cells and induces apoptosis. *Subhas Mukherjee*[1], Monica Chau[1], Carol Tucker-Burden[1], Changming Zhang[1], Jun Kong[2], Renee Read[1], Daniel Brat[1]. 1) Emory University School of Medicine, Atlanta, GA; 2) Emory University, Atlanta, GA.

Cancer stem cells exert enormous influence on neoplastic behavior, in part by governing asymmetric cell division and the balance between self-renewal and multipotent differentiation. Growth is favored by deregulated stem cell division, which enhances the self-renewing population and diminishes the differentiation program. Mutation of a single gene *Brain Tumor (brat)* in *Drosophila*, leads to disrupted asymmetric cell division resulting in dramatic neoplastic proliferation of neuroblasts. To uncover mechanisms relevant to deregulated cell division in human glioma stem cells, we developed a novel adult *Drosophila* brain tumor model in which *brat-RNAi* is driven by the neuroblast specific promoter inscuteable. Suppressing Brat in this population led to accumulation of actively proliferating neuroblasts and a lethal brain tumor phenotype. *brat-RNAi* also caused *Drosophila* eye-overgrowth when driven by the eye-specific promoter *ey-GAL4*, providing a valuable screening phenotype. Cdk5 signaling is critical for neurogenesis and has been found to be hyperactive in neurodegenerative diseases. Paradoxically, many cancers also show abnormal activation of cdk5 signaling that drives uncontrolled proliferation, suggesting a unique therapeutic strategy where suppressing CDK5 can kill cancer cells and save dying neurons at the same time. In a screen of kinases that might oppose the actions of *brat* mutation on stem cell proliferation, we found that genetic suppression of Cdk5 in *Drosophila* partially reversed the eye over growth phenotype following Brat knock down. There is almost 79% identity between *Drosophila* Cdk5 and human CDK5. Additionally, IDH1 wild type glioblastomas in human show significant upregulation of *CDK5* mRNA compared to its lower grade glioma counterparts. We translated our findings from *Drosophila* to patient-derived glioblastoma neurosphere cultures and *in vivo* xenograft tumors in mice, where we further demonstrated that a novel pharmaceutical suppressor of cdk5 signaling axis was capable of suppressing self-renewal properties and glioma stem cell viability by inducing apoptosis. Together, our results demonstrate a previously unappreciated role of the cdk5 signaling in glioma stem cell maintenance and survival and that suppressing cdk5 could be a novel therapeutic approach to specifically eliminate glioma stem cells.

D1325A Investigating novel roles for HELQ and BLM helicases in *Drosophila melanogaster*. *B. T. Sands-Marcinkowski*, M. McVey. Tufts University, Medford, MA.

In *Drosophila melanogaster*, the conserved 3' → 5' DNA helicases Bloom (BLM) and HELQ (DmMus301) have important roles in the maintenance of genomic stability, specifically in the repair of DNA double-strand breaks during homologous recombination. The Bloom helicase has both Holliday Junction dissolvase and D-loop/Rad51 filament disruptase activity, which both promote genomic stability by suppressing promiscuous crossover events and inappropriate strand invasion (recombination between regions of homeology, etc). DmMus301 mutants are deficient in both meiotic and mitotic break repair, and its human orthologue, HELQ, is involved in recombinational repair of double strand breaks. In this study, a synthetic larval-stage lethality between *blm* and *mus301* mutants was identified and analyzed. A *mus301* mutant lacking the helicase domain was combined with two different *blm* mutant alleles. The blm^{N1} mutant consists of a deletion which interrupts the helicase domain; the blm^{N2} mutant has a smaller deletion within the second exon, and does not interrupt the helicase domain. Crosses generating blm^{N1}*, mus301* and blm^{N2}*, mus301* double mutants produced both viable and synthetically lethal double mutant isolates for each combination of alleles. Interestingly, the timing of the lethality occurred at an earlier larval stage in the blm^{N2}*, mus301* double mutants, consistent with a dominant negative effect with the helicase-possessing BLM protein. We hypothesize that a third mutation on the *mus301* chromosome is responsible for the synthetic lethality and are currently using whole genome sequencing to identify this mutation. Taken together, our data suggest there are novel roles for the BLM and HELQ helicases outside of their functions in homologous recombination repair. Furthermore, the identification of a third mutation which causes the observed larval lethality in *blm, mus301* mutants will provide additional insight about their roles in maintaining genomic integrity.

D1326B A novel genetic screen in *Drosophila* designed to discover secreted factors that drive glioblastoma initiation and progression. *N. N. Shah*, R. D. Read, C. C. Rowe. Emory University, Atlanta, GA.

Glioblastomas (GBMs) are highly proliferative, invasive primary brain tumors derived from glia and glial progenitor cells, and are incurable with current treatments. GBMs often possess mutations that activate epidermal growth factor receptor tyrosine kinase (EGFR) and Pi-3 kinase (PI3K) signaling pathways. Studies show that additional factors and mechanisms in the tumor and the tumor microenvironment cooperate with EFGR and PI3K mutations to drive tumorigenesis, although the identity of these factors remains unclear. To address this problem, we sought to identify proteins that, when overexpressed and secreted into the tumor microenvironment, contribute to tumor initiation and progression in glial cells transformed by constitutive co-activation of EGFR and PI3K signaling. To test the activity of secreted factors on GBM initiation and progression, we used a GBM model in the fruit fly *Drosophila melanogaster* in which co-activation of EGFR and PI3K drives neoplastic transformation of glial progenitor cells. In the *Drosophila* GBM model, tumorous glia arise *in vivo* in the central nervous system in live

Drosophila larvae, and create large easily visualized tumors that kill their hosts in 5-6 days. Thus, this GBM model system allows us to view the effects of overexpressed secreted factors on tumorigenesis in an intact brain microenvironment. Using this *Drosophila* GBM model, we performed an enhancer/suppressor screen wherein individual overexpression constructs for nearly every secreted and transmembrane gene in the *Drosophila* genome were tested using the *Gal4-UAS* system for their phenotypic effects on tumor growth, tumor progression, over-all brain size, and host survival. Thus, both the cell-autonomous and cell-nonautonomous effects of the tested secreted factors were phenotypically assessed in our screen. From this screen, we identified several genes as candidate enhancers. Using immunohistochemistry and fluorescent microscopy to stain and image whole dissected brains from *Drosophila* larvae, we analyzed the phenotypes caused by overexpression of the candidate enhancer genes on neoplastic glia transformed by co-activation of EGFR and PI3K. The results of our screen and the phenotypes of candidate enhancers will be presented. Our findings could reveal novel genes that, if evolutionarily conserved in humans, may drive GBM initiation and progression in the brain.

D1327C Investigating the role of inflammatory cytokines on tumor progression and metastasis in a *Drosophila* cancer model. *K. SNIGDHA*, I. WAGHMARE, A. SINGH, M. KANGO-SINGH. UNIVERSITY OF DAYTON, DAYTON, OH.

Cancer cells are surrounded by the Tumor microenvironment (TME) - a unique milieu generated by the interactions between the normal cells surrounding the tumor cells. The TME supports the survival and proliferation of tumors. Current models suggest that cancer cells induce inflammation, and the TME responds by activation of an anti-inflammatory response. The core inflammatory pathways like Jun N-terminal Kinase (JNK), Tumor Necrosis Factor (TNF), Toll-like Receptor (TLR) and Immune Deficiency pathway (IMD) are conserved in *Drosophila* and likely participate in an evolutionarily conserved interaction amongst the TME and cancer cells. However, little is known about the molecular mechanisms underlying this interaction, and it is unclear if the inflammatory response is required for maintenance and progression of the tumor. We co-activated oncogenic *Yki* activity in *scribble* mutant epithelial cells by “flp-out” or GAL4 mediated drivers to model aggressively growing tumors in *Drosophila* epithelia. Our preliminary data showed that the key inflammatory pathway like TNF is induced in the neighboring normal cells whereas TLR and JNK pathways are upregulated in tumor cells. Using genetic interaction and epistasis approaches we have analyzed the effect of modulating levels of TLR and inflammatory cytokines on tumor growth and progression. Our research will help understand the interactions between inflammatory pathways and tumor progression in an *in vivo* model, and if targeting cytokine production in the TME or cancer cells is a useful strategy to suppress the growth and spread of cancer.

D1328A Development of new colon cancer models in *Drosophila* by a targeted genetic screen of cancer pathways. *N. Underwood*, J. Farrar, J. Ahlander. Northeastern State University, TAHLEQUAH, OK.

Drosophila melanogaster is emerging as a useful system to model cancer. Using a luciferase reporter gene, tumor growth in *Drosophila* gut tissue in response to oncogene activation can be quantified. Our goal is to develop new *Drosophila* models of colon cancer. We performed a targeted screen of genes in cancer pathways to identify candidates that show excessive tissue growth when expressed in adult gut tissue. Cancer genes affecting the PI3 kinase and receptor tyrosine kinase signaling pathways produced significant tissue growth relative to negative controls. Genes affecting G1 and G1/S phases of the cell cycle also produced a significant increase in tissue growth, whereas genes affecting G2 and M phases had little effect. Candidate genes from this study will be used for future experiments to understand why cells transformed by one cancer pathway or another may respond differently to chemotherapies.

D1329B Hipk promotes tumorigenesis through JAK/STAT signaling. *E. M. Verheyen*, J. A. Blaquiere, N. B. Wray. Simon Fraser Univ, Burnaby, BC, CA.

Signal transduction pathways are crucial for coordinated development and growth of multicellular organisms. Dysregulation and mutations of components in these pathways can often lead to tumourigenesis. The evolutionarily conserved Homeodomain-Interacting-Protein-Kinase (Hipk) is a potent growth regulator and elevated levels of Hipk in Drosophila lead to tumour-like masses resembling those found with activated JAK/STAT signaling. A point mutation similar to those seen in human blood cancers in the Drosophila Janus kinase (called hop) causes constitutive activation of the JAK/STAT pathway and results in blood cell tumours in larval and adult stages. We investigated whether Hipk causes tumours through JAK/STAT. First we show that elevated Hipk in blood cells phenocopies effects seen with the hyperactive form of Hop. Furthermore, Hipk induces enhanced proliferation of hemocytes. We find that reduction of Hipk can suppress the tumorigenic effects of activated Hop. RNAi against Hipk in hemocytes can suppress both the timing of lethality and the tumour load in activated hop flies. Furthermore, we find that Hipk is required for endogenous JAK/STAT pathway activity, since homozygous mutant tissue shows markedly reduced expression of a STAT reporter. To investigate the mechanism underlying this interaction, we performed a proximity ligation assay (PLA) between Hipk and STAT92E, the Drosophila STAT. Cells co-expressing Hipk and STAT92E show a robust PLA signal indicating an interaction. We are currently confirming this through in vitro and in vivo binding studies. Our work shows that Hipk is required for JAK/STAT signaling during normal development and in fly blood cancer.

D1330C A Wingless dependent Jun kinase-Yorkie signal amplification loop promotes tumor growth in *Drosophila* epithelial tumor models. *I. Waghmare*[1], A. Singh[1,2,3], M. Kango-Singh[1,2,3]. 1) Department of Biology, University of Dayton, Dayton, OH; 2) Premedical Programs, University of Dayton, Dayton OH; 3) Center for Tissue Regeneration and Engineering at Dayton (TREND), University of Dayton, Dayton, OH.

Cell-cell signaling interactions are of immense significance to both normal, and tumor cells. Alterations in these signaling interactions cause critical changes in cell behavior, and may underlie diseases like cancer where cells are capable of unrestrained proliferation. Studies in *Drosophila* imaginal discs have identified key cell-cell interactions like cell competition, and key molecular signals (Wingless, Dronc, Jun N-terminal Kinase, Yorkie) that regulate these intercellular interactions. These signals also play important roles during compensatory proliferation- a response that cells employ to restore tissue homeostasis. However, if these intercellular interactions are involved in the aggressive growth of cancers remains poorly understood. Using the well-established *in-vivo* clonal models in flies, we found that Ras^{V12}, $scrib^{-}$ cells behave like 'supercompetitor winner cells'. Furthermore, Wg, Dronc, JNK, and Yki are all upregulated in Ras^{V12}, $scrib^{-}$ cells, and downregulation of these signals leads to reduction in tumor growth suggesting that these signals are required for the growth of Ras^{V12}, $scrib^{-}$ tumors. We identified that Yki, and JNK activities are simultaneously induced in Ras^{V12}, $scrib^{-}$ cells, and JNK-Yki form a self-reinforcing positive feedback loop downstream of Wg and Dronc that plays a key role in promoting tumorigenesis in Ras^{V12}, $scrib^{-}$ cells. The signal amplification loop is important for aggressive tumor growth, as activation of this loop does not occur in instances where oncogenes are individually activated or when apical-basal polarity is lost. We have thus identified a novel molecular network in which Wg dependent activation of Dronc controls a JNK-Yki mediated positive feedback signal amplification loop that promotes tumor growth. Our findings are important because tumor cell specific molecular networks may generate key insights into signaling interactions during oncogenic cooperation, and therefore provide a powerful model for reconstructing key biologically meaningful changes in signaling pathways that drive growth, and altered signaling in cancer cells in flies and humans.

D1331A Diet rescues lethality in a model of a human deglycosylation disorder. *Clement Y. Chow*, Katie G. Owings. University of Utah, Salt Lake City, UT.

Autosomal recessive loss-of-function mutations in N-Glycanase 1 (*NGLY1*) cause *NGLY1* deficiency, the only known human disease of deglycosylation. Patients with *NGLY1* deficiency display developmental delay, movement disorder, hypotonia, and alacrima. NGLY1 is a conserved component of the endoplasmic reticulum associated degradation (ERAD) pathway. ERAD is responsible for degrading misfolded proteins that accumulate in the ER lumen under ER stress conditions. NGLY1 deglycosylates misfolded proteins in the cytoplasm as they are translocated from the ER lumen for degradation. While little is known about the pathogenesis underlying *NGLY1* deficiency, it is thought that loss of NGLY1 activity results in accumulation of highly N-glycosylated misfolded proteins in the cytoplasm, acting as a 'sink' for free UDP-GlcNAc. In turn, this might deplete the circulating pool of free UDP-GlcNAc in the cell, resulting in disease. We hypothesized that restoring the levels of UDP-GlcNAc in the cells might rescue some of the phenotypes associated with *NGLY1* deficiency. We used ubiquitous RNAi knockdown of *Pngl* (*Drosophila* ortholog of *NGLY1*) to model complete loss of NGLY1 activity seen in human patients. We show that supplementing the normal diet with GlcNAc can rescue lethality associated with loss of Pngl activity. When raised on normal food, without GlcNAc supplementation, we observed significant lethality, with eclosion of only 18% of expected *Pngl* knockdown adults. *Pngl* knockdown lethality occurs throughout larval and pupal development. When diet is supplemented with 100 ug/ml of GlcNAc, we observed significant rescue of the developmental lethality, raising the adult *Pngl* knockdown eclosion rate to nearly 70%. We also demonstrate that genetic alterations in the ERAD and cytoplasmic heat shock pathways can influence the lethality of *Pngl* knockdown. Finally, we provide evidence that GlcNAc rescue of lethality likely functions through the ERAD and cytoplasmic heat shock pathways. These data provide a plausible pathophysiology for *NGLY1* deficiency. More importantly, our study points to a potential therapy through a simple diet supplement.

D1332B Neuronal *Nhe3* (Solute Carrier Family 9, Subfamily A) depletion causes neurodevelopmental and behavioral defects in *Drosophila*. *Monique van der Voet*, Benjamin Harich, Michaela Fenckova, Barbara Franke, Annette Schenck. Radboud university medical center, Donders Institute for Brain, Cognition and Behaviour, Nijmegen, NL.

Members of the solute carrier family 9 (SLC9A1–9) are connected to a spectrum of neurodevelopmental disorders. Mutations in SLC9A6 cause syndromic X-linked intellectual disability Christianson-type, with microcephaly, epilepsy, and ataxia, and shows phenotypic overlap with Angelman syndrome. Mutations in SLC9A9 causes autism with seizures, and variants in the gene are associated with Attention Deficit Hyperactivity Disorder-related deficits.

The *Drosophila* homolog of human *SLC9A6* and *SLC9A9* is *Nhe3*. The protein codes for a Na^{+}/H^{+} hydrogen exchanger that is highly expressed in the brain. We have dissected *Drosophila* larvae to study the structure of synapses at the neuromuscular junction and dendritic branching of the class IV dorsal dendritic arborization C (ddaC) neurons. In addition we have performed behavioral characterization in adults, namely habituation and locomotor activity profiling.

We observe strong neurodevelopmental defects and behavioral aberrations, consistent with the neurodevelopmental defects observed in humans. We want to exploit this *Drosophila* model of early onset cognitive disorders to gain mechanistic insight in the neuronal defects and development clinical applications[1].

D1333C Functional screen of autism candidate genes using *Drosophila* studies *in vivo*. *M. F. Wangler*[1,2,3,4,5], Oz Kanca[1], Sathiya Manivannan[1], Xi Luo[1], Ning Liu[1], Matthew Lagarde[1], Yu-Hsin Chao[1], Hsiao-Tuan Chao[2,4,5], Shinya Yamamoto[1,2,3,4,6]. 1) Department of Molecular and Human Genetics, Baylor College of Medicine (BCM), Houston, TX, 77030; 2) Texas Children's Hospital, Houston, TX, 77030; 3) Program in Developmental Biology, BCM , Houston, TX, 77030; 4) Texas Children's Neurological Research Institite, Houston TX 77030; 5) Department of Pediatrics, Baylor College of Medicine, Houston, TX, 77030; 6) Department of Neuroscience, BCM, Houston, TX, 77030.

Autism spectrum disorders (ASDs) are a highly heritable developmental nervous system disorders with varying degrees of impaired social interaction, defects in verbal and non-verbal communication and repetitive behavior. Symptoms typically begin before age 3 years and are accompanied by cognitive deficits. There is significant locus heterogeneity as evidenced by a number of Mendelian disorders with ASD as a feature. In addition, several large genomic sequencing studies have been undertaken in thousands of families with as ASD proband. The incomplete functional annotation of the majority of genes in the human genome leads to problems in interpreting the results of these studies as the functional impact of variants is usually not known. Studies in model organisms such as *Drosophila* have consistently contributed to our understanding of gene function including genes involved in neuronal development, neuronal function and maintenance. We are conducting a functional screen in *Drosophila* to analyze ASD candidate genes. We examined whole-exome sequencing data from 2,500 families with a proband with ASD from the Simon's Simplex collection (SSC). Of these we focused on 2,437 human genes with *de novo* missense or in-frame indels in ASD cases. We focused on missense and in-frame alleles to study variants with unknown impact on gene function. Of these 1,931 genes (79.2%) are conserved in Drosophila. The ASD candidate genes are cross-referenced to independent genomic data from non-Autism cohorts in order to aid in prioritization. From a group of priority genes we have selected 62 *Drosophila* Mi[MIC] lines with insertions in introns between coding exons for functional screens. These lines are currently being converted to loss-of-function strains using the versatile artificial exonic element to generate a 2A-Gal4 line. These strains will be scored for viability, longevity, and a number of basic behavioral phenotypes. Strains with strong phenotypes will be studied for nervous system expression, knockdown and the human reference and ASD-related variant forms are being tested to determine the functional effect of the variants of interest. This synergy between human genomics and a versatile functional analysis pipeline in *Drosophila* should allow stronger links between the growing list of ASD candidate genes and the wealth of conserved neurobiology in model organisms.

D1334A Genome-wide association study to examine insulin resistance in a *Drosophila* model. *K. Slater*, B. Wininger, J. Stamm. University of Evansville, Evansville, IN.

Dietary factors can alter *Drosophila* metabolism and induce insulin resistance in a similar fashion as in humans. *Drosophila* therefore provides a simple and genetically tractable model for identifying genetic factors associated with human diabetes. We are carrying out a genome-wide association study to identify genomic regions that contribute to the development of insulin resistance, using the *Drosophila* Genetic Reference Panel (DGRP), a collection of ~200 fully sequenced inbred *Drosophila* lines.

Mated females from each line were fed either a normal diet or a high sugar, insulin resistance-inducing diet, and weight gain, fertility, and lifespan were measured under each dietary condition. We have completed the analysis for 30 lines, and have identified several lines in which the high sugar diet had an extreme effect on these traits. We are currently verifying these results with metabolite assays, and continuing our analysis of additional DGRP lines to identify correlations between particular genomic regions and increased or decreased susceptibility to insulin resistance. Our efforts will lead to increased understanding of the genes underlying insulin resistance and type II diabetes.

D1335B Enteroendocrine cell-derived Act-β enhances AKH action and contributes to hyperglycemia under a high sugar diet. *W. Song*[1], D. Cheng[1], S. Hong[2], B. Sappe[1], Y. Hu[1], N. Wei[1], M. O'Connor[3], P. Pissios[2], N. Perrimon[1]. 1) Department of Genetics, Harvard Medical School, Boston, MA; 2) Division of Endocrinology, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, MA; 3) Department of Genetics, Cell Biology and Development, University of Minnesota, Minneapolis, MN.

Insulin and glucagon play fundamental and counteractive roles in carbohydrate homeostasis. In addition to insulin resistance, enhanced glucagon action also contributes to hyperglycemia in the context of high caloric diet. In contrast to the wealth of knowledge regarding insulin action regulation, little is known about the physiological regulation of glucagon signaling. To identify new regulators of glucagon signaling, we established a conserved glucagon-induced hyperglycemia model in Drosophila overexpressing fly glucagon encoded by Akh (Adipokinetic hormone). We combined in vivo RNAi screen and genetic validation and identified the activin type I receptor, Baboon (Babo), and one of its ligand, Activin-β (Actβ), as important regulators of glucagon/AKH signaling. Deficiency of Babo or Actβ significantly impaired AKH action in the fat body which is equivalent to the liver, and abolished hyperglycemia associated with high-sugar diet in Drosophila. Importantly, Actβ production in enteroendocrine cells was significantly increased and promoted fat body AKH action and elevated glycemic level in response to high-sugar diet. Finally, we found that in mouse primary hepatocytes Activin A treatment potently enhances glucagon signaling as well as glucagon-induced glucose production. In summary, we have identified an evolutionarily conserved mechanism whereby activin signaling enhances glucagon action to impact hyperglycemia and/or diabetes pathogenesis.

D1336C The Spen family of RNA-binding proteins coordinate energy balance in the fatbody. *T. Reis*, K. Hazegh. Univ Colorado Medical School, Aurora, CO.

Hereditary components are responsible for 40-70% of variation in body weight and obesity, yet we currently know only ~5% of the underlying causal genes. In order to develop new treatments for obesity, we must develop a mechanistic understanding of the pathways in which the other 95% of predisposing alleles normally function. We previously developed a novel, buoyancy-based assay for body fat in *Drosophila* larvae and used it in an unbiased forward genetic screen to identify *split ends* (*spen)* as a new fat regulator. Spen is an RNA-binding protein previously

implicated in transcriptional control of conserved signaling pathways. Interestingly, despite being fat, larvae in which Spen is depleted from the fat body (FB) are sensitive to starvation, suggesting that these animals are incapable of using their excess fat stores. Consistent with this phenotype, metabolomics and RNAseq demonstrate metabolic alterations in Spen-depleted FBs indicative of a defect in mobilization of energy stores, and utilization of other metabolites (proteins and carbohydrates) as primary sources of energy. We further find that Spen function is necessary and sufficient to promote fat depletion in the FB, and that another Spen family member, Spenito (Nito), plays an opposing role in fat storage. FB overexpression of an N-terminal Spen fragment containing the RNA Recognition Motifs (RRMs) causes a dominant-negative high-fat phenotype, whereas overexpression of a C-terminal fragment lacking the RRMs but containing a nuclear localization signal and the conserved Spen paralog and ortholog (SPOC) domain had no effect on larval buoyancy. Thus, the RRMs are required for the ability of overexpressed full-length Spen to deplete fat stores, and when overexpressed alone may sequester important Spen-associated RNAs into non-functional complexes. We propose that Nito, which contains RRMs and a SPOC domain but is much smaller than Spen, may act as a negative regulator of Spen function. Finally, we find that the mammalian Spen ortholog also regulates fat storage in cultured adipocytes. No other study has implicated Spen in the regulation of metabolism or body fat control. Our work provides a new direction for understanding metabolic disease as well as a molecular handle to generate novel mechanistic insights into the causes of obesity.

D1337A Cardiomyocyte regulation of systemic lipid metabolism by the apoB-containing lipoproteins in *Drosophila*. *Hui-Ying Lim*[1,2,4], Sunji Lee[1], Hong Bao[1], Weidong Wang[3,4]. 1) Aging and Metabolism Research Program, Oklahoma Medical Research Foundation, Oklahoma City, Oklahoma; 2) Department of Physiology, University of Oklahoma Health Science Center, Oklahoma City, Oklahoma; 3) Department of Medicine and Harold Hamm Diabetes Center, University of Oklahoma Health Sciences Center, Oklahoma City, Oklahoma; 4) Corresponding authors.

Lipid dysregulation is a key contributor to the pathogenesis of obesity and its related disorders. The heart has emerged as an important organ in the regulation of systemic lipid homeostasis; however, the underlying mechanism remains poorly understood. Here, we show that *Drosophila* cardiomyocytes control systemic lipid metabolism by expressing *mtp* and *apoLpp*, genes so far known to be essential for apoB-lipoprotein biosynthesis only in the fat body (insect adipose tissue and liver). We found that on normal food diet, knockdown of *mtp* or *apoLpp* in the fat body or cardiomyocytes decreases systemic triglyceride (TG) levels, suggesting equal contribution of the cardiomyocyte- and fat body-derived apoB-lipoproteins in the regulation of whole-body lipid metabolism. Unexpectedly, on high fat diet (HFD), knockdown of *mtp* or *apoLpp* in the cardiomyocytes, but not in fat body, protects against the gain in systemic TG levels, suggesting that cardiomyocyte-derived apoB-lipoproteins are the predominant regulators of systemic lipid metabolism in response to HFD. We further found that HFD significantly up-regulates *mtp* and *apoLpp* expression in the cardiomyocytes, but paradoxically down-regulate their expression in the fat body, culminating in higher Mtp and apoLpp levels in the cardiomyocytes than in fat body and possibly underlying the differential systemic metabolic effects of apoB-lipoprotein inhibition in the cardiomyocytes versus the fat body. Our findings reveal a novel and significant function of heart-mediated apoB-lipoproteins in the control of systemic lipid homeostasis.

D1338B Investigating Mitochondrial Respiratory Chain Disorders(MRCD) in *Drosophila*. *K. Ohnuma*[1], Y. Sato-Miyata[1], Y. Kishita[2], M. Kohda[2], K. Murayama[3], A. Ohtake[2], Y. Okazaki[2], T. Aigaki[1]. 1) Tokyo Metropolitan University, Tokyo, Japan; 2) Saitama Medical University, Saitama, Japan; 3) Chiba Children's Hospital, Chiba, Japan.

Mitochondrial respiratory chain disorders (MRCD) are rare diseases that affect multiple organs with varying severity. MRCD can be caused by mutations in mitochondrial or nuclear genes. At present, approximately 250 nuclear genes have been identified as candidates for MRCD. However, the pathogenic mechanisms of MRCD are not fully understood. Model organisms provide unique opportunities to study molecular basis of human diseases. The fruit fly, *Drosophila melanogaster* is one of the best model organisms, in which one can utilize advanced knowledge and techniques of genetics, and a large number of resources, such as mutant stocks, and cDNA collections. Here, we established *Drosophila* models of MRCD through knocking down the orthologs of 13 human MRCD candidate genes identified in Saitama Medical University. We used the Gal4/UAS system-mediated transgenic RNAi to produce knockdown (KD) flies for each candidate gene, and analyzed MRCD-related phenotypes. Among the candidate genes (MRCD1-13), MRCD11-KD flies exhibited remarkable phenotypes: reduced body size and severe defects in locomotor activity, respiratory dysfunction and short lifespan. In addition, biochemical analysis revealed that they have symptoms of lactic acidosis and mitochondrial respiratory chain complex I defects which were similar to symptoms of the MRCD patient. These results suggested MRCD11 gene is a causative gene for MRCD. MRCD11-KD flies should be useful as a model to investigate the role of the gene and to understand the molecular pathogenesis of MRCD.

D1339C Untargeted metabolomics elucidates the role of diet and triglyceride storage in *Drosophila melanogaster* larvae. *Vishal Oza*, Laura Reed. Department of Biological Sciences, University of Alabama, Tuscaloosa, AL.

Untargeted Metabolomics has been used to identify altered metabolic pathways in disease state. Here we employ ***Drosophila*** as a model organism to evaluate various aspects of Metabolic Syndrome (MetS), a complex disease that increase the risk for heart disease and diabetes. The prevalence of MetS has been attributed to the westernized dietary habit and sedentary lifestyle. Our previous studies have established, diet as one of the important contributors to metabolic phenotypes. Using untargeted metabolomics we have isolated and identified global metabolites in ***Drosophila*** larvae. We then employed Random Forest algorithm to obtain important metabolites that differed between the High fat (HFD) and normal (ND) diet as well as between reaction norm phenotypes (flies that store more triglyceride on normal diet and flies that store less triglyceride on normal diet). We found that in flies fed on HFD had an upregulation of the omega fatty acid oxidation pathway which is an alternative to the more common beta fatty acid oxidation. Furthermore, there was no correlation observed between triglyceride storage phenotype and fatty acids, indicating diet played more important role over triglyceride phenotype. In conclusion, although untargeted

metabolomics allows for elucidation of global metabolic profile, the lack of ***Drosophila*** specific metabolites and pathways database hinders the use of ***Drosophila*** as a model organism for metabolomics studies.

Keywords: Untargeted metabolomics, *Drosophila melanogaster*, *Drosophila* metabolomics.

D1340A The power of food: how diet during development programs adult lifespan. *Irina Stefana*[1,2], Paul C. Driscoll[1], Fumiaki Obata[1], James I. MacRae[1], Alex P. Gould[1]. 1) Francis Crick Institute, Mill Hill Laboratory, London, United Kingdom NW7 1AA; 2) Current address: Dept. of Physiology, Anatomy and Genetics, University of Oxford, South Parks Road, Oxford, United Kingdom OX1 3QX.

The developmental origins of adult health and disease are well established in human populations and mammalian models. For example, malnutrition during early life predisposes the future adult to an increased risk of metabolic disease. Despite much research in this area, the molecular mechanisms underlying this process of nutritional programing remain poorly understood. We have therefore established a *Drosophila* model for programing of adult metabolism and lifespan by the diet during development. We show that larval diet can program long-lasting perturbations of metabolism in adult flies. Importantly, larval diet can also dramatically increase median lifespan by up to 145%, a larger change than that obtained with adult dietary restriction (DR). Genetic manipulations suggest that the altered size of Insulin producing cells – analogous to β-cell mass in mammals – can explain only ~10% of this programed lifespan increase. We find, instead, that the programing mechanism depends upon endogenous compounds deposited onto the substrate, which alter the lifespan of both same- and opposite-sex adults. This reveals, for the first time, the existence of a transferrable component in the regulation of lifespan between same-sex animals. Biochemical, NMR, mass spectrometry and genetic approaches identify these compounds as a specific class of lipids that impact negatively upon lifespan in a dose-dependent manner. Importantly, the production of these toxic lipids by adults is programed by diet during development. We also find that the lifespan-extending effect of decreased Insulin signaling correlates with increased resistance to toxic lipids. Together, these findings establish *Drosophila* as a powerful new integrative physiology model for uncovering new mechanisms underlying the nutritional programing of metabolism and lifespan.

D1341B Investigating the effect of acute injury on gene expression in the embryonic *Drosophila* nerve cord. *S. Benjamin*, H. Mistry. Widener University, Chester, PA.

In humans, spinal cord injuries can have long-term physical effects due to critical cellular and molecular changes that occur during the acute phase of injury. To better understand the cellular and molecular mechanisms underlying these critical and complex injuries, we are using the *Drosophila* embryonic nerve cord as a model to assess the effect of acute injury on gene expression. We anchored late stage embryos on coverslips and injured the ventral nerve cord using a glass needle. Control embryos were similarly treated, but not injured. Experimental and control embryos were harvested and total RNA was extracted from each sample. High-quality RNA thus generated was sequenced and analyzed. These data show that the expression levels of 700 genes changed significantly in the injured embryos in comparison to the uninjured embryos. The differential gene expression changes thus revealed are likely characteristic of the acute phase of trauma. We have functionally categorized these genes using specific gene ontology terms. We will first analyze genes pertinent for the regulation of cellular processes involved in axon guidance, synapse growth, and the mitotic cell cycle.

D1342C Actin isoforms in *Drosophila* muscle function. *T. Dohn*, R. Cripps. University of New Mexico, Albuquerque, NM.

Actins are critical components of sarcomere structure and muscle function. Mammals and *Drosophila* each have six actin genes that exhibit distinct expression patterns spatially and temporally. Although the actins are highly conserved sequences they maintain distinct biochemical properties and affinities within the cell. Regardless, some of the actin isoforms can partially compensate for each other, making it unclear what the role of specific actin isoforms are during muscle formation and development. Therefore, using CRISPR technology we created two *Drosophila* actin mutants to determine the role of each actin in muscle development and function. *Actin57B* is a predominantly embryonic muscle actin isoform and *Actin79B* is the predominant actin isoform expressed in the *Drosophila* tergal depressor of the trochanter (TDT or jump) muscle. Mutations of each gene were created leading to null mutants. Through viability assays and structural analysis of embryonic muscles we determined that depletion of *Actin57B* results in an embryonic lethal phenotype with disrupted sarcomere structure. Although there is an increase in *Actin87E* mRNA by *in situ* hybridization, this increase is insufficient to rescue the sarcomere structural defects in *Actin57B* embryos. *Actin79B* deficient flies were structurally and functionally normal, showing a normal jumping ability despite the loss of the predominant jump muscle actin. This rescue of jump muscle function is due to compensation by low levels of *Actin88F* expression in the jump muscles. Double mutants deficient in both *Actin79B* and *Actin88F* show deficiencies in TDT muscle function. Therefore, *Actin57B* and *Actin79B* have distinct roles in muscle structure organization, however, *Actin57B* deficiency cannot be compensated for by increased levels of embryonic *Actin87E* while *Actin79B* deficiency is completely rescued by low levels of *Actin88F.* This demonstrates that secondary actin genes will expand their expression domain to compensate for deficiencies in other actin isoform, however, this genetic expansion does not necessarily translate to functional compensation.

D1343A Developmental causes of Nemaline Myopathies. *Aaron N. Johnson*, Brenna Clay. Univ Colorado, Denver, Denver, CO.

Congenital myopathies are a heterogeneous collection of disorders defined by neonatal muscle weakness, or hypotonia, and many myopathies can progress to extreme conditions in which patients require clinical interventions for proper respiration and mobility. Over 23 distinct heterozygous mutations in *Tropomyosin 2* (*TPM2*) have been identified in patients with Nemaline Myopathy (NM), yet the mechanisms by which these mutations contribute to the disease phenotype remain largely unknown. The current clinical hypothesis is that *TPM2* NM alleles are gain-of-function mutations that disrupt sarcomere contractility in otherwise normal muscle. Based on our previous developmental

studies, we hypothesized that *TPM2* NM alleles also disrupt multiple aspects of myogenesis prior to sarcomere assembly. We expressed 9 human *TPM2* NM alleles in *Drosophila* embryonic body wall muscles and assayed muscle development. Each *TPM2* NM allele disrupted myogenesis, and multiple alleles caused myotubes to attach to the wrong tendon or to no tendon at all. These results strongly support our hypothesis that the NM disease etiology is due in part to defects in myogenesis. This is the first study to systematically characterize *TPM2* NM alleles in an *in vivo* system, and highlights the utility of using *Drosophila* genetics to functionally annotate human disease alleles. Our studies will also be a foundation for studying *TPM2* NM alleles during mammalian myogenesis.

D1344B Using *Drosophila* to uncover the molecular mechanisms underlying Pontocerebellar Hypoplasia. *Vafa Bayat*[1], Xue Yang[1,2], Zhihao Wu[1], Yen-Chi Wu[1], Hannes Vogel[1], Bingwei Lu[1]. 1) Stanford University, Stanford, CA; 2) Peking University, Beijing, China.

The molecular and cellular pathology of the neonatal/fetal disease Pontocerebellar Hypoplasia (PCH) is poorly understood. PCH is a rare congenital disorder displaying autosomal recessive inheritance characterized by hypoplasia and atrophy of the cerebellar cortex, dentate nuclei, pontine nuclei and inferior olives. A growing number of mutated genes have been implicated in this disease. Several hypotheses have been proposed regarding the relationships between these recently identified genes and the potential mechanisms, but evidence is lacking. Molecular genetic analysis in model organisms such as *Drosophila* has the potential to make up for the deficits in our understanding of PCH pathogenesis and offer more in-depth mechanistic insights. We have obtained and are generating mutants using imprecise excision and CRISPR in all of the TSEN complex genes, which have all been found to be mutated in this disease. Our data is supportive of a neurodegenerative process taking place in these mutants and our hypothesis that dysregulation of levels of key proteins implicated in other neurodegenerative diseases is present and are testing which of these are pathogenic using genetic interactions with RNAi lines, loss of function lines and overexpression. Determining which pathways and proteins are involved in the pathogenesis will also give clues to potential treatments, which are presently only supportive in nature.

D1345C Activation of lipophagy protects neurons from neurodegeneration caused by sphingolipid imbalance. *Y. Chang*[1], W. Jung[1], C. Liu[1], Y. Yu[1], W. Lien[1], H. Chao[2], C. Kuo[2], H. Ho[3], C. Chan[1]. 1) Graduate Institute of Physiology, College of Medicine, National Taiwan University, Taipei, Taiwan; 2) School of Pharmacy, College of Medicine, National Taiwan University, Taipei, Taiwan; 3) Department of Anatomy, School of Medicine, Tzu-Chi University, Hualien, Taiwan.

Sphingolipids are essential membrane components of the neuron; hence their levels need to be tightly regulated. Infertile crescent (Ifc) is an evolutionarily conserved dihydroceramide (DHC) desaturase which converts DHC to Ceramide (Cer) for the *de novo* synthesis of Cer in *Drosophila*. While the imbalance of Cer, a bioactive sphingolipid, has been associated with several neurodegenerative diseases, the neuronal function of its precursor DHC remains unknown. To investigate the role of *ifc*, we generated *ifc* knockout flies (*ifc*-KO). Sphingolipidomic analysis showed that loss of *ifc* resulted in increased DHC. Prolonged light stimuli to the *ifc*-KO eye led to activity-dependent degeneration of photoreceptors. Clonal analysis of *ifc*-KO photoreceptors revealed the accumulation of lipophagic structure and the increased H2DCF signals upon light stimuli, suggesting that DHC accumulation may activate lipophagy and induce the production of reactive oxygen species (ROS). However, it remains to be determined whether the degeneration is attributed to lipophagic cell death or the ROS insults. Reduction of *ifc* led to the increase of Atg8/LC3 puncta in the acidified compartment and elevation of lysosomal proteases, indicating the activated lipophagy can promote subsequent lysosomal function. *ifc*-dependent neurodegeneration can be partially rescued by an antioxidant AD4, indicating that ROS is at least partially responsible for the degeneration. In addition, both ROS elevation and lipid accumulation in *ifc*-KO was suppressed by treating with the autophagy inducer Rapamycin, suggesting that enhanced lipophagy plays a protective role in *ifc*-dependent neurodegeneration. Conversely, lipophagy can be downregulated by AD4, indicating ROS insults lead to the feedback upregulation of protective lipophagy. In summary, loss of *ifc* results in DHC accumulation and ROS generation, the latter of which subsequently activates lipophagy to protect against neurodegeneration. These findings support our hypothesis that DHC is bio-active and lipophagy can be protective, highlighting their potential as therapeutic targets for regulating sphingolipid homeostasis.

D1346A Knockdown of the Sleep and Circadian Rhythm-Regulating Protein Insomniac Exacerbates Decreased Longevity in a *Drosophila* model of Alzheimer's Disease. *Thomas S. Finn*, Tyler Dewitt, Sarah Deleon, Jeremy C. Lee. University of California, Santa Cruz, Santa Cruz, CA.

Alzheimer's Disease (AD) is the leading cause of dementia in the elderly population, currently affecting over 5 million Americans. AD is characterized by an accumulation of extracellular plaques composed of Amyloid-beta (Aβ) peptides as well as accumulation of intracellular neurofibrillary tangles (NFTs). Recently, it was reported that patients with AD who also suffer from low sleep quality, have increased Aβ deposition in the brain compared to patients with AD that experience normal sleep patterns. Experiments in mice have shown that sleep is associated with a 60% increase in the interstitial space of the brain and greatly increases the rate at which Aβ is cleared (Xie, *et al.*, 2013). In a recent Genome Wide Association Study, the KCTD2 locus in humans was further implicated in AD (Boada, *et al.*, 2013). Interestingly, homologs of this locus are present in many animal models, such as the *insomniac* locus in *Drosophila*. Loss-of-function mutations of *insomniac* result in a severe sleep deprivation and dysfunction in circadian regulation (Stavropoulos & Young, 2011; Pfeiffenberger & Allada, 2012).

We have conducted experiments to test the effects of sleep and/or circadian dysfunction on AD-like pathology in a *Drosophila* model of AD. Our central hypothesis is that inducing sleep deprivation/circadian dysfunction, as a result of knocking down Insomniac, will accelerate and increase Aβ deposition, resulting in more severe AD-like pathology. To test this hypothesis, we are using a *Drosophila* AD model that expresses human Aβ42 in the CNS under an *elav*-Gal4 driver. These flies exhibit decreased longevity as compared to control flies; they also exhibit abnormal behavior and deposition of Aβ aggregates in the brain. In these AD model flies, we have knocked down Insomniac levels by also expressing shRNA that targets *insomniac* mRNA. We find that the severity of AD-like pathology, as measured by decreases in longevity, are

significantly exacerbated by knocking down Insomniac levels; i.e. the AD model flies in which Insomniac is knocked down have a shorter mean lifespan than AD model flies which express wild type levels of Insomniac. This exacerbation of the longevity defect appears to be an interaction between the Insomniac knockdown and the effects of Aβ, and is not simply an additive effect on longevity. Control flies only expressing the Insomniac shRNA showed no deviation in their survivorship compared to wild-type flies. We are currently conducting experiments to assess whether the knockdown of Insomniac also exacerbates other aspects of AD-like pathology in our flies, including effects on behavior, as measured by the RING assay, and on levels of Ab deposition in the brain.

D1347B Role of a soy protein Lunasin in Aβ42 mediated neurodegeneration in Alzheimer's Disease. *N. Glenn*[1], A. Sarkar[1], A. Giaquinto[1], M. Moran[1], G. Jones[2], A. Srivastava[2], M. Kango-Singh[1,3,4], A. Singh[1,3,4]. 1) Department of Biology, University of Dayton, 300 College Park Drive, Dayton OH; 2) Department of Biology and Biotechnology Center, Western Kentucky University, 1906 College Heights Blvd, Bowling Green, KY; 3) Premedical Program, University of Dayton, 300 College Park Drive, Dayton OH; 4) Center for Tissue Regeneration and Engineering at Dayton (TREND), University of Dayton, Dayton, OH.

Alzheimer's Disease (AD) is a neurodegenerative disease caused by a number of factors. One of the leading factors behind the onset of AD is the accumulation of amyloid plaques in the brains of affected individuals. These plaques are formed with amyloid precursor protein (APP) is processed incorrectly and cleaved to be 42 amino acids long (Aβ42) instead of 40 (Aβ40). These two extra amino acids cause the protein to become hydrophobic in nature and form plaques which aggregate around neurons in the brain. This aggregation induces oxidative stress on the neurons which then leads to cell death. Due to the conserved genetic properties of the *Drosophila melanogaster*, fruit fly, visual system with that of humans we have developed a Drosophila eye model. In this model the Aβ42 protein is misexpressed in the developing photoreceptors of the fly eye which results in extensive cell death of the photoreceptor neurons and produces a highly reduced eye field in the adult fly. Our aim is to understand the function of a soy protein called Lunasin in Alzheimer's disease. It has been shown that Lunasin acts as an anti-inflammatory within the somatic cells. Inflammation is also one of the characteristic of AD. Therefore, we investigated the effects of Lunasin on Aβ42 accumulation mediated neurodegeneration. We found that Lunasin can rescue the Aβ42 mediated neurodegeneration in the retinal neurons as well as the axonal targeting from the retina to the brain. We are looking into the mechanism of this Lunasin mediated rescue.

D1348C Exploring the nature of mitochondrial fragmentation and loss in a Parkin loss-of-function *Drosophila* Model of Parkinson's disease. *S. Gutierrez*, J. Cackovic, K. Pearman, G. Call, L. Buhlman. Midwestern University, Glendale, AZ.

Parkinson's disease (PD) is a neurodegenerative disorder characterized by dopaminergic neuron loss in the substantia nigra. Loss-of-function mutations in *PARK2* are the leading cause of autosomal recessive juvenile parkinsonism (AR-JP). An AR-JP *Drosophila melanogaster* model exhibits pathologies associated with loss-of-function mutations of the *parkin* (*park*, the *Drosophila PARK2* ortholog) gene including swollen mitochondria and mitochondrial dysfunction. Preliminary results from our lab show that mitochondrial networks have smaller volumes and more fragmentation in dopaminergic neurons in heterozygous *Drosophila park*^{25} (loss-of-function allele) flies, suggesting that *park*^{25} causes pre-mitophagic fragmentation. Disruptions in oxidative phosphorylation increase reactive oxygen species (ROS) production, which can lead to oxidative stress, mitochondrial fragmentation and aberrant mitochondrial morphology. Disruptions in mitochondrial respiration have been observed in Parkin loss-of-function models as well as in patients. Although Parkin-mediated mitophagy has been described in a number of cell lines and in different physiological conditions, contradicting ideas about the relationship between Parkin and mitophagy persist. An *in vivo* assessment of mitophagy would help determine how Parkin affects mitochondrial function and thus provide further insight in the role of mitochondrial pathology in the etiology of PD. To assess ROS production, we are utilizing a MitoTimer construct that consists of a mitochondrial-targeted DsRed variant that shifts from green to red fluorescence upon oxidation. Using confocal microscopy we are measuring this fluorescent ratio in TH-Gal4, UAS-MitoTimer PPL1 dopaminergic neurons in control (*park*$^{+/+}$), heterozygous (*park*$^{+/-}$) and homozygous (*park*$^{-/-}$) flies. To measure mitophagy in the PPL1 neurons, we are analyzing co-localization of mCherry-Atg8a and mitoGFP constructs driven by TH-Gal4 in these same *park* genotypes. We hypothesize that the decrease in mitochondrial network volume we have detected in Parkin loss-of-function flies is due to higher rates of oxidation and subsequent increases in mitophagy. Our results, which will be presented at the meeting, will provide insight on the dose-dependent effect of *park* mutation toxicity within the mitochondria of dopaminergic neurons and shed light on morphology and mitophagy. This will promote a better understanding of the mechanisms of degeneration caused by Parkin loss-of-function.

D1349A The influence of misregulation of inositol trisphosphate receptor on a *Drosophila* model of MJD. *D. Hahn*, J. Warrick. Richmond Univ., Richmond, VA.

Spinocerebellar ataxia 3, more commonly known as Machado Joseph Disease (MJD), is a fatal, hereditary disease characterized by muscle control loss and neuronal degeneration. Inositol Trisphosphate Receptor (IP3R) expression is a crucial component of the calcium-mediated signaling mechanism in cells and has been linked to other similar neurodegenerative diseases. Thus we investigated the effects of IP3R on the progression of MJD. Using a *Drosophila* model for MJD, IP3R expression was first upregulated and found to increase neurodegeneration in flies over the course of seven days as compared to control models. IP3R expression was then downregulated via RNAi which was found to decrease neurodegeneration after seven days. Based on these results, it has been concluded that IP3R is a significant factor of the overall MJD progression mechanism. Future experiments will be conducted to accurately describe the role of IP3R signaling in MJD pathology.

D1350B Use of a *Drosophila* model of Alzheimer's Disease to screen GPCR ligands for potential AD therapeutics. *K. A. Innamorati*[1], S. D. Mhatre[2], P. T. Nguyen[1], D. R. Marenda[1]. 1) Drexel University, Philadelphia, PA; 2) Stanford University, Stanford, CA.

Alzheimer's Disease (AD) is a progressive, neurodegenerative disease characterized by global cognitive decline and neuronal death. As of 2015, 5.3 million Americans are suffering from AD, but only five drugs are available for palliative treatment. A major challenge for AD drug discovery is the lack of animal models for the disease. One popular model, *Drosophila melanogaster*, is valued for a variety of reasons, including quick generation times- making it a good model of aging. Our lab has created a transgenic *Drosophila* model of AD which displays amyloid-containing puncta in adult brains, motor coordination difficulties, and memory deficits that can be rescued with gamma secretase inhibitor L-685,458. The model also displays altered external morphology, including melanotic plaques on the proboscis and abdomen, and crumpled wings. Using this model, our lab performed a drug screen of 264 GPCR-binding ligands. Results were organized into enhancers and suppressors of external morphology. Both Memantine (Namenda) and Donepezil (Aricept), palliative drugs available for AD treatment, scored as suppressors on our model. From our screen, we will study new compounds for the treatment of Alzheimer's Disease.

D1351C Gene interaction network in *Drosophila* reveals connections between Huntington's disease and FTD/ALS. *K. Kannan*, P. Zhang. Department of Molecular and Cell Biology, University of Connecticut, Storrs, CT.

Nucleotide repeat expansions are a common characteristic of Neurodegenerative disorders such as Huntington's disease (HD), spinocerebellar ataxia, Fragile X syndrome and Frontotemporal dementia/amyotrophic lateral sclerosis (FTD/ALS). The mechanisms by which these repeats confer toxicity remain largely elusive. Using a sensitized genetic screen in the *Drosophila* eye, we report a series of modifiers that interact with the toxicity of both the expanded CAG repeats (HD) and the expanded GGGGCC repeats (FTD/ALS), with synthetic lethality as a readout. Synthetic lethal interactions represent strong interactions that could indicate a functional relationship between genes. Our data suggests that common functional modules exist between HD and FTD/ALS.

D1352A Role of Dpp signaling pathway in promoting survival of retinal neurons in Aβ42 mediated neurodegeneration. *J. Kleppel*[1], A. Sarkar[1], J. Little[1,2], J. Kirwan[1,3], M. Kango- Singh[1,4,5], A. Singh[1,4,5]. 1) Department of Biology, University of Dayton, OH; 2) The Ohio State University, School of Biomedical Engineering, Columbus, OH; 3) Drexel University, School of Biomedical Engineering, Science, and Health Systems, PA; 4) Premedical Program, University of Dayton, Dayton, OH; 5) Center for Tissue Regeneration and Engineering at Dayton (TREND), University of Dayton, Dayton, OH.

Alzheimer's disease is a progressive neurodegenerative disorder with no known cure to date. One cause of Alzheimer's neuropathy is the generation of Amyloid-beta-42 (Aβ42) aggregates that trigger cell death by unknown mechanisms. Using a transgenic *Drosophila* eye model misexpressing human Aβ42, we observed the AD-like neuropathy. In a forward genetic screen we have identified Decapentaplegic (Dpp), a morphogen, as one of the genetic modifiers of Aβ42 mediated neurodegeneration. Dpp acts as the ligand for the *Dpp* pathway, which exhibits suppression of retinal neuron's cell death. The Dpp signaling pathway involves several key components. We examined the Dpp signaling pathway and its members in modifying Aβ42 mediated neuropathy. We have demonstrated that upregulating Dpp signaling pathway, by misexpressing Dpp (using *UAS dpp*) and Thickveins (using *UAS tkv*) can rescue Aβ42 mediated neurodegeneration. The number of dying cells marked with TUNEL staining was also reduced and the axonal targeting was restored from the retina to the brain, which was marked by 24B10 staining. We will test the role of Dpp signaling in Aβ42 plaques mediated neurodegeneration. Furthermore, we will analyze, if these modifiers act independent and/or parallel of each other or whether they have a linear relationship in triggering neurodegenerative response due to accumulation of Aβ42. The results from our studies will be presented.

D1353B Role of sarah/nebula in Aβ42-induced neurological impairments in *Drosophila*. *J. Lee*, S. Lee, S. Bang, K. Cho. Konkuk university, Seoul, KR.

Expression of the Down syndrome critical region 1 (DSCR1) protein, an inhibitor of the Ca(2+)-dependent phosphatase calcineurin, is elevated in the brains of individuals with Down syndrome (DS) or Alzheimer's disease (AD). Although increased levels of DSCR1 were often observed to be deleterious to neuronal health, its beneficial effects against AD neuropathology have also been reported, and the roles of DSCR1 on the pathogenesis of AD remain controversial. Here, we investigated the role of *sarah* (*sra*; also known as nebula), a *Drosophila DSCR1* ortholog, in amyloid-β42 (Aβ42)-induced neurological phenotypes in *Drosophila*. We detected *sra* expression in the mushroom bodies of the fly brain, which are a center for learning and memory in flies. Moreover, similar to humans with AD, *Aϐ42*-expressing flies showed increased Sra levels in the brain, demonstrating that the expression pattern of DSCR1 with regard to AD pathogenesis is conserved in *Drosophila*. Interestingly, overexpression of sra using the *UAS-GAL4* system exacerbated the rough-eye phenotype, decreased survival rates and increased neuronal cell death in *Aϐ42*-expressing flies, without modulating *Aϐ42* expression. Moreover, neuronal overexpression of *sra* in combination with Aβ42 dramatically reduced both locomotor activity and the adult lifespan of flies, whereas flies with overexpression of *sra* alone showed normal climbing ability, albeit with a slightly reduced lifespan. Similarly, treatment with chemical inhibitors of calcineurin, such as FK506 and cyclosporin A, or knockdown of calcineurin expression by RNA interference (RNAi), exacerbated the *Aϐ42*-induced rough-eye phenotype. Furthermore, *sra*-overexpressing flies displayed significantly decreased mitochondrial DNA and ATP levels, as well as increased susceptibility to oxidative stress compared to that of control flies. Taken together, our results demonstrating that sra overexpression augments Aβ42 cytotoxicity in Drosophila suggest that *DSCR1* upregulation or calcineurin downregulation in the brain might exacerbate Aβ42-associated neuropathogenesis in AD or DS.

D1354C The expression and role of Apolipoprotein D in Aβ42-induced Alzheimer's disease *Drosophila* model. *S. Lee*, K. S. Cho. Konkuk university, Seoul, Seoul, KR.

Apolipoprotein D (ApoD) is a member of the lipocalin family which is secreted from subsets of neurons and glial cells. Previously, it has been reported that the expression level of ApoD is strongly up-regulated in the brain of Alzheimer's disease (AD) patients, and that ApoD has a protective function against oxidative stress in several animal models. However, the role(s) of ApoD in the pathogenesis of AD is still not understood. Here, we demonstrated the role of Glial Lazarillo (GLaz), a gene for a *Drosophila* ApoD homolog, in the AD-like phenotypes of *Aβ42*-expressing flies. *GLaz* overexpression mitigated the Aβ42-induced phenotypes such as rough eyes, locomotive defect, reduced survivability and neuronal cell death. In addition, increased ROS level and sensitivity to oxidative stress in the AD model flies were significantly reduced by pan-neuronally overexpressed *GLaz*, without alteration of the amount of Aβ42 accumulations. Taken together, our results suggest that ApoD plays a protective role against the AD-like phenotypes of AD model flies by inhibiting oxidative stress, and that ApoD can be a potential genetic marker and therapeutic target of AD.

D1355A Genetic variation and mechanisms of paraquat susceptibility in *D. melanogaster*. *Pamela Lovejoy*[1], Kate Foley[1,2], Anthony Fiumera[1]. 1) Binghamton University, Binghamton, NY; 2) Tufts University, Boston, MA.

It is estimated that over a billion pounds of pesticides are applied each year in the United States. Many of these pesticides have potentially detrimental effects on non-target organisms, including humans. Paraquat is a commonly used herbicide in the U.S. that is known to increase oxidative stress in *Drosophila melanogaster* and many other organisms. Increased oxidative stress of the mitochondria leads to dopaminergic cell death and loss of motor ability, which results in a model of Parkinson's disease. The response of *D. melanogaster* to common pesticides, such as paraquat, can be informative of their effect on other non-target organisms. The purpose of this work is to map the genetic basis for natural variation affecting low-dose paraquat susceptibility in *D. melanogaster*. In order to quantify the naturally occurring variation in susceptibility to paraquat that exists, one hundred lines from the Drosophila Genetic Reference Panel (DGRP) were assayed for climbing ability under control conditions and after exposure to paraquat. Paraquat reduces climbing ability in both males and females but males show much greater variation in susceptibility. A GWAS was used to map 31 and 15 genes in males and females respectively, which contribute to susceptibility to paraquat. A subset of these are being verified using RNAi. In addition, these results will also be compared via correlations and genetic network analyses to other measures of susceptibility that have been determined in the DGRP lines. This comparison may perhaps reveal correlated responses or tradeoffs in response to different xenobiotics, and also compare genes involved in susceptibility to paraquat at different concentrations.

D1356B *Effects of altered expression of apoptotic and autophagic gene products in novel Drosophila models of Parkinson disease*. *P. M'ANGALE*, B. STAVELEY. MEMORIAL UNIVERSITY OF NFLD, ST. JOHN'S, NL, CA.

The directed expression of genes associated with apoptosis and autophagy, two very important cellular processes, under the direction of the *Ddc-Gal4* transgene in dopaminergic (DA) neurons has distinct effects upon behavioural attributes of *Drosophila melanogaster*.

Buffy, the single pro-cell survival member of the *Bcl-2* family, extends lifespan and improves locomotor ability when overexpressed in the dopaminergic neurons. Furthermore, we showed that *Buffy* overexpression was sufficient to restore lifespan and age-dependent loss in locomotor ability in the robust *α-synuclein*-induced Parkinson disease model in Drosophila. In addition, the overexpression of the pro-apoptotic *Bcl-2* homologue *debcl* leads to a greatly shortened lifespan and severely reduced climbing ability, phenotypes that are strongly associated with Parkinson disease (PD), and may as well provide a novel model for PD.

Subsequently, we have been able to demonstrate that the directed inhibition of two autophagic genes; *Atg6* and *Pi3K59F*; apoptotic genes; *Bax inhibitor-1 (BI-1)*, *Lifeguard (LFG)*, *Growth hormone-inducible transmembrane protein (GHITM)*, *High temperature requirement A2 (HtrA2)*; and multifunctional genes; *pyridoxal kinase (Pdxk)* and *voltage-dependent anion channel (VDAC/porin)* results in shortened lifespans and defective climbing abilities. We show that the overexpression of the anti-apoptotic *Bcl-2* homologue *Buffy* in DA neurons when co-expressed with the apoptotic and autophagic genes suppresses the PD-like phenotypes described above.

The loss in function of a number of autophagic and apoptotic genes in the dopaminergic neurons of Drosophila leads to shortened lifespans and the progressive loss of locomotor abilities and *Buffy* is able to improve the "healthspan" of these flies.

Funded by a School of Graduate Studies Fellowship and by an NSERC Discovery Grant.

D1357C Polyglutamine tract expanded Androgen Receptor and SBMA: humans and flies. *S. MokHTAR*, M. Paliouras, M. Trifiro. McGill Univ., Montreal, Canada.

Introduction: The role of the androgen receptor (AR) in disease pathology is determined by its mutational status and androgen hormone-dependent activity. There is a class of mutations in the AR gene that results in an expansion of a polymorphic trinucleotide-CAG repeat, coding for a polyglutamine tract in exon 1 of the AR gene. Normally, the CAG tract is 20 repeats, whereas in the disease known as spinal and bulbar muscular atrophy (SBMA) the repeat is expanded to >37 repeats. SBMA is a motor neuron disease directly linked to an androgen-dependent toxic gain of function caused by the polyglutamine expansion in the AR. The characteristics of SBMA are weakness, atrophy, and fasciculations of bulbar, facial and limb muscles that are attributable to degeneration of lower motor neurons in the spinal cord and brainstem. Understanding the molecular pathological mechanisms the AR polyglutamine polymorphism disorder could yield potential candidate therapeutic targets.

Aims of the Study: The aim of this project is to reveal mechanistic pathways involved SBMA pathogenesis. We employed an AR transgenic *Drosophila* genetic interaction screen of homologues of protein interactors of the expanded polyglutamine AR (polyQ-AR).

Results: A proteomics-coupled systems biology approach was used to characterize the proteome of wild-type (WT)-AR vs. polyQ-AR complexes. Through this process we have identified a number of androgen-dependent protein interactors known to be involved in RNA splicing. To investigate the role of polyQ-AR in RNA splicing, we undertook a genetic interaction screen using an *UAS-polyQ-AR* and *UAS-WT-AR* humanized-Drosophila transgenic lines and crossing them to *UAS-RNAi* or enhancer trap lines of fly homologues to our polyQ-AR protein interactors, in the presence or absences of androgen hormone ligand. The genetic interaction screen has identified a number of suppressors of the androgen-dependent polyQ-AR phenotype.Most interestingly, we identified *HNRNPA2B1*gene to be the strongest genetic interactor. No observable phenotypes have been noticed in WT-AR files, supporting the novel gain-of-function properties of the polyQ-AR in RNA splicing.

Conclusions: The proteomics and systems biology approach has allowed us understand AR functionality beyond its classical role as a transcription factor. Using Drosophila as a genetic interaction screening tool, we have robustly explored a novel mechanistic property of polyQ-AR. Through these investigations, it is now clear that the polyQ-AR is involved in RNA splicing pathways and has provided new dimensions to our understanding of SBMA disease and potential therapeutic avenues.

D1358A Investigate the Effects of Cyclopamine on *Drosophila melanogaster* Model of Alzheimer's Disease. *P. T. Nguyen*[1], M. Sharoni[1], N. Latcheva[2], M. Krach[1], K. Innamorati[2], A. Saunders[1], D. Marenda[1,2,3]. 1) Drexel University Department of Biology, Philadelphia, PA; 2) Molecular Cell Biology and Genetics Program, Drexel University College of Medicine, Philadelphia, PA; 3) Department of Neurobiology and Anatomy, Drexel University College of Medicine, Philadelphia, PA.

Alzheimer's disease (AD), a progressive neurodegenerative disorder, is the most common cause of dementia in older adults. AD pathology includes formation of amyloid plaques, a major component of which is the Amyloid β peptide (Aβ) generated from sequential proteolytic cleavage of Amyloid precursor protein (APP) by β- and γ-secretases. Aβ accumulation is neurotoxic and leads to synaptic dysfunction, neuronal death, and learning and memory defects. Our lab identified the Smoothened receptor of the Sonic Hedgehog signaling pathway in a genetic screen as a regulator of APP metabolism. In a later study, Cyclopamine (an antagonist of the Smoothened receptor) was shown to alter the subcellular trafficking of APP C-terminal fragments (substrates for γ-secretase cleavage) in HeLa cells and primary rat cortical neurons. Thus, we hypothesized that Cyclopamine would have a similar mechanism of action in an *in vivo* AD model. To test this, we used transgenic *Drosophila melanogaster* which overexpress human APP and β-secretase in all postmitotic neurons under the control of the Gal4-UAS system. We showed that Cyclopamine rescues a number of defective phenotypes observed in our AD *Drosophila* model including external morphology, larval locomotion, adult motor reflex, and neuroanatomy. These data suggest Cyclopamine can be investigated further for AD therapeutics.

D1359B Altered metabolism in a TDP-43 model of ALS in Drosophila. *Abigail O'Conner*, Ernesto Manzo, Sylvia Zarnescu, Mary-Beth Roberts, Daniela Zarnescu. University of Arizona, Tucson, AZ.

ALS, or amyotrophic lateral sclerosis, is a fatal progressive neurodegenerative disease for which there is currently no cure. Several genes have been linked to ALS, including TDP-43, which encodes an RNA binding protein and has been associated with the vast majority of ALS cases. While only 2-3% of ALS cases harbor mutations in TDP-43, more than 95% of patients exhibit TDP-43 positive cytoplasmic inclusions. A *Drosophila* model of ALS using both wild-type and mutant TDP-43 expression has been shown to recapitulate several pathogenic hallmarks of the disease, including motor dysfunction and decreased survival.

Because metabolic changes have been seen in ALS patients, we have investigated whether similar defects are also present in our fly model. Indeed, metabolomics studies show that, as in ALS patients, flies expressing TDP-43 in motor neurons exhibit a significant increase in pyruvate, the end product of glycolysis, and alterations in the TCA cycle. Using a larval locomotion assay that quantifies differences in locomotor function, we have tested the effects of dietary changes on larvae expressing TDP-43 in motor neurons or glia. Increased dietary glucose appears to alleviate motor dysfunction in wild-type and mutant larvae (both in motor neuronal and glial expression), while also increasing survival time in adult flies. Consistent with these findings, expression of the glucose transporter GLUT4 in diseased larvae shows a similar improvement in motor function. Additionally, the introduction of different fats into the diet of larvae expressing TDP-43 in motor neurons appears to improve motor function at specific dosages. Taken together, these data suggest that the TDP-43 based fly model of ALS experiences specific alterations in metabolism that parallel the changes seen in patients and offer novel strategies for therapeutic and dietary intervention for ALS.

D1360C Assaying tissue-specific functions of SMN using *Drosophila* models of Spinal Muscular Atrophy. *A. Raimer*, A. G. Matera. University of North Carolina Chapel Hill, Chapel Hill, NC.

Survival Motor Neuron (SMN) protein is essential for development across metazoans, and in humans a reduction of SMN leads to Spinal Muscular Atrophy (SMA). SMA is the leading genetic cause of death in infants, characterized by degeneration of α-motor neurons and atrophy of proximal muscles. In severe cases, these children do not live past two years old. The reduction of SMN in these patients is due to mutations in the *Survival Motor Neuron 1 (SMN1)* gene, but how this disruption of SMN protein levels leads to SMA phenotypes is not well understood.

SMN is known to be involved in small nuclear ribonucleoprotein (snRNP) biogenesis, where it helps load Sm proteins onto snRNAs during snRNP maturation. At the same time, SMN has been implicated in alternative functions, such as mRNA transport and RNP assembly. It is unclear which SMN function is disrupted in SMA or what tissue it is disrupted in. Motor neurons and muscles are the tissues that show abnormal phenotypes in SMA patients, so it is possible that there is a cell autonomous function of SMN that is disrupted in these tissues. Another possibility is that the effect of SMN reduction is cell nonautonomous and a different cell type is losing an important function of SMN, indirectly affecting the motor neurons and muscles.

To test spatiotemporal functions of SMN, we are using *Drosophila* lines that contain mutations orthologous to SMA patient mutations. This set of lines has mutations in each of SMN's functional domains: Gemin2 binding domain, Tudor domain, and self-oligomerization domain.

Previously our lab has shown that these lines display a spectrum of viability phenotypes. We are using the GAL4-UAS system to express wild-type Smn in specific sets of tissues in the mutant backgrounds, then observe any changes in viability. Through these studies we will determine the minimal set of tissues that require functional Smn for proper development. We are also further characterizing these mutant lines by conducting locomotor assays and snRNP assembly assays. These assays will examine the effect of each mutated domain/residue on motor function and Smn's canonical role in snRNP biogenesis. Through these studies we hope to determine the tissues that are severely affected by SMN reduction, and learn more about SMN's function in these tissues.

D1361A Role of steroid-responsive Ecdysone (Ecd) pathway in Aβ42-mediated neurodegeneration. *Matthew Riccetti*[1], Ankita Sarkar[1], Kenneth Moberg[2], Madhuri Kango-Singh[1], Amit Singh[1]. 1) University of Dayton, Dayton, OH, United States; 2) Department of Cell Biology, Emory University School of Medicine, Atlanta, GA, United States.

Alzheimer's disease (AD) is a chronic neurodegenerative condition that affects nearly 44 million people worldwide. The hallmark of Alzheimer's pathology is the accumulation of extracellular Amyloid Beta 42 (Aβ42) protein plaques generated by defective endoproteolysis of amyloid precursor protein (APP) by α– and γ-secretase. We misexpressed human Aβ42 in the third instar larval eye imaginal disc of Drosophila. This stable transgenic line results in GMR-GAL4 driven Aβ42-mediated cell death in the eyes of nearly 100% of adult flies. In a forward genetic screen, we identified the Ecdysone signaling pathway as a modifier of neurodegeneration caused by Aβ42 accumulation in the eye. It has been shown that Ecdysone (Ecd) signaling pathway modulates Hippo transcriptional activity in imaginal disc cells. Our preliminary data suggests that upregulation of the involved Yki-Tai transcription complex rescues Aβ42-mediated neurodegeneration in our Drosophila eye model. We propose to understand the underlying molecular genetic mechanism responsible for Ecd/Hippo-mediated rescue of Aβ42 mediated neurodegeneration.

D1362B Investigating the role of glycogen accumulation in neurodegeneration within brain. *A. Rostami*[1,2], G. L. Boulianne[1,2]. 1) University of Toronto, Toronto, ON, CA; 2) The Hospital for Sick Children, Toronto, ON, CA.

Background: Aging is a complex process involving both genetic and environmental factors. Aging and neurodegeneration share some of these influential risk factors, with aging itself being the most robust risk factor for neurodegeneration. Several recent studies have demonstrated that aberrant accumulation of glycogen in neurons can lead to premature aging and neurodegeneration in both flies and mice. Moreover, granular glycogen bodies have also been observed in postmortem cerebral cortex sections of Alzheimer's disease (AD) and dementia patients. Whether glycogen accumulation in the brain occurs in all neurodegenerative diseases and contributes to disease pathogenesis remains unclear. Thus, my main objective is to determine whether accumulation of glycogen within the brain leads to premature brain aging and neurodegeneration.

Methods: To study the impact of increased levels of glycogen in brain aging and neurodegeneration two approaches are used. First, transgenes encoding constitutively active and catalytically dead versions of human muscle glycogen synthase (hMGS) were expressed within neurons of *Drosophila melanogaster* and an amyloglucosidase-based assay was used to measure glycogen levels from fly brains. The effect of glycogen accumulation was determined by measuring sensitivity to oxidative stress. Alternatively, the glycogen concentration in the heads of AD model flies will be manipulated using pharmacological approaches and its effects will be determined by measuring sensitivity to oxidative stress, lifespan and cognition using an olfactory learning assay.

Results: Flies overexpressing a constitutively active hMGS showed higher sensitivity to oxidative stress compared to control flies.

Conclusion: This study will show us whether glycogen accumulation within the brain is a pathogenic feature of neurodegeneration in AD and whether neurodegenerative phenotypes of AD can be ameliorated by reducing glycogen levels.

D1363C Understanding the role of Wingless (Wg) signaling pathway in Amyloid-beta 42 (Aβ42) mediated neurodegeneration in Alzheimer's Disease. *A. Sarkar*[1], M. Kango-Singh[1,2,3], A. Singh[1,2,3]. 1) Department of Biology, University of Dayton, Dayton, OH; 2) Premedical Program, University of Dayton, Dayton,OH; 3) Center for Tissue Regeneration and Engineering at Dayton (TREND), University of Dayton, Dayton, OH.

Alzheimer's disease (AD), an age related progressive neurodegenerative disorder manifests as memory loss and reduced cognitive ability. One of the hallmarks of AD is formation of the Amyloid-beta (hereafter Aβ42) plaques, which initiates oxidative stress due to impaired signaling and finally leads to the death of neurons by unknown mechanism. However the exact mechanism causing cell death is still not well understood. We misexpressed high levels of human Aβ42 protein in the developing fly retina, which mimics AD like neuropathology. In a forward genetic screen we have identified members of highly conserved Wingless (Wg) signaling pathway as modifiers of the Aβ42 mediated neurodegeneration. Furthermore, Wg protein levels are upregulated in the dying cells marked by TUNEL staining. We have demonstrated that blocking Wg signaling pathway, by misexpressing negative regulator of Wg like Shaggy kinase (*sgg*) or a dominant negative form of *Drosophila* T-cell factor ($dTCF^{DN5}$) or blocking Wg transport specifically by downregulating Porcupine (using $porcupine^{RNAi}$) can rescue Aβ42 mediated neurodegeneration by reducing the number of dying cells and restoring the axonal targeting from the retina to the brain. We have developed a drug feeding regimen for flies and will test if we can use chemical inhibitors to block Wg signaling in neurons expressing high levels of Aβ42 and thereby prevent neurodegeneration in the *Drosophila* eye. We will test antagonists and agonist of Wg signaling to determine if they can work as chemical inhibitor/modifier of Aβ42 mediated neurodegeneration. The results from our studies will be presented.

D1364A A Drosophila model for neurodegeneration based on gain- and loss-of function of the Cdk5 activator, p35. *Arvind K. Shukla*, Joshua Spurrier, Edward Giniger. National Institute of Health, Bethesda, MD.

The incidence of neurodegenerative diseases rises in parallel to the aging of human being, but the intricate relationship between aging and neurodegeneration (ND) remains extremely murky. We are exploring this relationship in *Drosophila* that lack or overexpress *p35, a* neuronal specific activator of the *Cdk5* protein kinase. Deregulation of Cdk5 activity in humans has been associated with different neurological disorder such as Alzheimer's and Parkinson's, and either gain or loss of Cdk5 activity causes neurodegeneration in mouse models and neuronal loss in cultured mammalian neurons. We now describe a variety of clear neurodegeneration phenotypes in flies with altered expression of p35. Loss of dopaminergic (DA) neurons is the hallmark of Parkinson's disease, and we find significant DA neuron loss in the brain of *p35* deletion and over-expressing flies. DA neuron counting was done in the brains of 3, 10, 30 and 45 days old flies in control, a *p35* deletion mutant and strains that overexpress p35 modestly (2.5-3x). No significant DA neuron loss was observed in control flies till the age of 30 days. However, *p35* null and OE strains showed significant loss of neurons as early as 10days, with substantial loss by 30days, compared to the control. We also observed that the *p35* mutant and OE strains were sensitive towards oxidative stress generator (H_2O_2 and paraquat). In case of H_2O_2 challenge median survival of p35 mutant and OE were 36 and 48 hrs respectively, which was 60 hrs for age matched (30 days) control. *p35* mutant and OE strains also had higher level of reactive oxygen species in comparison to age- matched control (~1.5 and ~2.5x, respectively). Analysis of autophagy markers in the mutant brains revealed ~2.0x higher accumulation of Ref(2)P (homologue of mammalian p62) and similar increase in LC3 cleavage.The alteration in autophagy, is presumably linked to the ND, which we observed in our *p35* gain- and loss-of-function models. Finally, we observed an early onset of impaired locomotor performance in the mutant and OE strains as compared to control flies. All the phenotypes described above in the p35 mutant were significantly rescued by inserting transposon carrying the genomic *p35* locus, demonstrating the specificity of the phenotypes. These data suggest that analysis of the p35 model should be informative for unravelling the complex cellular endophenotypes associated with neurodegenerative disorders.

D1365B Illegally Parked: Investigating the role of Hip1 in a model of Parkinson Disease. *F. A. Slade*, B. E. Staveley. Memorial University of Newfoundland, St. John's, Newfoundland, CA.

Parkinson Disease (PD) is a progressive neurodegenerative disorder characterized by the gradual loss of motor control and cognitive functions. These symptoms, resulting from the breakdown of dopaminergic neurons, often present in mid-late life and may lead to premature death. A number of molecular pathways have been implicated in the progression of Parkinson Disease to provide a variety of treatment options that offer temporary relief from disease symptoms. The search for preventative therapies and cures for the sporadic and inherited forms of the disease is ongoing.

A polymorphism in the *Huntingtin Interacting Protein 1 related* (*Hip1r*) gene in mammals has recently been associated with PD but its role in disease progression remains uncharacterized. Directed manipulation of the single *Drosophila Hip1r* homologue *Hip1* in the dopaminergic neurons was carried out to provide an *in vivo* model of disease progression and symptom development. Investigation of motor ability and longevity of *D. melanogaster* upon overexpression and loss of function of *Hip1* was completed. Motor analysis was examined by ranking the climbing ability of flies weekly in a glass vessel of regulated size and conditions. Longevity was analyzed by scoring experimental genotypes every two days for the presence of deceased individuals, beginning at day two post-eclosion and continuing until the death of all experimental samples. Directed expression of *Hip1-RNAi* in the dopaminergic neurons decreased the locomotor ability of the flies and increased the average lifespan. Overexpression of *Hip1* in the dopaminergic neurons revealed the opposite effect, improving locomotor ability and slightly decreasing average lifespan. This suggests that a delicate balance of *Hip1* exists in the dopaminergic neurons, and alteration of expression influences the motor ability and life expectancy of *D. melanogaster*. Maintaining a healthy balance of *Hip1* in the dopaminergic neurons may offer a new therapeutic option for loss of locomotor ability and pre-mature death. Further investigation of *Hip1r* and its role in human disease progression is needed, and may be crucial to our understanding of PD, and perhaps Huntington Disease, in order to provide new therapeutic targets.

Funded by a School of Graduate Studies Fellowship to FAS and an NSERC Discovery Grant to BES.

D1366C Yorkie Regulates PolyQ Mediated Neurodegeneration in *Drosophila melanogaster*. *Madhu G. Tapadia*, Sandeep Dubey. Banaras Hindu University, Varanasi, 221005 Uttar Pradesh, INDIA.

Expansion of CAG trinucleotide repeats within open reading frame causes the protein to gain toxic properties resulting in dysfunction and degeneration of specific subpopulation of neurons in the brain. Hippo pathway regulates cell number by cell proliferation or cell death by regulating Yorkie, which is the major downstream target of Hippo pathway. Yorkie in turn, when activated leads to activation of *cyclin E*, microRNA *bantam* and apoptosis inhibitor *diap1* which are involved in cell proliferation and apoptosis. Here, we show that Yorkie is robust genetic modifier of polyQ mediated neurodegeneration. Overexpression of Yorkie in polyQ background reduces the severity of pathogenecity caused by inclusion bodies while downregulation has the opposite effect. Yorkie suppresses cytotoxic effect of polyQ by Cyclin E and bantam but does not show significant rescue by Diap1, suggesting that apoptotic pathway is not involved. PolyQ inclusion bodies causes overexpression of Antimicrobial peptides in neurons by activating the Nuclear Factor-κB (NF-κB) transcription factor Relish, a key activator of IMD pathway. We show upregulation of Yorkie downregulates expression of Relish and other components of Toll and IMD pathway in eye imaginal disc. Downregulation of antimicrobial peptides significantly rescues polyQ phenotypes. Finally we show that polyQ interacts with Yorkie to modulate its functions making it a strong genetic modifier of polyQ mediated neurodegeneration by regulating cell cycle genes and innate immune response. .

D1367A Restoration of mitochondrial morphology rescues impaired axonal distribution caused by loss of Opa1 and Mitofusin in Drosophila melanogaster. *T. Trevisan*, A. Daga. IRCSS E. Medea, Ass. La Nostra Famiglia, Conegliano, Italy.

Mitochondrial dynamics play a critical role in the control of organelle shape, size, number, function and quality control of mitochondria. It is regulated by several GTPases that play an important role in fusion and fission processes. In mammals, mitochondrial fusion is controlled by Mitofusin 1 (Mfn1), Mitofusin 2 (Mfn2) and Optic atrophy protein 1 (Opa1), while mitochondrial fission is regulated by Dynamin related protein 1 (Drp1). A significant imbalance of mitochondrial fusion and fission results in iperfused or fragmented mitochondria.

We use *Drosophila melanogaster* as model to study how loss of fusion and fission protein modify the axonal distribution and motility of mitochondria.

We demonstrate that loss of Marf (Mitochondrial associated regulatory factor) or Opa1 cause accumulation of mitochondria in the soma, a severe depletion of mitochondria in neuromuscular junctions (NMJs) and reduced mitochondrial motility. Loss of Drp1 rescue Marf and Opa1 phenotype. This suggests that restoring mitochondrial dimension and morphology is necessary to maintain normal mitochondrial trafficking in axons. .

D1368B The influence of the altered regulation of histone acetyltransferase Tip60 on degeneration in a *Drosophila* model of Machado-Joseph Disease. *A. Watterson*, J. Warrick. University of Richmond, Richmond, VA.

Machado-Joseph Disease (MJD) is a human spinocerebellar ataxia caused by a polyglutamine repeat expansion in the Ataxin-3 protein that leads to motor neuron degeneration. The mechanisms by which the toxic ATX3 protein causes degeneration are not yet known. In MJD, the ATX3 protein misfolds, leading to the formation of aggregates. Histone acetyltransferases (HATs) may get trapped in the aggregates, therefore preventing proper regulation of protein acetylation and gene transcription. As a result, neurons may become dysfunctional and die due to transcriptional dysregulation or other dysregulation. The histone acetyltransferase Tip60 functions in neuronal gene control and apoptosis, and elevated levels have been found to rescue axonal transport defects, characterized by locomotive phenotypes, in a *Drosophila melanogaster* model of Alzheimer's disease. However, HAT Tip60 has not yet been studied in MJD. Polyglutamine expansions have been associated with axon transport defects. This research investigates the effect of up-regulating and down-regulating HAT Tip60 in a MJD *Drosophila melanogaster* model to determine how levels of Tip60 expression affect the progression of the disease. This research may lead to an effective target for MJD, Alzheimer Disease, and other neurodegenerative diseases.

D1369C *In vivo* evidence for a moving HTT-Rab4 vesicle complex in *Drosophila* larval axons. *J. A. White*, K. Zimmerman, H. G. Hoffmar-Glennon, S. Gunawardena. University at Buffalo, Buffalo, NY.

Huntingtin (HTT), the protein responsible for Huntington's disease (HD), is ubiquitously expressed and enriched in neurons. HTT associates with microtubule motors, kinesin-1 and dynein, and is involved in the movement of vesicles within axons. However the type of vesicle or cargo complex that HTT transports within axons is unknown. We previously found that reduction of *Drosophila* HTT perturbed the movement of Rab4 GTPase- containing vesicles in larval axons. Simultaneous dual-view imaging revealed that HTT and Rab4 likely move together within *Drosophila* larval axons. Sub-pixel co-localization analysis revealed that Rab4, HTT, and motor proteins co-localize suggesting that a HTT-motor complex likely exists *in vivo*. Reduction of the huntingtin interacting protein 1 (HIP1) and a known Rab effector, Rip11, perturbed the movement of both HTT and Rab4 *in vivo*. However, reduction of Milton (a protein with some sequence homology to HAP1) and Nemo (a Rab8 effector) had no effect. Taken together, our observations suggest that HIP1 and Rip11 may aid in linking HTT-Rab4-containing complexes to motor proteins. Since expansion of poly-glutamine repeats in the context of human HTT perturbed the motility of Rab4, perhaps HTT normally functions to facilitate Rab4 motility within axons for functions at the synapse.

D1370A Identification and Characterization of the ΔExon7 *PINK1* Mutation Associated with Parkinson's Disease in *Drosophila* and Mammalian Cells. *Huan Yang*[1,2*], Ting Zhang[1,2], Susan Perlman[1], Brent Fogel[1], Ming Guo[1,2,3,4,5]. 1) Department of Neurology; 2) Molecular, Cellular and Integrative Physiology; 3) Department of Molecular and Medical Pharmacology; 4) Brain Research Institute, David Geffen School of Medicine; 5) Molecular Biology Institute, UCLA, Los Angeles, CA.

Mutations in *PTEN-induced Kinase 1* (*PINK1)* and *parkin* lead to autosomal recessive forms of Parkinson's disease (PD). *PINK1* encodes a putative Ser/Thr kinase with a mitochondrial targeting sequence, and *parkin* encodes an E3 ubiquitin ligase. We and others have previously shown that *PINK1* and *parkin* function in the same genetic pathway to regulate mitochondrial integrity and quality in *Drosophila*. *PINK1/parkin* null mutant flies show motility defects and apoptotic muscle death, and mitochondria in neurons and muscles exhibit abnormal morphology and compromised function. Loss of *PINK1* in human cells block Parkin-mediated autophagy of damaged mitochondria (mitophagy), an important mechanism of mitochondrial quality control. Here we identified a new familiar form of *PINK1* mutation in a PD patient family. We found that two PD patients in this family carried two different *PINK1* mutant alleles: one was a previously characterized *PINK1* L347P allele; the other was an uncharacterized splicing mutant resulting in skipping of *PINK1* Exon7. As *PINK1* Exon7 encodes the C-terminus of the kinase domain, we investigated whether ΔExon7 *PINK1* is a loss-of-function allele. We showed that overexpression of human ΔExon7 *PINK1* failed to rescue mitophagy defects in *PINK1* knockout HeLa cells, in contrast to the human wildtype *PINK1*; overexpression of the *Drosophila* homolog of ΔExon7 *PINK1* also failed to rescue mitochondrial morphology defects and apoptotic muscle death in *PINK1* null mutant flies, in contrast to the wildtype *Drosophila PINK1*. In this study, we validated two model systems (*Drosophila* muscle *in vivo* and human cell-based mitophagy assay) for future characterization of newly discovered PD-linked mutations.

D1371B Exploring the molecular basis of the PCH-associated RNA Exosome phenotypes in *Drosophila* . *Xue Yang*[1,2], Vafa Bayat[1], Zhihao Wu[1], Yen-Chi Wu[1], Hannes Vogel[1], Bingwei Lu[1]. 1) Stanford School of Medicine, Stanford, CA; 2) Peking University, Beijing, China.

Pontocerebellar Hypoplasia (PCH) is a rare congenital disorder displaying autosomal recessive inheritance characterized by hypoplasia and atrophy of the cerebellar cortex, dentate nuclei, pontine nuclei and inferior olives. Two of the RNA exosome subunits, EXOSC3 and EXOSC8, have been identified as mutated in PCH type 1 patients, who also exhibit a spinal muscular atrophy phenotype indicating possible motor neuron involvement too. *Drosophila* has a predicted single copy of all of the known RNA Exosome subunits, and is therefore an excellent model organism to investigate potential molecular mechanisms. We have obtained and are generating mutants using imprecise excision and CRISPR in as many of the RNA exosome subunits as possible with the purpose of comparing their null phenotypes. We have already discovered in rrp4 mutants that the expression of key neurodegenerative disease-related proteins is altered, and are further investigating this. Using this data, we are targeting specific pathways to determine whether their RNAi phenotypes can be suppressed using genetic interactions and determining whether the molecular mechanisms are similar to those we are in parallel studying in the PCH-associated TSEN complex. We are in parallel determining whether the cellular and molecular phenotypes we observe are also seen in human cell lines. We hope that our data will give clues to potential treatments, which are presently only supportive in nature.

D1372C Translation Dysregulation in ALS. *S. Yao*, A. Coyne, D. Zarnescu. University of Arizona, Tucson, AZ.

Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease that affects the lives of at least 30,000 people in the United States, annually. It is often categorized by the progressive neurodegeneration of motor neurons. TAR DNA Binding Protein (TDP-43) is normally found within the nucleus having known roles in RNA splicing as well as DNA-binding. Mislocalization of TDP-43 to the cytoplasm, either due to mutations or to environmental stressors leads to accumulation of TDP-43 in cytoplasmic inclusions. Notably, in the cytoplasm, TDP-43 associates with RNA stress granules and also affects mRNA translation, both of which are thought to contribute to disease pathology. In order to study the effects that cytoplasmic TDP-43 mutations have on translation, a technique called polysome fractionation is utilized. This technique uses sucrose gradients to effectively separate different ribosomal populations. The mRNAs that are bound to multiple ribosomes, or polysomes, are separated from the mRNAs bound to single ribosomes. This allows the pinpointing of specific defects in protein production as well as potential explanations to how it may affect cellular metabolism. Furthermore, this technique is able to provide information about the halting of protein production in response to stress which is a potential factor that contributes to ALS. Western blotting and quantitative PCR (qPCR) allow us to observe the protein and transcript distribution within the polyribosome fractions, respectively. Using these approaches we found that TDP-43 associates with both translating polyribosomes as well and untranslated fractions (RNP and the ribosomal subunits). qPCR of *futsch*, an mRNA target of TDP-43 showed a shift in transcript levels from actively translated to untranslated fractions in the context of TDP-43, indicating that *futsch* mRNA is being repressed by TDP-43 in motor neurons. Taken together, these findings indicate that TDP-43 regulates the translation of specific mRNAs and defects in translation may contribute to ALS. Experiments will focus on additional candidate mRNA targets that will be tested for their distribution within polysome fractionations to determine their translational status in disease. Candidate mRNAs that are identified by Translating Ribosome Affinity Purification (TRAP) that also associate with TDP-43 in complex will be tested. Specifically, qPCR will used to distinguish shifts in translational targets in polysomes. Targets that are downtranslated should exhibit a shift into the RNP fractions while uptranslated targets will exhibit a shift into the polysomes.

D1373A Rescue of neurotoxicity in a TDP-43-based Drosophila model of ALS by a 4-aminoquinoline analog. *Ben Zaepfel*[1], Alyssa Coyne[1], Joel Cassel[2], Allen Reitz[2], Daniela Zarnescu[1]. 1) University of Arizona, Tucson, AZ; 2) ALS Biopharma, LLC, Doylestown, PA.

Amyotrophic Lateral Sclerosis (ALS) is a neurodegenerative disease affecting upper and lower motor neurons. TAR DNA-binding protein (TDP-43) is an RNA and DNA binding protein that has been implicated in ALS, both as a causative factor and at the level of pathology. Although TDP-43 has been shown to play a key role in RNA metabolism, its mechanism is not fully understood. Specifically, evidence has shown that TDP-43 binds TG-rich sequences within RNA targets. In the context of disease, this binding can lead to alterations in splicing and/or proper regulation of its targets, and is partially responsible for the neurotoxicity that is associated with ALS. A 4-aminoquinoline analog (i.e. AAQ-2) has been shown to inhibit the binding of TDP-43 to TG oligonucleotides. To evaluate the effect of this small molecule in vivo, we administered AAQ probes to larvae expressing wild-type or mutant TDP-43 in motor neurons (D42 GAL4>TDP-43). Our experiments show that feeding of AAQ-2, but not a structurally similar negative control (AAQ-9), rescues the lethality caused by overexpression of TDP-43 in motor neurons. Additionally, AAQ-2 feeding also leads to improved locomotor function of larvae, as well as increased lifespan of flies overexpressing both wild-type and mutant TDP-43. In exploring the role of TDP-43-associated proteins in mediating the protective effect of AAQ-2 in motor neurons, we find that rescue of TDP-43-induced neurotoxicity by AAQ-2 is dependent in Fragile X Mental Retardation Protein (FMRP) in a TDP-43 variant-dependent manner. Currently, experiments are being performed to determine the effect of AAQ-2 on the solubility of full-length TDP-43 and its cleaved C-terminal fragment within motor neurons. These results provide insight into the role of TDP-43 in RNA metabolism, as well as suggest a possible therapeutic strategy for TDP-43-based ALS and related neurodegenerative diseases.

D1374B p97/VCP overexpression suppresses the mitochondrial defects in *PINK1*, *parkin* and *parkin mul1* mutants. *T. ZHANG*[1], M. Guo[2]. 1) UCLA,Brain Research Institute, Los Angeles,U.S.A; 2) Neurology and Pharmacology, UCLA ,Los Angeles, U.S.A.

Mutations in *PINK1* and *parkin* lead to autosomal recessive forms of familial Parkinson's disease (PD). Studies in *Drosophila* first showed that *PINK1* and *parkin* function in the same pathway*, with PINK1* positively regulating *parkin* to control mitochondrial integrity and quality control. Mitochondrial morphology is maintained by a dynamic balance of mitochondrial fusion and fission. Mitofusin (Mfn) is a GTPase located on the mitochondrial outer membrane and controls mitochondrial fusion. Importantly, downregulation of Mfn suppresses the mutant phenotypes in

PINK1 and *parkin* mutants. Parkin, an E3 ubiquitin ligase, degrades Mfn. Mul1 is another E3 ligase that functions in parallel to Parkin to degrades Mfn. *parkin mul1* double mutants have more severe mitochondrial phenotypes and much increased Mfn levels than those flies lacking either *parkin* or *mul1* alone. p97/cdc48/Valosin-containing protein (VCP) encodes a highly conserved and abundant AAA+ ATPase which participates in multiple cellular processes. We have found that overexpression of VCP results in a dramatic rescue of defects of mitochondrial integrity, cell death and tissue damage due to lack of *PINK1* and *parkin.* VCP overexpression significantly decreases Mfn levels in wildtype flies. Overexpression of VCP also decreases the accumulated Mfn levels in *PINK1* or *parkin* null mutants. In addition, VCP overexpression suppresses the mitochondrial morphological defects in *parkin mul1* double mutants. These results suggest that VCP-dependent suppression of *PINK1* and *parkin* phenotypes occurs through downregulaton of Mfn protein level.

D1375C ER shaping protein REEP1 regulates neuronal lipid droplets *in vivo*. *N. D'Elia*[1], S. Gumeni[2], M. Fantin[2], A. Forgiarini[1], M. Corrà[2], A. Martinuzzi[2], G. Orso[1,2]. 1) Institute of Pediatric Research, Padova, PD, IT; 2) Scientific Institute IRCCS Eugenio Medea, Conegliano, TV, IT.

Defects in endoplasmic reticulum (ER) membrane shaping and its interactions to other organelles seem to be crucial mechanisms underlying Hereditary Spastic Paraplegia (HSP) neurodegeneration.

Here we report the analysis of a *Drosophila* model for HSP caused by mutations in the *SPG31* gene, which are linked to autosomal dominant HSP. SPG31 codifies for REEP1, which is a transmembrane protein belonging to the TB2/Dp1/HVA22 family. REEP1 interaction with atlastin-1 (*SPG3A*) and spastin (*SPG4*), the other two major HSP linked proteins, has been demonstrated to modify ER architecture. The last evidence that both atlastin-1 and REEP1 play a role in lipid droplets (LDs) biology prompted us to investigate the *in vivo* role of REEP1 in ER membrane shaping and LDs biogenesis using *Drosophila melanogaster* as a model organism. We show that *Drosophila* REEP1 mutant flies present altered ER membrane morphology in neurons and reduced LDs number in both neuronal and non neuronal tissues. In addition, overexpression of wild type DREEP1 affects LDs number and size. Furthermore, we generated and *in vivo* expressed the mutated pathological form of DREEP1 p.P19R. The p.P19R missense mutation increases LDs size, reduces their number and modifies DREEP1 subcellular localization relocating it from ER to LDs membrane. Modification of LDs biogenesis is also associated to triglyceride levels perturbation *in vivo*, suggesting an altered lipid metabolism.

Our data demonstrate that REEP1 is involved in ER morphogenesis and LDs biogenesis/turnover in neuronal tissues. Our findings support and highlight the importance of lipid metabolism in neural functionality and the neurodegeneration mechanism of HSP disorder. Therefore, lipid metabolism can be considered as a novel HSP target towards which pharmacological efficient treatments could be developed.

D1376A Analysis of glucose metabolism during pathogenesis of Spinocerebellar Ataxia Type 1. *J. R. Diaz*[1,2], A. Perez[1,2], T. Gallego-Flores[1,2], Y. Wan[1,2], T. Inoue[1], A. Chai[1,2], C. Karakas[1,2], I. Al-Ramahi[1,2], M. Maletić-Savatić[1,2], M. Gaber[1], R. Samaco[1,2], Z. Liu[1,2], H. Orr[3], J. Botas[1,2]. 1) Baylor College of Medicine, Houston, TX; 2) Jan and Dan Duncan NRI, Texas Children Hospital. Houston, TX; 3) University of Minnesota, Institute for Translational Neuroscience, Minnesota.

Spinocerebellar ataxia type 1 (SCA1) is one of nine Polyglutamine Diseases caused by CAG expansion in the coding region of the corresponding gene. In SCA1, CAG expanded repeats cause an abnormally long glutamine tract in ATXN1 protein and trigger a gain of function pathogenic mechanism that leads to a progressive neurodegenerative disorder. The brain regions primarily affected are the cerebellum and the brainstem. Previous study reported that insulin sensitivity and insulin secretion are abnormal in SCA1 patients. We hypothesize that expression of mutant ATXN1 impairs glucose metabolism and use multiple approaches to test this hypothesis using mice and Drosophila disease models. Gene expression analyses in SCA1 mice and flies suggest glucose uptake deficiency in neuronal cells. Confirming these results, positron emission tomography imaging suggests lower glucose level in the cerebellum of SCA1 transgenic mice. Metabolomic analyses in SCA1 fly neurons reveal a decrease in glucose metabolism metabolites. We carried out a genetic screen in Drosophila of all genes encoding glycolytic enzymes for potential modifier genes of SCA1 pathogenesis. We found that knocking down glycolytic genes ameliorates neurodegeneration by reducing steady-state levels of mutant ATXN1 protein. Together these data suggest that glucose metabolism impairments contribute to SCA1 pathogenesis and reveal new therapeutic approaches to decrease ATXN1 neurotoxicity.

D1377B *Drosophila* spastin regulates lipid droplets and lipid metabolism *in vivo*. *A. Forgiarini*[1], S. Gumeni[2], N. D'Elia[1], A. Daga[2], G. Orso[1,2]. 1) Institute of Pediatric Research, Padova, PD, IT; 2) Scientific Institute IRCCS Eugenio Medea, Conegliano, TV, IT.

Hereditary spastic paraplegias (HSPs) are a group of neurodegenerative diseases characterized by progressive weakness and spasticity of the lower limbs, owing to progressive retrograde degeneration of the long corticospinal axons. Mutations in the gene *spastin* (*SPG4*) are responsible for the prevailing form of pure HSP. Spastin is an ATPase that contains a microtubule-interacting domain and has been implicated in several processes involving remodeling of membrane structures. Moreover, spastin harbors a lipid droplet (LD) targeting sequence that allows its targeting to LDs surface. Our group has previously shown that the highly conserved *Drosophila spastin* homolog (*Dspastin*) regulates microtubule stability and synaptic function of the *Drosophila* larval neuromuscular junction.

Considering the lipid droplets formation and maintenance as a possible common pathway in HSP neurodegeneration, we wanted to further investigate a possible role of spastin in lipid metabolism.

We observed that ubiquitous overexpression of Dspastin in *Drosophila* increased triacylglycerol levels and led to bigger and less numerous LDs in fat bodies. In contrast, Dspastin specific overexpression in skeletal muscles or nerves increased LDs number. Downregulation of Dspastin and expression of a dominant-negative variant (Dspastin K467R) decreased LDs number in *Drosophila* nerves, skeletal muscles and fat bodies, and reduced triacylglycerol levels in the whole larva.

Our results suggest the role of spastin as a regulator of lipid metabolism, enforces and strongly support the recent discoveries that dysfunction of LDs in axons may contribute to the pathogenesis of HSP.

D1378C Uncovering cellular energetics at the neuromuscular junction in a Drosophila model of ALS. *E. Manzo*[1], I. Lorenzini[2], A. Joardar[1], A. O'Conner[1], J. Barrows[1], R. Sattler[2], D. Zarnescu[1]. 1) University of Arizona, Tucson, AZ; 2) Barrow Neurological Institute, Phoenix, AZ.

Amyotrophic Lateral Sclerosis (ALS), also known as Lou Gehrig's Disease, is a fatal neurodegenerative disorder affecting upper and lower motor neurons. TAR DNA-binding protein 43 (TDP-43) is found in cytoplasmic inclusions in almost all non-SOD1 mediated ALS cases and is thought to play a major role in pathogenesis of the disease. Our lab has previously shown that overexpression of either wild type or mutant human TDP-43 in motor neurons of *Drosophila* melanogaster induces motor deficits and reduces lifespan. Using this model we have performed global metabolomics profiling and identified several significant changes consistent with alterations in glucose and lipid metabolism. Specifically, increased pyruvate in both TDP^{WT} and disease associated TDP^{G298S} models is suggestive of altered glucose metabolism. We also found increased tricarboxylic (TCA) cycle intermediates and pyruvate, which are also upregulated in plasma from ALS patients. Based on these preliminary results we hypothesize that improving glucose and lipid metabolism through genetic and dietary intervention can provide protection against neurodegeneration. We employed molecular and genetic techniques to determine the basis of altered glucose metabolism. Our preliminary data indicate that a high sugar diet, or the genetic expression of either the human glucose transporters 3 or 4 (Glut3 or Glut4) in motor neurons, suppresses toxic effects caused by of TDP-43. Additionally, Glut3 expression is altered in both fly and human iPS motor neurons (MNs) . To further test whether the expression of TDP-43 affects glucose transporter dynamics, we have used total internal reflection fluorescence (TIRF) microscopy, and found that in primary MNs expressing TDP^{WT}, there are comparable levels of Glut4-GFP at the plasma membrane immediately after insulin stimulation. In contrast, 14 min after stimulation, Glut4-GFP persists at the surface in TDP-43 expressing cells but not in controls. These data suggest Glut3/Glut4 alterations in expression and dynamics, in both both fly and iPS MNs, and are consistent with defects in glycolysis identified through metabolomics. Indeed, pfk mRNA, a key indicator of glycolytic activity is significantly upregulated in TDP-43 expressing flies and iPS MNs with TDP-43 pathology. Taken together, our findings indicate specific metabolic alterations in ALS and highlight the predictive power of *Drosophila* as a model organism for human disease.

D1379A A Ketogenic Dietary Supplement Eliminates Seizure-Like Activity and Paralysis in the Bang-sensitive (BS) Paralytic Mutants. *M. Nelson*, C. Radlicz, J. Rubera, T. Taylor, A. Chambers, C. Bittner, D. Kuebler. Franciscan University of Steubenville, Steubenville, OH.

The *Drosophila* Bang-sensitive (BS) paralytic mutants undergo seizure-like activity (SLA) and paralysis following a variety of insults such as mechanical shock. While the etiology underlying this defect is poorly understood, a number of recent studies in our lab have demonstrated that metabolic and dietary alterations can suppress, but not complete eliminate, SLA and paralysis in these mutants. Given that a ketogenic diet is known to reduce seizures in many children with refractory epilepsy, we examined the effect this diet had on the BS mutants *easily-shocked (eas), bang-senseless (bss),* and *technical knockout (tko)*. These mutants were fed a standard cornmeal/yeast/sugar diet supplemented with 10% KetoCal 4:1, a commercially available ketogenic formula consisting of a 4:1 ratio of fats to carbohydrates. Newly eclosed BS flies were fed this diet for 3, 5 or 7 days and all three genotypes displayed significant reductions in SLA and paralysis following mechanical shock. After only 3 days on the diet, over 90% of *tko* flies no longer exhibited SLA or paralysis, and complete suppression of the BS phenotype was seen by day 7. In the case of *eas*, only 30% still displayed SLA after 3 days on the diet and SLA was completely suppressed by day 7. The *bss* flies showed a similar but less robust reduction of SLA on the diet as 35% of flies still exhibited SLA and paralysis following 7 days on the diet. In addition to reducing SLA, the diet partially rescued the reduction in basal activity that is normally seen in the BS mutants. Taken together, the data indicates that the BS mutants represent an attractive model for investigating the underlying mechanism by which the ketogenic diet can suppress seizures.

D1380B Tissue specific overexpression of *c-myc* mitigates human poly(Q) induced neurodegeneration in *Drosophila* disease model. *K. Raj*, S. Sarkar. University of Delhi, New Delhi, INDIA.

Polyglutamine or poly(Q) disorders such as Spinocerebellar ataxia(s) (SCAs), Huntington's disease (HD), Spinal and Bulbar Muscular Atrophy (SBMA), Dentatorubral pallidoluysian syndrome (DRPLA) etc. represent a class of dominantly inherited neurodegenerative disorders which develop due to expansion of glutamine (Q) repeats in the coding region of target gene. The key factors for poly(Q) disease pathogenesis involve mis-folding of the mutated poly(Q) bearing protein and their subsequent accumulation in the cell in the form of inclusion bodies, which in turn leads to cellular toxicity and neurodegeneration. However, in spite of several pointers, the precise mechanism of poly(Q) disease pathogenesis and their suitable therapeutic approaches remains elusive. While finding a suitable drug target, we have demonstrated earlier that tissue specific upregulation of *Drosophila myc* (a homologue of human *c-myc* proto-oncogene) dominantly suppresses poly(Q) mediated cellular toxicity *via* histone acetylation and global transcriptional upregulation. Further, the rescue potential of human *myc (c-myc)* in alleviation of poly(Q) mediated neurotoxicity was examined utilizing multiple *Drosophila* transgenic lines expressing three different isoforms of transcripts encoded by human *c-myc gene* under the control of UAS promoter. Extensive genetic crosses, several immunostaining assays and appropriate microscopy techniques revealed that targeted over-expression of human *myc* (*c-myc*) also mitigates poly(Q)-induced cellular toxicity and neurodegeneration in SCA3 and HD models of *Drosophila.* Subsequent investigations suggest that transactivation domain of c-Myc protein which helps in restoring the poly(Q) induced cellular transcriptional impairments might be essential to achieve the rescue events.

We, therefore, propose that enhanced level of *c-myc* make a significant impact on the pathogenesis of human poly(Q) disorders and could be explored as a potential therapeutic target.

D1381C Defining the transcriptional defects of KDM5 mutations associated with Intellectual Disability. *s. zamurrad*, X. Liu, J. Secombe. Albert Einstein College of Medicine, bronx, NY.

KDM5 proteins are multi-domain transcriptional co-factors that function by recognizing and enzymatically altering specific histone modifications. There are four broadly expressed KDM5 orthologs in mammalian cells (KDM5A-D) and a single KDM5 in Drosophila. Emphasizing the importance of KDM5 proteins, KDM5A and KDM5B are over expressed in a number of metastatic cancer types, and KDM5A, B and C are mutated in patients with intellectual disability (ID). To-date, 30 mutations in KDM5C, 7 in KDM5B and 1 in KDM5A have been identified in patients with either syndromic or non-syndromic ID. How mutations in KDM5 family genes result in cognitive phenotypes remains elusive.

As a first step in establishing Drosophila as a model system to understand KDM5-induced ID, we defined direct KDM5 target genes in adults, as this is the stage used to model cognitive disorders. By combining RNA-seq from kdm5 hypomorphic adults with anti-KDM5 ChIP-seq, we identified numerous direct targets. Among these were several genes previously implicated in neurological disorders. Using *Drosophila,* which encodes a single KDM5 protein, our lab carried out RNA-sequencing experiments using *kdm5* hypomorphic adult flies. This revealed that KDM5 is required for the activation of several genes previously implicated in intellectual disability disorders such as fragile-X syndrome, Down syndrome, Autism and Alzheimer's disease. Anti-KDM5 ChIP-seq experiments from wildtype flies demonstrate that many of these genes are direct KDM5 targets. Because patients with mutations in KDM5 genes show cognitive impairment, we used a behavioral assay in flies and found that the *kdm5*^{hypomorph} have impaired appetitive-olfactory associative learning. To complement our analyses of kdm5 hypmorphic mutant adults, we have generated seven fly strains harboring mutations in KDM5 that are analogous to disease-associated missense mutations in KDM5 proteins. 6/7 of the ID mutants generated thus far are expressed at wild type levels re-enforcing that these mutations affect function and not protein stability. To-date, we have examined one ID mutant fly strain in more detail and found it to have a severe learning and memory defect. We are currently testing other ID allele fly strains for similar cognitive impairment, and defining the transcriptional defects in these strains. These analyses will allow us to define for the first time whether similar or distinct target genes are affected by disease-associated alleles. These studies will allow us to define the mechanistic link between KDM5 dysfunction and intellectual disability.

D1382A Use of *Drosophila* wing discs as a model to study the function of miRNAs in epithelial cell invasion. *C. Chang*, F. Chang, S. Cheng, Y. Su, Y. Lee, G. Khoo, Y. Huang, Y. Tsai. Department of Life Science, Tunghai University, Taichung, Taiwan.

Most solid tumors are derived from epithelial tissues. The epithelial cells are highly polarized and hold together by junction proteins. During tumorigenesis, multiple steps are required to transform epithelia into tumor cells. The molecular mechanism of cell migration/ invasion is extensive studied in the culture cells. However, it is difficult to trace the process of tumorigenesis *in vivo*. *Drosophila* wing disc is a monolayer epithelium and pattern formation of wing discs is well studied. miRNAs are endogenous noncoding RNA. Mature miRNAs are 21-22 nucleotides and negatively regulate gene expression at posttranscriptional level. Several miRNAs function as oncogenes. In this study, we use *Drosophila* wing epithelia as a model to establish a system to study whether miRNAs induce tumorigenesis and promote the epithelial cells into invasive cells. To explore whether expression of miRNAs promotes epithelial cells into invasive cells, we use the GAL4/UAS system to express miRNAs in developing wing cells. *dpp-GAL4* is expressed in the anterior/posterior boundary. We expressed UAS-miRNA and UAS-GFP by the *dpp-GAL4* driver. The GFP reporter marks the miRNA expression cells. If the miRNAs promote epithelial cell invasion, the GFP expression cells will move from anterior/posterior boundary to the lateral regions. One hundred and fifty UAS-miRNA lines were screened. Preliminary, we isolated several microRNAs, *mir-8*, *mir-274, mir-310, mir-318* and *mir-1000* which can induce cell migration/invasion in wing epithelial cells. We further examine the epithelial and mesenchymal markers and possible downstream signalings induced by microRNAs. In this study, we established a novel system to study the function of microRNAs on cell invasion in *Drosophila* wing epithelial cells. This system will be useful to study the roles of *microRNAs* and their human *homolog* on tumor metastasis.

D1383B *Bicaudal C* mutation causes *myc* and TOR pathway up-regulation and Polycystic Kidney Disease-like phenotypes. *C. Gamberi*[1], D. Hipfner[2], M. Trudel[2], W. D. Lubell[3]. 1) Concordia University, Montreal, PQ, CA; 2) Institut de recherches cliniques de Montréal, 110 Pine Avenue West, Montréal, QC H2W 1R7, Canada; 3) Département de Chimie, Université de Montréal, P.O. Box 6128, Station Centre-ville, Montréal, QC H3C 3J7, Canada.

Progressive cystic kidney degeneration underlies diverse renal diseases, including the most common cause of kidney failure, autosomal dominant Polycystic Kidney Disease (PKD). Genetic analyses of patients and animal models have identified several key drivers of this disease. The precise molecular and cellular changes underlying cystogenesis remain, however, elusive. *Drosophila* mutants lacking the translational regulator Bicaudal C (BicC, the fly ortholog of vertebrate *BICC1* implicated in renal cystogenesis) exhibited progressive cystic degeneration of the renal tubules (so called "Malpighian" tubules) and reduced renal function. BicC bound to *myc* mRNA in tubules. Elevation of Myc protein levels caused tubular degeneration in *BicC* mutants. Activation of the Target of Rapamycin (TOR) pathway, another common feature of PKD, was found in *BicC* mutant flies. In flies rapamycin administration reversed substantially the cystic phenotype and improved survival. New mechanistic insight on *BicC* function leads us to propose *Drosophila* as a genetically tractable model for dissecting the evolutionarily-conserved molecular mechanisms of renal cystogenesis and for chemical and genetic screens to identify modifiers of the phenotype towards novel therapeutic strategies.

D1384C Short amyloid-β peptides attenuate amyloid-β42 toxcitiy *in vivo*. *B. D. Moore*, J. Martin, L. deMena, J. Sanchez, P. Cruz, C. Ceballos, A. Rosario, C. Janus, D. Rincon-Limas, P. Fernandez-Funez, T. E. Golde. University of Florida, Gainesville, FL.

An attractive therapeutic strategy to treat Alzheimer's Disease is to halt the accumulation of amyloid plaques by decreasing the production of Aβ1-42. A class of compounds called g-secretase modulators (GSMs) shift the g-secretase cleavage site of amyloid precursor protein resulting in

a selective decreased production of amyloid beta (Aβ) peptide 1-42 and a concomitant increased production of the shorter Aβ peptides, Aβ1-37, Aβ1-38 and Aβ1-39. However, the biological significance of these peptides is still unclear. Our initial studies with transgenic mouse models suggest that one such short peptide, Aβ1-40, is a robust inhibitor of Aβ1-42 deposition *in vivo*. The last two hydrophobic residues at the C-terminal of Aβ1-42 are proposed to be critical for its enhanced rate of nucleation. Therefore we **hypothesize** that shorter Aβ peptides are anti-amyloidogenic and modify the toxicity of Aβ42 *in vivo*. In this study we examined the role of shorter Aβ peptides, Aβ1-36, Aβ1-37, Aβ1-38, Aβ1-39, Aβ1-40, Aβ1-42 and Aβ1-43, by generating transgenic *Drosophila melanogaster.* The Aβ peptides were expressed independently or co-expressed with Aβ1-42 specifically in the eye to assess phenotype and the neurons to measure behavioral function. Furthermore, we examined the effect of Aβ38, expressed using our BRI2 fusion strategy, in an APP mouse model. Overexpression of the shorter Aβ peptides, Aβ1-36, Aβ1-37, Aβ1-38 and Aβ1-39, was not toxic in the eye. Overexpression of Aβ1-42 resulted in a degenerative eye phenotype while expression of Aβ1-40 or Aβ1-43 had a slight effect on eye phenotype. Importantly, in flies co-expressing Aβ1-42 and the shorter Aβ peptides, Aβ1-36, Aβ1-37, Aβ1-38 and Aβ1-39, the degenerative phenotype and behavioral function was improved. These studies validate g-secretase modulation as a clinical strategy by characterizing the attenuating effect of shorter Aβ peptides.

D1385A Drug discovery in *Drosophila*. *Tamy Portillo Rodriguez*, Tom Hartl, Ethan Perlstein. Perlstein Lab, PBC San Francisco, CA.

Perlstein Lab is a public benefit corporation that discovers small molecule therapies for orphan diseases. Since our conception in 2014, we have focused on the rare diseases Niemann Pick type C (NPC) and N-glycanase 1 (NGLY1) deficiency. *Drosophila* with mutations in these disorders' causal genes, *npc1* and *ngly1*, are developmentally delayed during larval stages. We will present our *Drosophila* high throughput drug screening platform and our progress on discovering small molecule modifiers of NPC and NGLY1 larval developmental delay.

D1386B The anti-migration/anti-metastatic compound Dihydromotuporamine C signals through RhoI1 and the non-muscle myosin heavy chain and is antagonized by Rac1. *C. Seavey*[1], M. Wang[1], A. Muth[2], O. Phanstiel IV[3], L. von Kalm[1]. 1) University of Central Florida, Orlando, FL; 2) Department of Chemistry, University of Central Florida, Orlando, FL; 3) Department of Medical Education, College of Medicine, University of Central Florida, Orlando FL.

Cancer chemotherapeutics with good anti-migration/anti-metastatic activities are significantly underrepresented in the arsenal of anti-cancer agents. One compound with excellent anti-migration properties in mammalian cell culture is dihydromotuporamine C (Motu 3,3) that was isolated from a sea sponge near Motupore Island, New Guinea. Motu 3,3 has been reported to activate RhoA and to influence sphingolipid metabolism in mammalian cells however the mechanism by which Motu 3,3 inhibits migration in cell culture is not currently understood. Using a leg imaginal disc eversion assay, we show that Motu 3,3 acts through Rho1 in a pathway leading to the activation of the myosin non-muscle heavy chain (Zipper) and the formin actin nucleation (dia) pathway. Additionally, Motu 3,3 activity is antagonized by Rac1. Motu 3,3 exhibits toxicity in cell culture so we tested the mechanism of action of chemical derivatives of Motu 3,3 that have reduced cell culture toxicity but increased ability to inhibit migration. Our data show that the derivatives have the same mode of action as Motu 3,3.

D1387C Effects of Antimalarial Drugs on Motor and Behavioural Programs in *Drosophila melanogaster*. *A. A. Adedeji*, E. Kwikiriza, M. Vicente-Crespo. Kampala International University- Western Campus, Ishaka, Bushenyi, UG.

Background: Antimalarial drugs, used for the control and prevention of malaria infection, affect other parts of the human body to alter certain physiological functions. The neurons form discrete circuits that mediate complex behaviours including circadian rhythms, sleep, learning and memory, courtship, feeding, aggression, grooming, and flight navigation. However, little is known of how the use of antimalarial drugs affects these physiological processes that defines wellness. In the present study, we evaluate the effects of antimalarial drugs on the motor and behavior program activities using *Drosophila melanogaster* fly model.

Materials and Methods: Anti-malarial drugs (fansidar, chloroquine, artesunate, mefloquine and quinine) were administered to Drosophila melanogaster (wildtype) flies on filter paper. The locomotion (climbing), feeding and grooming-aggression assays were performed according to standard methods. The climbing performance indices, feeding events and aggressive presentations were determined. The findings were analyzed and $P< 0.05$ was taken as significant.

Results: The mean performance indices for locomotion were high (>0.6) in all flies treated with the antimalarial drugs but highest (1.0) in female *Drosophila* flies treated with Artesunate and lowest (0.31) in male flies treated with mefloquine. Quinine and mefloquine treated flies had suppressed aggression and grooming behavior compared to untreated flies. The artesunate treated flies had highest indices for aggression and grooming performance ($P=0.021$), In all drugs treated groups, female flies had increased feeding rate ($P = 0.0001$) than male flies. The mean feeding times was 47.25 ± 26.08 minutes and significantly shorter in artesunate treated group (46.07 ± 26.78 min).

Conclusion: The findings from this study provide preliminary information that antimalarial drugs do not only act on parasite but may alter locomotion, feeding, aggression and grooming behaviours in treated individuals. More studies are required to elucidate on molecular basis for these findings using available *Drosophila melanogatser* genetic tools.

D1388A A Drosophila Model of Chronic Traumatic Encephalopathy. *Mingkuan Sun*, Sheng Wang, Liam Chen. Neuropathology Division, Department of Pathology, Johns Hopkins University School of Medicine, Baltimore, Maryland 21205 USA.

Chronic traumatic encephalopathy (CTE) is a neurodegenerative disease associated with repeated concussive and subconcussive brain injury. It has been found most often in contact sports athletes, less frequently in non-athletes including military service members. There is characteristic gross and microscopic changes in the brain, including frontal and temporal atrophy, hyperphosphorylated tau deposition in neurons and astrocytes in a pattern that is distinct from that of other tauopathies, including Alzheimer's disease and frontotemporal lobar

degeneration. In order to understand the mechanisms responsible for its complex spectrum of pathologies, we exploited the versatile molecular tools available for *Drosophila melanogaster* and developed a fruit fly CTE model. Repetitive head trauma inflicted flies demonstrated persistent neuroinflammation, abnormal accumulation of phosphorylated tau protein, and neurodegeneration in the absence of macroscopic tissue damage. Our model offers a new platform to investigate the pathogenetic mechanisms of CTE and provide a rapid means to develop efficacious interventions for prevention and treatment of CTE.

D1389B Human Disease Model Reports in FlyBase. *Sian Gramates*, Madeline Crosby, Kathleen Falls, Beverly Matthews, The FlyBase Consortium. Harvard Univ, Cambridge, MA.

The use of Drosophila melanogaster as a model for studying human disease is well established, reflected by the steady increase in both the number and proportion of fly papers describing human disease models in recent years. In order to improve both the visibility and accessibility of human disease model research, FlyBase has recently begun producing Human Disease Model Reports.

These reports provide an integrated informational resource regarding specific diseases and fly disease models and their potential impacts on translational research. Each report presents background information on a specific disease, including links to outside resources, most notably Online Mendelian Inheritance in Man (OMIM®); a tabulation of related disease subtypes; information concerning relationships between human disease-linked genes and their fly orthologs; and a summary of experimental data and results using fruit flies. We have also incorporated relevant data described elsewhere in FlyBase, including physical interactions, Disease Ontology annotations of alleles, and genetic reagents. These reports are specifically designed to be accessible to non-fly researchers in order to promote collaboration across model organism communities working in translational science, while also providing a convenient entry point for Drosophila researchers interested in disease model systems.

D1390C Genetic screen for Wnt signaling factors that regulate *Drosophila* nociception. *P. R. Freeman*, Andew Bellemer. Appalachian State University, Boone, NC.

The mechanisms that regulate the transduction of noxious stimuli and generation of appropriate behavioral responses in *Drosophila melanogaster* are not fully understood. In larvae, Class IV multidendritic neurons are highly branched sensory neurons that are responsible for detecting noxious chemical, thermal, or mechanical stimuli and generating appropriate behavioral responses. Recent studies have demonstrated involvement of Wnt signaling in regulating nociception and the development of chronic pain in vertebrate models, but the underlying cellular and molecular mechanisms are still not understood. In order to better understand the roles of Wnt signaling in *Drosophila* nociception, I have selected 77 Wnt signaling-related genes and obtained UAS-RNAi lines for each from the Drosophila TRiP collection for an RNAi screen for nociception defects. I have crossed these RNAi lines with flies carrying the Class IV-specific *ppk-GAL4* driver and tested the larvae progeny with a well-established thermal nociception assay. We found the Wnt RNAi behavior phenotypes can be divided into three classes: 1) hypersensitivity to noxious stimuli; 2) insensitivity to noxious stimuli; 3) no change in response to noxious stimuli. These phenotypic categories are established by comparing the response latencies of RNAi animals to the latency of a transgenic control strain. Once candidate genes that produce significant hypersensitivity or insensitivity to thermal stimuli have been identified based on their behavioral phenotypes, I can then further analyze these genes to identify the cellular and molecular mechanisms of how they control nociceptor development and function maintain appropriate sensitivity to noxious stimuli. I have identified the protein tyrosine kinase 7 homolog, *off track2*, as a promising candidate for further analysis based on its reduced sensitivity to noxious thermal stimuli and previously established role in Wnt2 signaling. This further analysis consists of 1) genetic conformation with additional RNAi lines and genetic mutants; 2) gain and loss of function studies and epistasis analysis; 3) functional studies to determine the role of off track2 in Class IV neuron morphological development and electrical activity.

D1391A The Effects of various heavy metals on Drosophila melanogaster third Instar Larvae Polytene Chromosomes. *Osamah Batiha*, Christina Canavati, Ahmed Elbetieha, Rami Alkhatib. Jordan university of science and technology, Irbid, JO.

Heavy metals are naturally present on earth; nevertheless, their bioaccumulation in the environment triggers severe ecological issues, jeopardizing the ecological balance and ultimately producing detrimental effects on human beings and different living systems. To assess the genotoxic effect of various heavy metals, we used *Drosophila* third instar larvae polytene chromosomes as a model. Many chromosomal aberrations (breaks, semibreaks, constrictions and asynapsis) were observed. The frequency of chromosomal aberrations was significantly increased (P-value= 0.001) in groups treated with heavy metals at a concentration of 1000ppm compared to the control group. Understanding the genotoxicity of heavy metals is of great importance. Lack of such information could lead to difficulty in evaluating the danger of such environmental pollutants. For this reason, studying the various effects of these environmental contaminants on *Drosophila melanogaster* polytene chromosomes could aid in measuring their impact at the chromosomal level rather than going to the chemical analysis.

D1392B Polyamines: simple molecule, complex transport system. *D. Brown*, Elena Coronado, Nicole Barnette, Laurence von Kalm. University of Central Florida, Orlando, FL.

Polyamines are small cationic molecules found in all organisms and are essential in growth and proliferation. Intracellular polyamine concentrations are maintained by a combination of biosynthesis, transport, and degradation. Biosynthesis and degradation have been well studied, but even a basic understanding of the transport system remains elusive. Previously our lab identified a membrane-associated P-type ATPase with six protein isoforms necessary for polyamine transport using an in vivo RNAi approach. Current work looks to build on prior work by identifying proteins in complex with the P-type ATPase through Tandem Affinity Purification (TAP) and Tandem Mass Spectroscopy (MS/MS).

The description of components involved in transport will allow us to characterize a poorly understood biological system relevant to all organisms.

D1393C Flies and human disease: Resources at the Bloomington Drosophila Stock Center for human disease-related research. *A. L. Parks*, K. Matthews, K. R. Cook. Bloomington Drosophila Stock Center, Indiana University, Bloomington, IN.

An increasing number of researchers are utilizing the powerful genetic and molecular tools offered by Drosophila to develop and study fly lines which faithfully recapitulate aspects of human disease or human health-related processes. Drosophila models are being used in all aspects of human disease research, including basic research into the underlying mechanisms of disease, screens for disease modifiers for use in drug target discovery, and direct drug screening. To facilitate research into human disease, we are assembling lists of human disease genes, identifying their fly counterparts, and generating a catalog of stocks at the BDSC that can be used to model a disease or study pathways associated with the disease (http://flystocks.bio.indiana.edu/Browse/HD/HDintro.htm). We will present these efforts as well as give an overview of the many types of collections at the BDSC that can be screened for modifers of your favorite Drosophila human disease model.

D1394A Outfast, Outyield, Outlast: Modified foxo increases Drosophila survivorship during amino-acid starvation. *J. D. Slade*, B. E. Staveley. Memorial Univ, St John's, NL, CA.

Disordered eating may lead to diagnosable medical conditions such as anorexia and bulimia, to extreme weight loss or to obesity. While no animal model is able to mimic the entirety of any complex human disease or behaviour, *Drosophila melanogaster* can serve as an uncomplicated model to study the biological basis of abnormal eating patterns. The conserved insulin receptor pathway and its endpoint effector the foxo transcription factor are pivotal for survival during nutritional stress. The loss of *foxo* function results in a defective survival response to amino-acid starvation. Two modifiers of foxo activity, the Akt1 kinase and the Sir2 deacetylase, may adjust the activity of foxo to enhance survival. Novel *Akt1* mutant lines exhibit a moderate decrease in lifespan and growth when aged upon standard media, yet they show a significant increase in survival on amino-acid deprived media. Replacement of Akt1 activity is sufficient to suppress these phenotypes. Combination of the novel *Akt1* hypomorphs and the null *foxo* mutant reveal an epistatic relationship. Biometric analysis and longevity evaluation of these double mutants indicate a phenotype similar to the original *foxo* mutant signifying its necessity in the *Akt1* phenotype. Unlike the *Akt1* mutants, *Sir2* mutant heterozygotes do not have altered growth when raised upon standard conditions. However, the *Sir2* heterozygotes exhibit a greatly extended lifespan when reared on both a standard diet and when starved of amino-acids. These results indicate that the subtle manipulation of foxo, by either *Akt1* or *Sir2* mutants, can enhance survival during adverse nutrient conditions to model the survival of individuals undergoing nutrient deprivation. Ultimately, we believe that a Drosophila model of disordered eating could generate new avenues of potential therapies for related human conditions. Funded by an NSERC PGSD and a School of Graduate Studies Fellowship to JDS and an NSERC Discovery Grant to BES.

D1395B Annotation of the *Drosophila ficusphila* Contig 53 on Chromosome 4 Using Comparative Genomics. *Ahmad W. Al-Abduljabar*, James E. J. Bedard. University of the Fraser Valley, Abbotsford, BC, Canada.

Evidence-based comparative genomics was used to annotate contig 53 genomic sequence spanning 30,500 bp on the dot chromosome of *Drosophila ficusphila*. The project was completed with the help of the Genomics Education Partnership undergraduate student research initiative. In Drosophila the distal portion of the dot chromosome is of interest due to having heterochromatic characteristics but maintains a gene density similar to euchromatic regions. The databases and web-based tools of FlyBase, GEP UCSC Genome Browser Mirror, NCBI BLAST, Gene Record Finder, and Small Exon Finder were used for gene annotation of this region. The genomic DNA sequence was compared with the *Drosophila melanogaster* genome and five putative orthologs were annotated: CG33521, PIP4k, Mitf, Arf102F, and Dyrk3. These genes showed conservation with *D. melanogaster* genes, ranging between 64.1%-98.3% identity (%ID) conservation. Genes known to have many biologically crucial functions, such as Arf102F (%ID=98.3) and PIP4K (%ID=97.5), showed high amino acid sequence similarity. Mitf (%ID=74) and Dyrk (%ID=75.9) have less biologically important roles within the organism and showed lower similarity. Genes identified as not having biologically crucial functions, such as CG33521 (%ID=64.1), showed very low sequence similarity between the two species. CG33521 gene codes for a Zinc ion binding protein. PIP4K gene codes for a protein kinase involved in many pathways including cell growth, cell adhesion, and actin filament organization. Mitf gene codes for a transcription factor involved in the regulation of protein dimerization. Dyrk gene codes for a protein kinase involved in phosphorylating ATP-binding proteins. These findings will help contribute a better understanding of the characteristics and evolution of the dot chromosome within Drosophila.

D1396C The use of comparative genomics in the evidence-based annotation of contig10 on the 3L chromosome of *Drosophila elegans*. *Vivienne K. Beard*, James E. J. Bedard. University of the Fraser Valley, Abbotsford, British Columbia, Canada.

Genomic annotation is the process of locating functionally relevant regions within a stretch of DNA. Specifically, the annotation of genes includes locating gene start sites, stop sites and determining the coordinates of coding exons in addition to describing the function of these genes. The genome of *Drosophila melanogaster* has been entirely annotated, and is therefore an excellent reference species for the annotation of genes in related Drosophila species. The goal of the present study was to use comparative genomics to construct evidence based gene models for multiple isoforms of 8 orthologous genes present on contig10, a 50,000 base pair DNA sequence, of the 3L chromosome of *Drosophila elegans*. The bioinformatics tools utilized included FlyBase, Gene Record Finder, NCBI BLAST, Gene Model Checker, Small Exon Finder, and the UCSC Genome Browser Mirror. Together, these bioinformatics tools were used in conjunction with biological evidence to successfully construct high quality gene models for multiple isoforms of 8 putative orthologs present on contig10: ArfGAP3, CG32452, mael,

CG14450, CG11367, CG32454, CG11241, and l(3)04053. These genes showed variable conservation relative to the putative *D. melanogaster* orthologs, ranging between 38.6-90.4% protein identities. Genes with known crucial ontology, such as ArfGAP3 (ADP-ribosylation factor GTPase activating protein 3) showed high conservation with *D. melanogaster* (%ID = 90.0%), while lesser studied genes such as CG32452 showed much lower conservation (%ID = 38.6%). The construction of high quality evidence-based gene models will contribute to the understanding of the evolution of the heterochromatic dot chromosome compared to euchromatic regions in different Drosophila species.

D1397A Annotation and transcription start site discovery on the dot chromosome of *Drosophila ficusphila* and *Drosophila biarmipes*. *R. E. Boody*, C. M. Brown, S. A. Liber, J. L. Sanford. Ohio Northern University, Ada, OH.

The Muller F element, or chromosome 4 in *Drosophila,* is commonly referred to as the dot chromosome. This chromosome is unique among other *Drosophila* autosomes as it is highly heterochromatic and contains a high density of repetitive sequence. Remarkably, comparative genomic analyses of the dot chromosome show similar proportions of active genes in comparison to the euchromatic control regions. The Genomics Education Partnership (GEP) at Washington University, St. Louis, aims to elucidate the evolutionary mechanisms by which this uncommon gene expression occurs. Undergraduate students across the country work with the GEP to manually annotate genes, develop gene models, and search for transcription start sites in newly sequenced *Drosophila* genomes. The present work focuses on the annotation of contigs 32, 34, 36, 37, and 42 of the *Drosophila ficusphila* dot chromosome assembly and the discovery of transcription start sites (TSS) in contig 62 of the *Drosophila biarmipes* dot chromosome assembly. Annotation of genes relies on standard bioinformatic tools, including NCBI BLAST, *in silico* gene prediction programs, and a mirror to the UCSC Genome Browser to manually curate the gene models. These models include the determination of start and stop coordinates for all the exons of all the genes present on the contig. The process of TSS discovery depends on similar bioinformatic tools, using the UCSC Genome Browser in conjunction with Celniker data to determine the presence, location, and type of the ortholog in *D. melanogaster.* Ultimately, this data is used to determine the presence, location, and type of promoter in the target species. Data obtained from the annotation of contig 32 in the *D.ficusphila* dot assembly revealed 6 genes: Eph, Gat, mav, Ekar, CG11155, and Slip1. Genes gw, CG11360, and myo were found on contig 34. Contig 36 contains the genes ey, toy, and bt, which continues onto contig 37. The only remaining gene on contig 37 is MED26. Lastly, annotation of contig 42 showed the presence of 2 genes, unc and mGluR. TSS discovery in contig 62 of the *D. biarmipes* dot assembly included the elucidation of the transcription start site of the sv gene. Future work will further develop understanding of the TSS discovery via motif hunting for common promoter elements to determine potential differences in motif distribution along the dot chromosome in comparison to the heterochromatic control regions. Analysis of gene structure and TSS annotation in the dot and 3L control chromosomes across multiple *Drosophila* species, including the genes in this study, will aid in highlighting the mechanisms driving gene expression in the highly heterochromatic dot chromosome.

D1398B Messenger RNA-associated processes and their influence on exon-intron structure in *Drosophila*. *F. Catania*, G. Lepennetier. Institute for Evolution and Biodiversity, Muenster, DE.

It is well established that extensively interacting mRNA-associated processes in eukaryotes are crucial for the accurate processing of nascent transcripts. What is less clear—and almost entirely unexplored—however, is whether these interactions affect gene structure.

Drawing from a wealth of knowledge on *Drosophila melanogaster* genetics, molecular and cell biology, and biochemistry, we generated and tested three hypotheses as to how mRNA-associated processes might influence gene architecture. Our findings suggest that the interactions between capping, splicing, cleavage/polyadenylation, and telescripting may impose significant constraints on gene structure. Our study and its results offer an expandable framework for future cross-disciplinary investigations.

D1399C *De novo* evolved genes are essential for spermatogenesis in *D. melanogaster*. *Geoffrey Findlay*, Anna Gubala, Tery Vinh, Michael Kearns, Purva Rumde. College of the Holy Cross, Worcester, MA.

Gene duplication has long been considered the major evolutionary process that gives rise to new, lineage-specific genes. However, recent research in *Drosophila* and other taxa suggests that *de novo* evolved genes are also an important source of evolutionary novelty. *De novo* genes arise from non-protein-coding DNA at a surprisingly high rate, and their expression is often restricted to the male germline. Previous studies have attempted to use organism-wide RNA interference to infer the function of these genes, but interpretation of these results has been impaired by technical issues with the RNAi library that was used. By using tissue-specific knockdown in the testes, we have identified two *de novo* evolved genes, *saturn* and *goddard*, that have become essential for spermatogenesis and sperm function in *D. melanogaster*. RNAi depletion of *saturn* leads to a 60 percent reduction in sperm production and transfer and a near-complete inability of sperm to be stored in the female reproductive tract. Depletion of goddard prevents production of mature sperm by the testes. Molecular evolutionary analyses showed that *saturn* arose near the base of the *Drosophila* phylogeny and has a dynamic evolutionary history that includes gene duplication, gene loss, and positive selection in *D. melanogaster* and its closest relatives. In contrast, *goddard* is present only in the melanogaster group of species and has evolved under purifying selection. While males of all *Drosophila* species produce sperm, there is extensive interspecific variation in the type, size and number of sperm produced in males and in the patterns of sperm storage in females. Our data suggest that lineage-specific *de novo* genes may play a previously unappreciated role in boosting male fitness by shaping the critical process of spermatogenesis.

D1400A New genes play a key role in the reproductive fitness of *Drosophila melanogaster*. *A. R. Gschwend*, N. VanKuren, J. Mihaljevic, S. Allesina, M. Long. University of Chicago, Chicago, IL.

The ability to pass genetic material on to the next generation is a key driving factor of evolution, but the determinants of the evolution of reproductive fitness are relatively unknown. New genes have been shown to be essential for life in *Drosophila melanogaster*, but the extent to

which new genes are important for reproductive fitness has not been thoroughly explored. We assessed the reproductive fitness effects of 91 newly evolved genes, with ages ranging from <1-25 million years, by carrying out constitutive knockdowns using RNAi for each gene in male and female *Drosophila melanogaster*. We quantified male fertilization success and female fecundity by counting and comparing the resulting offspring number from each set of knockdown reciprocal crosses to the reproductive output of non-knockdown parallel control crosses. Over half of the newly evolved genes (53%) we tested had significant beneficial effects on offspring number, revealing important roles of newly evolved genes in the reproductive fitness of *Drosophila melanogaster.* In addition, 7 new genes showed extreme effects on offspring number, resulting in near sterility when knocked down, suggesting a handful of new genes are essential for normal *Drosophila melanogaster* fertility.

Overall, 47% of the new genes tested had a significant beneficial effect on male reproductive fitness compared to the controls, while only 5 new genes had a significant beneficial effects on female offspring number (one gene had a significant beneficial effect for both sexes), revealing differential fitness effects of new genes in males and females. 20% of the new genes had significant differential effects of the same gene on offspring number between males and females; in the majority of these cases (83%), the new gene was significantly beneficial to male reproductive success, whereas it did not significantly affect the female offspring number. Expression data revealed that the majority of new genes were highly expressed in the testis and male accessory gland, providing additional evidence for the role of new genes in male reproductive fitness. Male and female adaptive needs are often different, due to their unique reproductive roles. Our results support the idea that new genes are a driving force in the evolution of reproductive fitness and male-driven evolution is an important component contributing to the retention of new genes in the *Drosophila melanogaster* genome.

D1401B The recombination landscape of *Drosphila virilis* under hybrid dysgenesis. *L. Hemmer*, J. Blumenstiel. University of Kansas, Lawrence, KS.

DNA damage in the germline is a double-edged sword. On one hand, induced double-strand breaks establish the foundation for meiotic recombination, which is essential for proper chromosome segregation. On the other hand, double-strand breaks can also pose a significant challenge for genome stability. Within the germline, transposable elements are powerful agents of double-strand break formation. How different types of DNA damage are resolved within the germline is poorly understood. For example, little is known about the relationship between the frequency of double-stranded breaks, both endogenous and exogenous, and the decision to repair DNA through one of many pathways, including crossing over and gene conversion. We aim to use the *Drosophila virilis* hybrid dysgenesis model to determine how recombination landscapes change under transposable element activation. In this system, a cross between two strains of *D. virilis* with divergent transposable element loads results in the hybrid dysgenesis phenotype, which includes the germline activation of diverse transposable elements, reduced fertility and male recombination. However, only one direction of the cross results in hybrid dysgenesis. This allows us to examine recombination in genetically identical F1 females; those with baseline levels of programmed DNA damage and those with an increased level of DNA damage resulting from transposable element proliferation. We are using multiplexed shotgun genotyping to map crossover events to compare the recombination landscapes of hybrid dysgenic and non-hybrid dysgenic individuals. Finally, we are examining whether the additional crossovers are mitotic or meiotic in origin by characterizing the degree to which increased levels of recombination arising from transposable element activation are clustered among siblings.

D1402C How does replication level contribute to genome size evolution in *Drosophila* species? *C. E. Hjelmen*, J. S. Johnston. Texas A&M University, College Station, TX.

Underreplication (replication of a portion of the total complement of DNA in each chromosome) is well documented in the highly polytene chromosomes of *Drosophila* ovary nurse cells, follicle cells surrounding oocytes, abdominal histoblasts, fat body cells, gut cells, and cells of the late prepupal salivary glands. Recently we found that replication in a majority of thoracic cells in *D. melanogaster* stall between G1 and G2, which means these cells too are underreplicated. Since variation in genome size has been shown to be linked to the amount of repeat and noncoding sequence, we ask, "Is the percentage of replication in DNA of thoracic cells directly related to the genome size of a species, and Is this consistent among species*?"* We also ask, "How much does the late replicating portion of the genome contribute to overall genome size evolution?" To address these questions, we estimate, using flow cytometry, the underreplication level and genome size for more than 100 Drosophilidae from the UC San Diego Species Stock Center. These data are then analyzed using traditional statistic methods as well as newer comparative phylogenetic methods in an effort to measure phylogenetic signal and rate of evolution of genome size of replicated and underreplicated DNA. The *Drosophila* phylogeny used for this analysis was reconstructed with the super-matrix method using Bayesian reconstruction. Preliminary results have shown that with a few striking exceptions, larger genomes of *Drosophila* have lower replication percentages; whereas small genomes have complete or almost complete levels of replication. These data support the conclusion that genome size change is largely, but not always, an increase or decrease in noncoding sequence. Moreover, the rate and mode of change is different for the replicated and unreplicated portions of the genome.

D1403A A high frequency of transposable element tandems is a potential source of new satellite arrays. *M. P. McGurk*, D. A. Barbash. Cornell University, Ithaca, NY.

Eukaryotic genomes are replete with repeated sequences, either dispersed across the genome by transposition events (transposable elements, TEs) or in large tandemly arrayed blocs (satellites). Satellite arrays commonly comprise the centromeres and telomeres, forming structures essential to cell division and replication, evolve by expansions and contractions that are probably largely neutral in nature, and have a high turnover rate. This high turnover must arise through processes of rapid gain and loss. While it is not fully clear how new complex satellite arrays arise, some known satellites clearly originated from TEs, suggesting that TEs can provide source material for the emergence of new

arrays.

With this in mind, we sought to leverage the abundance of available Next-Generation Sequencing (NGS) datasets to assess the extent to which transposable elements form tandem arrays, and how these tandems vary across populations of *Drosophila*. To circumvent the difficulties of mapping repeat-derived reads, we employ an alignment strategy that maps paired-end reads to the consensus sequences of known repeats and implement an Expectation-Maximization algorithm to discover tandem structures in the aligned data.

We applied this method to the hundreds of available *D. melanogaster* NGS datasets. With the exception of a few previously known examples, we rarely detect large tandem arrays of TEs in *Drosophila melanogaster*, however we find that small tandems are surprisingly common. An exception is a rare instance where ~20 copies of the Hobo transposon are arrayed in tandem found in a single line. Further, P-element forms small tandem arrays (<8 copies in tandem) in over 50% of lines; because P-element invaded D. melanogaster in the last century, these tandems must be recently formed structures, suggesting that tandem transposable elements can form and expand into larger arrays over short time scales. These observations suggest that some TE families readily generate the small tandems, which are substrates necessary for the expansion of a larger array. These emerging tandems have the potential to modify chromatin state, concentrate regulatory elements at particular loci, and potentially regulate the expression of other TEs. Going forward, the identification of these strains with novel and low frequency tandems provides us the opportunity to assess the phenotypic impacts of tandem TEs and ask questions about the evolution of young satellite arrays.

D1404B Rapid acquisition of novel immune system genes via duplication and *de novo* origination in dipterans. *Tim Sackton*[1], Brian Lazzaro[2], Andrew Clark[2]. 1) Harvard Univ, Cambridge, MA; 2) Cornell Univ, Ithaca, NY.

Genes encoding immune system proteins are often among the most rapidly evolving genes in the genome due to host-pathogen arms race dynamics. Using new annotations and transcriptome sequencing of infected and control (naive) flies across 10 species of Drosophila and the house fly *Musca domestica*, we show that high rates of novel gene acquisition (by gene duplication and by *de novo* gene origination) also characterize dipteran immune systems. In the house fly, which occupies an unusually pathogen-rich niche among sequenced dipterans, we use new models of gene family evolution to investigate duplication and loss rates across several different classes of immune-related genes. We demonstrate that genes encoding proteins involved in either pathogen recognition or pathogen killing have been duplicating at a significantly accelerated rate along the *M. domestica* lineage compared to other dipterans, perhaps as a consequence of its septic habitat. Some of these same proteins also display marked patterns of nonneutral sequence divergence. Comparative post-infection RNA-seq analysis also indicates considerable functional evolutionary divergence among dipteran species. Taken together, our results suggest that changes in gene content, sequence and regulation may play a critical role in host adaptation to pathogen pressure.

D1405C The Hawaiian *Drosophila* genome project: Transcriptomes. *Haiwang Yang*[1], Terence Murphy[2], Kenneth Kaneshiro[3], Durrell Kapan[4], Brian Oliver[1]. 1) National Institutes of Health, Bethesda, MD; 2) National Center for Biotechnology Information, Bethesda, MD; 3) University of Hawaii at Manoa, Honolulu, HI; 4) California Academy of Sciences, San Francisco, CA.

Understanding how transcriptomes differ within and between species is key to understanding everything from personalized medicine to phenotypic changes on evolutionary timescales. Hawaiian flies provide an exceptional model for understanding population structure as well as sympatric and allopatric speciation. >500 species of *Drosophila* unique to the Hawaiian archipelago have been described. These islands are located thousands of kilometers from continents and it is believed that all the species in this extensive radiation developed from a single founder female approximately 25 million years ago. The individual volcanic islands arise in series as the pacific plate passes over a mantle hotspot, such that the geological age of each is well established, placing firm limits on when new founder populations arrived. In addition to reproductive isolation events due to initial founder effects, there are subsequent isolation events because of subsiding volcanoes and sea level rise that fragment old islands, and lava flows that fragment ecosystems on young islands. There are major microclimate differences due to island features such as altitude and rain shadows that promote adaptive radiation. Mating behavior is particularly striking as males perform elaborate displays and bouts in leks. There are also morphological specializations for male-male competitions (such as battering ram heads in *D. heteroneura*). At abstract submission, we have performed mRNA sequencing for a total of 149 samples (over 1.5 billion RNA-seq reads) to explore expression variance due to sex (N=2), tissue (N=8), strain or species (N=10), and island (N=4). We are assembling transcripts *de novo* and have mapped reads to the *D. grimshawi* genome (the only currently assembled hawaiian genome). Fortunately, >84% of our reads from *D. silvestris, D. hemipeza, D. heteroneura,* and *D. hawaiiensis* uniquely align to the *D. grimshawi* genome. We are also reannotating the *D. grimshawi* genome and evaluating the SNPs and Indels in transcriptome for within- and between-species variance in addition to expression level variance. Variance in male- and particularly testis-biased (sampled separately from male reproductive tract) gene expression is marked. These observations highlight the importance of sexual selection in speciation of these flies (the Kaneshiro hypothesis) at the genome deployment level, despite the many island niche features that one would expect to drive selection for individual fitness. These results indicate that this genomic model will be a powerful tool for exploring population and evolutionary questions.

D1406A The changing biodiversity of Alabama *Drosophila*: important impacts of climate variation, urbanization, and invasive species. *A. Bombin*, L. Reed. The University of Alabama, Tuscaloosa, AL.

Global warming and anthropogenic disturbances significantly influence the biosphere, tremendously increasing species extinction rates. In central Alabama we analyzed Drosophilidae species composition change 94 years after the previous survey. We found ten Drosophilid species that were not reported during the last major biodiversity survey, two of which are invasive pests. In addition, we analyzed the influence of environmental variables characteristic of the subtropical climate zone on *Drosophila* abundance and biodiversity. We found a significant

correlation between temperature and abundance of total *Drosophila* as well as for six out of the seven most represented species individually, with a maximum abundance at intermediate temperatures (18-26°C). In addition, temperature was positively correlated with biodiversity of *Drosophila*. Precipitation produced a significant effect on the abundance of five species of Drosophila, with different optima for each species, but did not affect overall biodiversity. We concluded that in the subtropical climate zone of central Alabama, temperature and precipitation produce a significant effect on *Drosophila* abundance and biodiversity, while local land use also impacts fly abundance, contributing to a substantial shift in species composition over the last century. We expect global climate change and other anthropogenic factors to further impact *Drosophila* species composition in the subtropical climate zone into the future.

D1407B The molecular difference between grey and black genotypes collected in Plopsoru village. *G. A. Butnaru*[1,2], I. Sarac[1], S. Popescu[1]. 1) Banat Univ Agricultural Sci, Timisoara, Banat, RO; 2) Academy of Romanian Scientists.

In 2010, from a sample of fruit flies collected from Plopsoru village a few individuals with a dark color and unusual behavior were separated. Plopsoru village represents a hilly-agro-ecosystem situated in miners' area. After phenotypic checking the sample was split into two: a large grey group – Grey Plopsoru (GP) and few black individuals that generated a new "population" named Black Plopsoru (BP). The new genotype showed different morphological features: very dark black body and eyes, the size of wing imaginal discs at L3 significantly lower, eggs with 6-8 appendices, larval motility during the night, the pupae located in the cotton stopper and strong reproductive barrier for other *Drosophila* lines even for GP ecotype. In comparison to standard genotypes Oregon and white (w1118) and GP the life cycle of BP was longer with 99.2%, 120% and 108% respectively and emphasized a nocturnal behavior. For each ecotype successive generations were produced (six for BP and seven for GP). To establish the similarity vs. evolutionary distance among the analyzed *Drosophila* genotypes the ISSR (*Inter Simple Sequence Repeat*) and RAPD (*Random Amplified Polymorphic DNA*) markers were used. Therefore the polymorphism was emphasized randomly in genome and also for the segments located between microsatellites. It was pointed out that all of the selected markers (eight ISSR and four RAPD) generated a number of fragments ranged between 7 and 23 per primer. For all of the RAPD primers the similarity was 100%. All of the primers amplified 163 fragments of which 159 (97.5%) were polymorphic. The UPGMA (*unweighted pair-group method*) clustering method was used to establish the similarity coefficients and the dendrogram.

According to their genetic background the accessions of BP and GP were grouped in two main clusters, with a coefficient of similarity of 40.20±4.38%. In the first cluster all of the BP generations were grouped, with a very high similarity 96.96±1.13%. All of the GP generations formed the second cluster emphasizing a higher variability compared with BP, the similarity coefficient inside the group being 72.58±10.69. The highest and the lowest coefficients were 87.25% between first and fourth generations for BP, respectively 55.03% between second and sixth GP generations. Therefore, two subclusters were separated, the first being made up from the first five generations and the second one from six and seven generations, pointing out a large distribution of the similarity coefficients. The molecular evaluation revealed the big difference between BP and GP even if they are the "product" of the same evolutionary conditions; BP pointed out a high stability in the offspring six generations.

D1408C Male genotype-specific transcriptional responses to mating in female *Drosophila melanogaster*. *S. Y. N. Delbare*, C. Y. Chow, M. F. Wolfner, A. G. Clark. Cornell University, Ithaca, NY.

Reproduction is a process that involves interactions between males and females at the level of the organism, at a cellular and molecular level, and at the level of the genotype. For *D. melanogaster*, several studies have demonstrated that natural variation in male genes involved in male-female genotype interactions affects female post-mating behavior and reproductive success. How natural variation in male genes affects female gene expression after mating is less well known.

To learn how male-female genotype interactions affect female gene expression after mating, we performed RNA-seq on female flies to detect transcriptome changes before mating and six hours after they had mated with genotypically different males. We used males and females from *melanogaster* inbred lines derived from five geographically dispersed populations. Females from each line were singly mated to a male from each of the same five inbred lines.

Post-mating mRNA levels were compared to those of unmated females from the same population. If a gene's expression changed after mating, we determined if its fold change differed depending on the genotype of the female or the male with which she mated. Linear models were fitted to assess the magnitude of the effect of male genotype, female genotype, and their interaction. Among the genes significant for this interaction effect, we found a highly significant enrichment of immune response genes (EASE score = 2.2×10^{-6}).

Additionally, over 20 transcripts that derive from genes exclusively expressed in male reproductive tissue were found in females after mating. This indicates that *D. melanogaster* males transfer RNAs, along with sperm and seminal fluid proteins during mating, as was reported previously in *D. mojavensis* and *D. arizonae* and in *Aedes* mosquitos. Our dataset expands the suite of male derived transcripts found in female flies after mating and opens the door to apply the technologies available to *D. melanogaster* to investigate potential functional roles of these transcripts.

This work was supported by NIH R01-HD059060.

D1409A Functional networks of locally adapted reproductive proteins in two Drosophila populations. *C. E. Stanley*, R. J. Kulathinal. Temple University, Philadelphia, PA.

Genomic patterns of variation offer powerful insights into the selective conditions that existed in the past. Previous studies highlight the role of rapidly evolving sex and reproductive genes in population divergence and subsequent isolation. Yet whether these highly diverged genes

represent population-specific (i.e., local) adapted functional networks is not well understood. Here, we compare the functional landscape of adaptive change across protein-coding genes involved in various aspects of male and female reproduction between two populations of *D. melanogaster*, an ancestral African population (Gambia) and a more recently derived North American population (Raleigh NC). .

D1410B Conservation and evolution of maternal RNA deposition and early zygotic transcription in *Drosophila* . *Joel Atallah*[1], Susan E. Lott[2]. 1) University of New Orleans, New Orleans, LA; 2) University of California - Davis, Davis, CA.

Transcripts corresponding to thousands of genes are deposited by the mother in the egg. Throughout the earliest developmental stages following fertilization, the embryo is transcriptionally silent, and these mRNA transcripts set the trajectory for subsequent development. During the maternal-zygotic transition (MZT), a substantial fraction of maternal mRNAs are targeted for degradation, and the first zygotic genes are transcribed. While some maternal and early zygotic genes have been exhaustively analyzed, the early embryonic functions of many others are unknown. The precise function of maternal mRNA degradation, and why only specific transcripts are degraded, has been debated. We created a transcriptomic dataset for 14 *Drosophila* species at stages before and after the maternal-zygotic transition, from single embryos, and compared our results with a previously published *Aedes Aegypti* developmental time course. Transcripts that that are represented at both stages are remarkably stable over evolutionary time, while the levels of transcripts that are present at only one stage vary widely between relatively close relatives. Maternally deposited genes that are degraded at the MZT vary dramatically across species, suggesting that these genes may either have an early function that is highly species-specific, or may represent developmental noise that is attenuated through degradation. While purely zygotic transcripts also vary considerably across evolutionary time, we found a small group of purely zygotic genes that are extremely conserved across hundreds of millions of years of evolution. This select group is highly enriched in transcription factors that play critical roles in early development. Our results suggest that the combined contribution of transcripts from the maternal and zygotic genomes meet the developmental constraints of the embryo, while genes expressed only from the maternal genome or zygotic genome evolve more freely.

D1411C Insect Egg Evolution: Diversity of Size and Shape at the Single-Cell Stage. *S. Church*, S. Donoughe, C. Extavour. Harvard University, Cambridge, MA.

Insects eggs come in all shapes and sizes. The morphological diversity at the single-cell stage has implications for the development and adult morphology of the insect. In *Drosophila*, we know of mutations which control egg size, and across flies in Drosophilidae a diversity of egg sizes has been recorded. However far less is understood about how insect eggs have evolved, and few studies compare the diversity of insect eggs across orders or by using methods that take into account the insect phylogeny. To address this problem, we assembled a database of thousands of insect egg size measurements which we used to analyze egg morphological evolution across the insect tree, including within Diptera and within Drosophilidae. Here we show the results of using this database to analyze how egg width and length vary across the insect tree, including repeated convergent evolution of very large and very small eggs. We also analyze the coevolution of egg size and shape with other traits, including body size, ecological habitat (ie aquatic vs terrestrial), and development type (ie syncytial vs holoblastic). The diversity at the single cell stage rivals the diversity of adult forms, and this study reveals rich and complex patterns in egg evolution.

D1412A Functional analyses of the transposable element-derived genes *DPLG1* and *DPLG4* in *Drosophila melanogaster*. *D. Jangam*[1], C. Feschotte[2], E. Betrán[1]. 1) University of Texas at Arlington, Arlington, TX; 2) University of Utah, Salt Lake City, UT.

Our laboratory has described several domesticated transposases from PIF/Harbinger DNA transposable elements (TEs) in *Drosophila* (Casola et al. 2007). Although, the exact functions of these genes are still unknown, these transposase-derived genes appear to have their DNA binding domain conserved but not their catalytic domain and we hypothesize that they might be regulatory proteins. Their regulatory function might include the regulation of TE activity. Here, we present work aimed to elucidate the function of two of the PIF/Harbinger derived transposases named *Drosophila PIF like gene 1* (*DPLG1*) and *DPLG4*. Taking advantage of the UAS/GAL4 system, these two *DPLG*s were knocked down ubiquitously and the effects on the viability and fertility were studied. Using light microscopy and fluorescent microscopy, defects in the testis of knock-down (KD) flies were identified. *In situ* hybridization was used to ascertain the level of transcript reduction in KD testis, and RNA-seq analyses were performed for KD testis and controls to quantify differentially expressed genes and TEs. KD of *DPLG1* does not affect viability in *D. melanogaster*; however, it resulted in male sterility. We observe that the elongated spermatids do not individualize into mature sperms and the seminal vesicles are empty. The testis of these KD males show increased activity of LINE TEs including all three telomeric elements. In addition, *DPLG4* came out in a screen designed to detect genes involved in TE control (Handler et. al 2013). KD of *DPLG4* reduces viability of *D. melanogaster*. This result has been independently validated using a *DPLG4* mutant line. *DPLG4* KD males showed a phenotype analogous to *DPLG1* KD males. Taken together, these results support that *DPLG4* might play a role in the viability of D. melanogaster, and *DPLG1* and *DPLG4* might be needed during spermatogenesis and could potentially have been recruited from PIF/Harbinger TEs to defend against the detrimental activities of other parasitic elements. We are in the process of generating resilient transgenes for *DPLG1* and *DPLG4* which will be used to rescue the defects resulting from the KD and KO experiments. To further advance our understanding of the functional importance of these genes, we are generating null mutants of *DPLG1* and *DPLG4* using CRISPR-Cas9 which will be used to further investigate the role of these genes. This will help us validate the results from our experiments. Additionally, the resilient constructs are HA tagged and will be used to test the nuclear localization of these genes and their interactions with chromatin remodeling proteins. .

D1413B Evolutionary cooperativity between mating position and rotation of male genitalia in Diptera. *I. Momoko*[1], C. Sakuma[2], H. Kanuka[2], K. Matsuno[1]. 1) Osaka Univ., Osaka , JP; 2) The Jikei Univ. Sch. of Med., Tokyo, JP.

In many cases, animal behavior depends on morphology. Thus, during evolution, morphology and behavior should change cooperatively. However, the mechanisms of such cooperative evolution are hardly understood. For example, dipteran insects, *Drosophila melanogaster* and *Aedes aegypti* (mosquitoes) have two typical mating positions, male-above and end-to-end positions, respectively. In these two mating positions, dorsal-ventral direction of the male genitalia is upside-down with respect to female genitalia. However, the genitalia of *Drosophila* and *Aedes* rotate 360 and 180 degree, respectively, which compromises the upside-down direction of male genitalia associated with the evolution of mating position.

In this study, we attempted to analyze the cooperative evolution between the genitalia rotation and mating position during the evolution of dipteran insects. In *Drosophila*, *Myosin31DF* mutation affects the rotation of genitalia. Using *Myosin31DF* mutant males with abnormally rotated genitalia, we found the proper direction of male genitalia is a prerequisite for mating in *Drosophila*, suggesting potential cooperative evolution of them.

Currently, we are making *Myosin31DF* mutant mosquitoes by CRISPR/Cas system to obtain male mosquitos with abnormally rotated genitalia. The effects of abnormally rotated genitalia on the end-to-end mating position will be analyzed. Comparative analyses involving *Drosophila*, *Aedes*, and other dipteran insects should provide us important insights into the cooperative evolution of animal morphology and behavior.

D1414C Step-by-step evolution of Bicoid's anterior patterning functions. *P. Onal*[1], Q. Liu[2], R. Datta[1], J. Cao[1], J. Thornton[2], S. Small[1]. 1) New York University, New York, NY; 2) University of Chicago, Chicago, IL.

How new molecular functions emerge is a fundamental question in evolutionary biology. Here we focus on the homeodomain (HD) transcription factor Bicoid (Bcd), which emerged from a gene duplication that also gave rise to the paralogous protein Zen. After the duplication, Bcd diverged rapidly from Zen throughout its protein sequence, and acquired a pivotal role in anterior embryo patterning. We have used an *in vivo* rescue assay to test chimeric proteins that swap the HDs between Bcd and Zen. These experiments show that the Bcd HD is essential for anterior patterning, and that it can provide many of Bcd's molecular functions when inserted into Zen. To understand how the Bcd HD gained novel functions during evolution, we took an ancestral protein resurrection approach. Using a maximum likelihood-based method, we predicted HD sequences of the ancestors of extant Zen and Bcd proteins. The "ancestral HD" of Zen and Bcd (AncZen-Bcd HD) prefers a consensus Zen DNA-binding motif (ZM), and chimeric Bcd proteins containing this HD sequences cannot replace any of the patterning functions missing in embryos lacking Bcd. Further conservation analysis identified eleven amino acids in the HD as critical for Bcd evolution. Only two of these amino acids significantly change the *in vitro* binding activities of the HD. Substitutions of one (K50) is sufficient to convert the *in vitro* DNA binding specificity of the AncZen-Bcd HD to that of present-day Bcd. *In vivo* analyses showed that this amino acid is also required for Bcd's patterning functions. However, when introduced into the AncZen-Bcd HD, there is only a partial rescue of the *bcd* mutant, and activation of only a subset of Bcd target genes. We also tested R54, a second amino acid previously shown to be required for Bcd's RNA-binding activity. We find that insertion of R54 into the AncZen-Bcd HD does not change its *in vitro* DNA-binding specificity or activate Bcd target genes on its own. However, when both K50 and R54 are introduced into the AncZen-Bcd HD, its DNA-binding activity changes, and it turns on a larger subset of Bcd target genes compared to the K50 substitution alone. Our results show an interdependence between K50 and R54 in DNA-binding activity, and suggest that the evolution of Bcd involved step-by-step single amino acid substitutions that enabled the evolving protein to activate different subsets of target genes.

D1415A Species-specific transcriptional variation underlying *Drosophila* olfactory system structure and development. *J. Pan*[1], P. Volkan[1], C. Jones[2]. 1) Duke University, Durham, NC; 2) University of North Carolina at Chapel Hill, Chapel Hill, NC.

In fast-evolving neural circuits like the olfactory system, some neuronal lineages, and their developmental programs may be more variable, for better adaptability to the environment, while others may be more stable to conserve important functions. To test this, we conducted a comparative analysis of the olfactory system transcriptome of four different *Drosophila* species at multiple points during development. Our analysis revealed that the olfactory receptor neurons (ORNs) expressing Or22a show the highest variation in developmental and transcriptional programs. Interestingly, Or22a ORNs play an important role in the chemosensory adaptations of specialist feeder species to their host plants. Or22a receptor detects host plant odors, and the number of Or22a neurons and their target antennal lobe glomeruli in the brain are increased in both species. To determine whether the species-specific variation in Or22a ORN lineage, number and gene expression is also represented in their developmental program, we analyzed three classes of transcription factors acting at three stages of ORN development: 1) prepatterning transcription factors, which we recently found to partition the antennal disc into multiple rings each with a restricted developmental potential; 2) proneural genes, whose expression selects specific cells from these rings to become the precursors to form specific sensilla and the ORNs they house; and 3) terminal selector transcription factors that regulate olfactory receptor gene expression. Among these three regulatory classes of transcription factors in ORN fate determination, we found the pre-patterning transcription factors to be the most dynamic, both individually and in combinations, across species during development, especially for the combinations that generate the ab3 fate. In contrast, other ORN lineages are very stable both in number and gene expression profiles regulating their identity and developmental programs. Interestingly, pairwise comparison of the developmental gene expression profiles of olfactory system in four species showed that the specialists species are also the more similar in each other then they are to the generalist species. Together, these studies suggest that not only is variation in structural properties of Or22a ORNs associated with behavioral variation, but that this variation is also reflected in the developmental programs culminating in Or22a ORNs fates. Together, these findings may shed light on variation and plasticity in development of specific ORN lineages that may facilitate the adaptation of *Drosophila* chemosensory behaviors to specific ecological niches.

D1416B Butterfly color vision: stochastic patterning mechanisms and expanded sensory receptor diversity. *M. W. Perry*[1], M. Kinoshita[2], G. Saldi[3], L. Huo[1], K. Arikawa[2], C. Desplan[1,3]. 1) New York University, New York, NY; 2) SOKENDAI, The Graduate University for Advanced Studies, Hayama, Japan; 3) New York University Abu Dhabi, Abu Dhabi, UAE.

Butterflies use color vision extensively to navigate the natural world. Their retinas are more complex than those found in *Drosophila*, where development and patterning has been heavily studied. Instead of the eight photoreceptors found in flies, butterflies have an additional ninth photoreceptor per ommatidium ("unit eye"). They also have three main types of ommatidia instead of the two distributed stochastically in the fly retina. We set out to determine how butterflies generate increased sensory receptor diversity to provide improved color vision, and more specifically, to determine how much of the retinal patterning network from *Drosophila* is reused or modified.

Using genome sequencing, gene expression, and CRISPR gene knock out we show that the regulatory network that defines photoreceptor subtypes in *Drosophila* is redeployed in butterflies (*Papilio xuthus* and *Vanessa cardui*) to generate additional subtypes. In *Drosophila,* a complex regulatory network combined with cell-cell signaling specifies photoreceptor subtypes within each ommatidium. Then, a stochastic decision of whether to express the transcription factor Spineless in R7 photoreceptors determines which of two types of ommatidia is specified. We find that the R7 marker Prospero is expressed in two photoreceptors per ommatidium in butterflies. CRISPR knock-out of *Spineless* shows that this gene also controls stochastic choice in each of the two R7s in butterflies, suggesting there is deep evolutionary conservation of stochastic patterning mechanisms. Having two stochastically distributed types of R7s allows for the specification of three ommatidial types instead of two, which in turn allowed for the evolution and deployment of additional opsins, tetrachromacy, and improved color vision. These efforts provide evidence that our extensive knowledge of patterning in the *Drosophila* visual system applies to other groups, and that adaptation for specific visual requirements can occur through modification of this network.

D1417C Next-Generation Approaches to Understanding Evolution of the Insect Germline. *H. Quan*, J. Lynch. University of Illinois at Chicago, Chicago, IL.

Germline cells are unique as they can produce gametes and regenerate themselves, and can be specified by either maternally inherited determinants or by zygotic inductive signals. In the maternal inheritance mode, the germ cells are specified very early by the germ plasm synthesized during oogenesis. This mode is found in most model organisms (fruit fly, zebrafish, frog and nematode), whereas the zygotic induction mode, may be the ancestral model of germline determination .

Among the invertebrates, the only arthropod in which the germ line has been studied in detail is *Drosophila melanogaster* which uses the maternal inheritance mode. However, this mechanism of germ cell specification is a derived feature in insects and seems to be limited Holometabola. The wasp *Nasonia*, like *Drosophila,* uses the maternal inheritance mode, and represents the most distantly branching holometabolous lineage relative to *Drosophila*. The assembly of *Nasonia's* germ plasm is dependent on a regulatory network that is very similar to that of *Drosophila*, and occurs in the same context of polytrophic ovaries, indicating that a regulatory network similar to both fly and wasp was present ancestrally in the Holometabola. Despite the overall similarity *Nasonia* and *Drosophila* germline determination, some aspects are quite distinct, such as the morphology of the germ plasm, the formation of the pole cells, and the migration of the pole cells into the embryo interior.

To characterization the ancestral and novel features of *Nasonia* germplasm relative to *Drosophila* at the molecular the mRNA composition of the *Nasonia* oosome, was characterized by RNAseq. The results confirmed that certain genes, such as *oskar, nasos*, etc., are conserved between the two species, and also revealed previously unknown genes, which could be crucial for the unique properties of *Nasonia* germ plasm and germline.

D1418A Changes in the regulation of *doublesex* led to the diversification of two novel traits. *Gavin Rice*, Kevin Hu, Artyom Kopp. University of California at Davis, Davis, CA.

Whether it is the brightly colored feathers of the male peacock or the horns of male dung beetles, scientists have been intrigued by sexually dimorphic traits. However, the molecular mechanisms responsible for the origin of these sex-specific traits are not well known. Comparative studies investigating the genetic basis of convergent, male-limited phenotypes, will lead to a better understanding of the constraints in the genes and pathways used in the generation of new traits.

We have studied two novel but phenotypically similar traits that arose independently: the sex combs bristles found in forelegs of *D. melanogaster,* and the brush bristles found in the forelegs of the *D. immigrans* species group. The sex combs and foreleg brush are both modifications of the transverse bristle rows of the first tarsal segment in the forelegs and are male-specific . In *Drosophila,* the transcription factor *doublesex* establishes sex-specific transcription in males and females, but is expressed in only a subset of cells. Therefore, for a new cell-type to become sexually dimorphic or for a trait to expand beyond the current set of *doublesex* expressing cells, expression of *doublesex* must be modified.

We have previously shown that changes in the expression of *doublesex* explains a large portion of phenotypic divergence in sex combs. In parallel, we have found that the gene *doublesex* shows a similar pattern in the origin and diversification of the foreleg brush. Species that have secondarily lost the foreleg brush have lost *doublesex* expression, while species that have reduced brush sizes also have corresponding reduced *doublesex* expression. These results indicate that changes to the regulation of *doublesex* may be vital in the origin and secondary modification of sexually dimorphic traits.

D1419B Effect of aging on the Responder satellite in Drosophila melanogaster. *Linhe Xu*, Emerson Khost, Danna Eichbush, Amanda Larracuente. University of Rochester, Rochester, NY.

Eukaryotes have a tight regulation on the expression of satellite DNA, but satellite DNA misexpression is associated with chromosome segregation problems and cancer. Satellite DNA also interests genomic and evolution researchers with its contributions to inter-species genetic incompatibilities. In the fruit fly *Drosophila melanogaster*, the *Responder* (*Rsp*) locus of satellite DNA is particularly interesting because *Segregation Distorter*, a notorious selfish genetic complex, targets it. While the *Rsp* satellite has intrigued researchers for decades, its repetitive and pericentromeric nature make it difficult to study. We took advantage of recent developments in long read single molecule real time sequencing (SMRT) technology from PacBio RS II to assemble the *Rsp* satellite and use this assembly as a platform to study the regulation of *Rsp* satellite expression. Our preliminary Northern blot demonstrates that *Rsp* is expressed and the *Rsp* transcripts differ between the ovary and the female carcass, indicating differences in regulation of the satellite between the germline and the soma. By aligning RNA expression profile data from the modENCODE project to our complete *Rsp* assembly, we show that the *Rsp* satellite expression increases from newly eclosed flies to 30-days-old flies. Our interpretation of these data is that the *Rsp* satellite is misregulated as the flies age, perhaps as a result of more global effects of age-related heterochromatin misregulation. We are studying detailed changes in expression level, transcript size and transcript composition in flies of increasing age using Northern blot analysis and RT-PCR. We aim to understand the molecular details behind this age-related misregulation of satDNA by studying the abundance and types of transcripts produced as flies age. Knowing how factors like aging can affect the *Rsp* locus' expression will shine light on our understanding of how satellite DNAs are regulated.

D1420C Sex-specific divergence for body size and desiccation-related traits in Drosophila hydei from the western Himalayas. *B. Kalra*[1], R. Parkash[2]. 1) Department of Genetics, Maharshi Dayanand University, Rohtak, IN; 2) Department of Genetics, Maharshi Dayanand University, Rohtak, IN.

Sex-specific-differences are awidespread source of genetic variation in various *Drosophila* species. In the present study, we have examined desiccation survival in males and females of Drosophila hydei from colder and drier montane conditions of the western Himalayas (altitudinal populations; 600–2202 m). In contrast with most other studies in drosophilids, *D. hydei* males exhibited comparatively higher desiccation resistance despite smaller body size compared to females. Accordingly, we tested the physiological basis of such adaptations in both sexes of *D. hydei*. Body size traits (wing length, wet weight and dry weight) were ~1.2 fold higher in females than males. However, desiccation resistance was 10 to 13 h higher in males than females. These differences matched enhanced storage of trehalose content (~1.2 fold), higher hemolymph content (~1.2 fold) and enhanced cuticular lipid mass (~1.5 fold) in males than females. Water loss before succumbing to death (dehydration tolerance) was much higher in males (~81%) than females (~64%). A greater loss of hemolymph water until death under desiccation stress was associated with higher desiccation resistance in males. Further, there were lacks of differences in the rate of water loss, rate of trehalose utilization and rate of hemolymph depletion between the sexes in *D. hydei*. Therefore, sex-specific differences in desiccation resistance of *D. hydei* were independent of body size aswell as the exhaustion of metabolite reserves and rather were caused by the higher dehydration tolerance as well as higher acquisition of hemolymph and trehalose contents.

D1421A Genomic regulation of limited lifespan and reproductive senescence in *Drosophila melanogaster*. *Grace A. Parker*, Trudy F. C. Mackay. North Carolina State University, Raleigh, NC.

Limited lifespan and senescence are near-universal phenomena. These quantitative traits exhibit variation in natural populations due to the segregation of many interacting loci and from environmental effects. Due to the complexity of the genetic control of lifespan and senescence, our understanding of the genetic basis of variation in these traits is incomplete. Our goal is to identify causal genes associated with increased lifespan and postponed reproductive senescence in *Drosophila melanogaster* by functional analyses of genetically divergent genes between five long-lived (O) lines selected for postponed reproductive senescence and five unselected (B) lines. Preliminary data assessing productivity of the reciprocal crosses of the O and B lines suggest that genes influencing reproductive senescence are maternally-controlled. Therefore, all of the candidate genes tested are expressed in the ovaries of females. To determine which of these candidate genes exhibit a quantitative change in lifespan or reproductive productivity, I have assessed lifetime reproduction of candidate genes from the Vienna collection of RNAi lines in which gene expression is knocked down in ovaries. Identifying specific genes affecting increased lifespan and delayed reproductive senescence will increase our knowledge of the evolutionary role of naturally segregating populations on overall fitness and may provide potential targets for therapeutic intervention to delay senescence in populations with increasing lifespans.

D1422B The TreadWheel: A novel apparatus to measure genetic variation in response to low impact exercise for *Drosophila*. *L. K. Reed*[1], S. Mendez[1], L. Watanabe[2], R. Hill[1], M. Owens[1], G. Rowe[2], N. Riddle[2]. 1) University of Alabama, Tuscaloosa, AL; 2) University of Alabama - Birmingham Birmingham, AL.

Obesity is one of the dramatic health issues affecting this country and exercise is a well-established intervention strategy. While exercise-by-genotype interactions have been shown in humans, overall little is known. Using the natural negative geotaxis of *Drosophila melanogaster*, an important model organism for the study of genetic interactions, a novel exercise machine, the TreadWheel, can be used to shed light on this interaction. The mechanism for inducing exercise is inherently low impact thus minimizing confounding effects of other stressors. Using this machine, we are able to assess large cohorts of adult flies from eight genetic lines for their response to exercise over one week of training. We have measured their triglyceride, glycerol, protein, glycogen content, and body weight, as well as their climbing ability and feeding behavior in response to exercise, and generally find that exercised flies are more fit than unexercised flies. We have also assessed expression in a panel of genes known to be associated with respiratory fitness and find that many of these genes show expected changes in expression level with

exercise. In addition to demonstrating and overall effect of exercise on flies, we find significant genotype-by-exercise interaction effects for many of the measured phenotypes, and those differences can be partially linked to innate differences in flies' persistence in maintaining activity during exercise bouts. With this study, we have established the TreadWheel as useful tool to study exercise effects in flies, shown significant genotype-specific impacts of exercise, and have laid the ground work for more extensive studies of how genetics, environment, and aging interact with exercise to influence metabolic fitness in *Drosophila*.

D1423C *Drosophila* Lifespan: Effects of RNA Interference (RNAi)-Suppression. *D. M. B. Unselt*, T. G. Campbell, K. Ward, A. Weitzel, T. F. C. Mackay. North Carolina State University, Raleigh, NC.

Understanding the genetic mechanisms affecting variation in lifespan in natural populations is crucial for understanding the genetic basis of age-related diseases. Lifespan is known to vary in natural populations due to the segregation of multiple genetic factors as well as to exposure to different environmental conditions with a heritability of approximately 10-30%. Further, many pathways associated with lifespan, such as the insulin or insulin-like signaling pathway, are evolutionarily conserved between humans and model organisms. *Drosophila melanogaster* is a powerful model for assessing naturally occurring genetic variation in lifespan because of the ability to perform genomic analyses on a large scale while effectively monitoring genetic backgrounds and controlling environmental conditions. The *D. melanogaster* Genetic Reference Panel (DGRP), which consists of 205 sequenced inbred lines, allows for the investigation of natural genetic variation on phenotypically variable traits. To identify polymorphisms associated with variation in aging, a genome wide association (GWA) study utilizing the DGRP was conducted. This resulted in the identification of 28 genes significantly associated with lifespan. To validate their effects on lifespan, we knocked down the expression of these genes using RNA interference (RNAi) and a ubiquitous driver. This revealed several significant results associated with lifespan in the RNAi knockdown genotypes relative to their controls. Specifically, 13 genes (48%) had an effect in at least one sex, demonstrating sex-specific genetic architecture of lifespan. Additionally, 8 of the most significant genes (p-value < 0.01) increased lifespan when knocked down, providing evidence that lifespan is regulated at the transcriptional level. In the future, we plan to further functionally validate the role of these genes in the genetic control of lifespan using an overexpression assay. These experiments will contribute to our overall goal in establishing novel genetic networks associated with variation in aging. Since basic biological processes, such as aging, are evolutionarily conserved, these studies will also provide candidate genes for investigation in other species, including humans.

D1424A Dissecting the Genetics Basis of Learning, Memory, and Thermal Tolerance in a Multi-parental Population. *P. Williams-Simon*, S. Mitchell, E. King, T. Zars. University of Missouri, Columbia, MO.

Learning and memory are complex traits, which are fundamental for the survival of many species. Understanding the complexity of the genes that control these traits, should be of high importance if we want to better comprehend how an individual either learns from or tolerates temperature changes. There have been multiple genes shown to have an effect on learning and memory, however the majority of these previous studies have been using mutagenesis or other "one by one" gene approaches. Here, we dissect the genetic basis of learning, memory and thermal tolerance, using the *Drosophila* Synthetic Population Resource (DSPR). This multi-parental population consists of approximately 1,800 Recombinant Inbred Lines, which allows for high-resolution genome wide scans, and the identification of loci contributing to naturally occurring genetic variation. Using a behavioral assay known as “place learning”, we are able to train flies with a highly sensitive apparatus, the “heat box”. Whenever a fly crosses the midline of the chamber, the whole chamber either warms or cools, and so we are able to test both how well the fly learns to avoid uncomfortable temperatures and how well the fly retains this memory. We found that there was approximately a 2-fold difference between the performance index of flies for learning (.5 – 1). Both memory and thermal tolerance showed a nearly 10 fold range of variation (Memory: 0.1 – 1; Thermal Tolerance: 60s - 600s). We then performed genome scans using the DSPRqtl R package, which uses a Haley Knott regression to test for an association between phenotypes and genotypes. Our results revealed that there is a genetic basis for variability in these traits, and that there are relatively few loci within the fly genome that are important for these traits. These loci have not been previously been implicated in learning or memory. Future work will aim to fine map these loci, identify candidate genes, and validate the function of these genes in learning, memory, and thermal tolerance.

D1425B Identification of QTLs for male courtship song using a high-resolution genetic map of *Drosophila athabasca*. *R. R. Bracewell*, K. Wong-Miller, D. Bachtrog. UC Berkeley, Berkeley, CA.

To understand the initial genetic changes that result in the formation of new species, we need to study species in the earliest stages of divergence. *Drosophila athabasca* is comprised of three closely related semispecies that differ dramatically in male courtship song and these song differences result in strong reproductive isolation among sympatric semispecies. To identify the genomic regions that are associated with these differences in song, we created a high resolution genetic map of *D. athabasca* using low coverage whole genome sequecing of F5 individuals. Our results provide important insights into the relative roles of the autosomes and sex chromosomes in the evolution of *D. athabasca* male courtship song differences and help identify regions of the genome that have promoted the evolution of behavioral isolation in this group.

D1426C Variable rescue of inviability in male hybrids of *Drosophila melanogaster* and the *Drosophila simulans* clade. *J. C. Cooper*, N. Phadnis. University of Utah, Salt Lake City, UT.

Speciation is poorly understood at the molecular level because of the difficulty in identifying hybrid incompatibility genes. Recently, we identified a new hybrid incompatibility gene, *gfzf*, that is required for hybrid F1 male inviability between *Drosophila melanogaster* and its sister species *Drosophila simulans*. Knockdown of only the *D.simulans* ortholog of *gfzf in* male hybrids is sufficient to rescue their viability. However, it

remains unclear whether the incompatibility driven by *gfzf* is a general isolating mechanism between *D.melanogaster* and the *D.simulans* clade (*D.simulans, D.mauritiana, and D.sechellia*) or evolved along the *D.simulans* lineage specifically. To investigate the role of *gfzf*-meditated incompatibility in the *D.simulans* clade, we constructed *D.melanogaster* transgenic flies that express RNAi constructs to knock-down expression from the *gfzf* ortholog of each *D.simulans* clade species. We crossed *D.melanogaster* females that contain the RNAi construct to males of the *D.simulans* clade and counted male and female progeny. We find that *gfzf* knockdown produces variable hybrid male rescue across the *D.simulans* clade.

Further, it is unknown if the cell cycle defects observed in *D.melanogaster* / *D.simulans* hybrids remain consistent in hybrids between *D.melanogaster* and other species in the *D.simulans* clade. To investigate the defects in cell proliferation in developing hybrid larvae, we used a pair of fluorescent constructs that mark cells in a cell cycle specific pattern. We crossed *D. melanogaster* females that contain these transgenic constructs to males of the *D.simulans* clade. Our analyses using developing brains and imaginal discs via immunofluorescent confocal microscopy suggest that the severity of proliferation defects in hybrids of *D.melanogaster* and the *D.simulans* clade may not be uniform. The variation in both rescue of hybrid males by *gfzf* knockdown and hybrid cell cycle defects suggests either the presence of other genes that contribute to dominant male lethality, or a variable role for *gfzf* in this hybrid incompatibility.

D1427A The genetic basis for mate choice evolution between sibling species. *D. Erezyilmaz*, K. Liu. Stony Brook University, Stony Brook, NY.

Although a great deal is known of how genes shape behavior, far less is known of how genes are modified to produce the meaningful differences in behavior that exist among natural populations. As an initial step towards finding natural genetic variants that influence mating behavior, we have focused on differences between two sibling species of *Drosophila*. *D. sechellia*, and *D. simulans*, diverged ~242,000 years ago. Crosses between the two species produce viable males and fertile females. While *D. sechellia* males and *D. simulans* females mate readily, the reciprocal cross, between *D. sechellia* females and *D. simulans* males, is rarely successful. Mate discrimination at courtship in *Drosophila* is believed to occur through 1) female preference for species-specific courtship songs, and 2) male preference for species-specific female contact pheromones. We tested *D. simulans-D. sechellia* recombinant flies in 2-choice mating assays and used a high-resolution seq-based method, Multiplexed Shotgun Genotyping (MSG) to identify regions of the genome that are associated with species-specific mate preference. In females, two large effect QTL overlie enzymes that produce the pheromone, 7,11 heptacosadiene (7,11-HD). Previous work has shown that both enzymes are expressed in *D. sechellia* females, but not *D. simulans.* Moreover, 7,11-HD is produced in *D. sechellia* females, but not *D. simulans* females, and transfer of 7,11-HD to *D. simulans* females has been shown to reduce courtship by *D. simulans* males. We are currently using tissue specific expression to test this prediction. Two different large effect QTL determine mate preference in males, and we are testing candidate genes from these regions. In contrast to previous work on interspecific mate choice and courtship, our data suggests that the genetic basis of a complex behavior can be fairly simple.

D1428B Genetic basis of X-linked hybrid incompatibility betweenDrosophila melanogaster and D. simulans. *C.-T. Ting*, J.-H. Lin. National Taiwan Univ, Taipei, TW.

Genetic basis of reproductive isolation is an important issue to study speciation. Hybrid incompatibility (HI) in the forms of hybrid lethality or sterility, are commonly found in closely related species causing reproductive isolation and thus lead to speciation. One classical model for studying HI is the hybrids from the cross ofDrosophila melanogaster and D. simulans. The cross between D. melanogaster females and D. simulans males only produces sterile F1 females and hybrid males are larval lethal. The reciprocal cross yields only sterile F1 males while the hybrid females are embryonic lethal. Using attached-X chromosome strain, it is proposed that the hybrid female lethality is caused by the present of D. melanogaster X chromosome (Xm) and maternal product from D. simulans. To identify loci which contribute to the hybrid lethality, we conduct a genetic screen by crossing D. simulans females to males of the D. melanogaster X chromosome duplication lines that contain an extra X fragments on Y chromosomes in Zhr background. We have screened 22 lines covering 97.22 % of the X chromosome, and the results show that 2 of the 22 duplications have significant effect on hybrid male lethality. Our results indicate that there are at least two regions on the Xm chromosome contributing to HI between D. melanogaster and D. simulans.

D1429C A comparative genomic approach reveals the rapid evolutionary changes in two putative accessory gland genes throughout the *Sophophora* subgenus. *M. L. Johnson*, K. Vitalone, J. Borja. Notre Dame College, South Euclid, OH.

Accessory gland proteins (ACPs) of *Drosophila* represent a group of proteins that are transmitted to females during mating; and, therefore, influence reproductive success through changes in female behavior, physiology, and sperm utilization. Additionally, ACPs are known to undergo rapid evolutionary changes that are thought to be due to important roles they play in reproductive success during mating. However, the reproductive advantage of ACPs in one species, do not necessarily convey an advantage in other species. Two such ACPs are Sfp79B (Seminal fluid protein 79B) and msopa (male specific opa containing gene). Both of these genes are highly expressed, specifically in the accessory glands of *D. melanogaster*. Additionally, Sfp79B peptides from males have previously been detected in the lower reproductive tracts of mated female in both *D. melanogaster* and *D. simulans*, but not in *D. yakuba*. In this study the two ACP encoding genes Sfp79B and msopa were annotated on the 3L chromosomal arm of *D. elegans* between the RpLP0 and olf413 homologues as part of the Genomics Education Partnership (GEP). To better understand the evolution of these genes, a survey of 19 species in the subgenus *Sophophora* were analyzed, including 16 from the melanogaster group and 3 from the *obscura* group. Both have not always been detected during previous annotations, which is likely due to their small size. Therefore, the genomic regions between the RpLP0 and olf413 homologues were analyzed for the presence of these genes in different species. Of these 19 species, Sfp79B was present in 13 of the species, but was absent in some members of

the *melanogaster*, *suzukii*, and *takahashii* subgroups. Furthermore, in both *ananassae* and *pseudoobscura* subgroups, duplications of Sfp79B were detected. While msopa is present in both the *melanogaster* and *obscura* group, it was not detected in the *ananassae* subgroup. Additionally, in some of the groups msopa was found to be under positive selection based on Ka/Ks values. Future analysis of RNA expression will be conducted to verify whether these annotated gene products of Sfp79B and msopa are produced in select representative species. Together, this data demonstrates while Sfp79B is absent from some species of *Drosophila*, it has a larger role in the *Sophophora* subgenus than originally recognized. Moreover, analysis of both Spf79B and msopa demonstrate that while ACP encoding genes can be found throughout the *Sophophora* subgenus, rapid evolutionary changes in these genes occur in reproductive pockets.

D1430A Functional evolution of *bag-of-marbles,* the key switch for oogenesis in *Drosophila melanogaster*. *Jaclyn E. Bubnell*, Charles F. Aquadro. Cornell University, Ithaca, NY.

In *D. melanogaster* females, *bag of marbles* (*bam*) acts as the master switch for germline stem cell differentiation during oogenesis and in males, plays a key role in regulating spermatogenesis. Interestingly, *bam* is rapidly evolving across the *Drosophila* genus with a strong burst of nonsynonymous changes in both the *D. melanogaster* and *D. simulans* lineages. We have previously shown that the major functional change associated with interspecific differences in the Bam protein is in oogenesis, and not spermatogenesis. We have also discovered a genetic interaction between *Wolbachia* and a *bam* hypomorphic mutant in *D. melanogaster*, where *Wolbachia* infection rescues the *bam* fertility defect. However, the nature of this rescue remains unclear. Our preliminary data shows that *Wolbachia* does not rescue the tumorous ovary phenotype characteristic of the *bam* hypomorph, implying the rescue is indirect. These results have led us to hypothesize that *Wolbachia* may be a driver of positive selection at *bam* in *D. melanogaster* and *D. simulans.* However, since *bam* shows high levels of amino acid diversification across the *Drosophila* genus, it is also possible that *bam's* function as the master switch in oogenesis has arisen in the lineage leading to *D. melanogaster* and *D. simulans* and the refinement of this function has thus been under positive selection in these species. We are currently characterizing the nature of the interaction between *Wolbachia* and *bam* as well as defining *bam* function in *D. simulans* using CRISPR-Cas9 editing to distinguish between these hypotheses.

D1431B The genetic basis of the energy budget in *Drosophila melanogaster* on different diets. *A. M. Perinchery*, P. Stanley, S. Winingear, H. Kleiboeker, E. G. King. University of Missouri, Columbia, MO.

Organisms need to adapt to dynamic environments over time. An organism consumes and stores a finite amount of resources that are used for all daily tasks. In order to survive and thrive, they must allocate these finite resources to different life history traits like reproduction or somatic growth. We used the genetic mapping population, the *Drosophila* Synthetic Population Resource (DSPR), to map the genetic loci responsible for carbohydrate, lipid and protein storage on different diets in *Drosophila melanogaster*. We crossed ~250 Recombinant Inbred Lines (RILs) to a standard inbred line. The adult offspring of these crosses were placed onto one of three diets for 10 days: a high sugar, low yeast or control diet. We then used biochemical assays to measure the total energy budget: lipid, carbohydrate and protein content on the same set of flies. Lastly, QTL analysis was performed to identify possible genetic loci responsible for storage of these different components on different diets.

D1432C The genetic architecture of thermal plasticity in *Drosophila melanogaster*. *Omid Saleh Ziabari*[1], Shampa M. Ghosh[2], Nicholas D. Testa[3], Alexander W. Shingleton[1]. 1) Department of Biology, Lake Forest College, Lake Forest, IL; 2) School of Biological Sciences, National Institute of Science Education & Research, Bhubaneswar, India; 3) Department of Zoology and Ecology, Michigan State University East Lansing, MI.

Little is known about the molecular, genetic, and physiological mechanisms that regulate phenotypic plasticity, while even less is known about how these mechanisms evolve. For selection to act upon phenotypic plasticity, there must first be genetic variation in a plastic response and the mechanisms that generate it. In this study, we measure the genetic variation in the thermoplasticity of abdominal pigmentation in female Drosophila melanogaster among 110 isogenic lineages from Drosophila Genetic Reference Panel (DGRP). We used a novel approach to quantify various aspects of dorsal pigmentation from digital images. Using these data, we characterize the genetic architecture of the thermoplasticity, correlating variation in the thermoplasticity of pigmentation with variation in the thermoplasticity of other morphological traits. In general, the thermal reaction norms for pigmentation were non-linear, and variation in the thermal plasticity of pigmentation among lineages was not correlated with variation in the thermal plasticity of body and organ size. Nevertheless, there was some overlap among the SNPs associated with the thermoplasticity of both pigmentation and size, suggesting some common mechanisms regulate the thermoplasticity of different traits.

D1433A Sex differences in *Drosophila* somatic gene expression: variation and regulation by *doublesex*. *R. M. Graze*[1], F. N. New[3], J. M. Fear[3], T. S. Howard[1], J. E. Dalton[2], M. N. Arbeitman[2]. 1) Auburn University, Auburn, AL; 2) Florida State University, Tallahassee, FL; 3) University of Florida, Gainesville, FL.

Sex differences in gene expression have been widely studied in *Drosophila melanogaster*. Sexually dimorphic expression varies across strains, but many molecular studies of regulation have focused on only a single strain or on genes that show robust sexually dimorphic expression in many strains. How extensive variability is across strains and whether this variability occurs among genes regulated directly by sex determination genes is unknown. To address these questions, we examine differences between strains in sexually dimorphic gene expression in Drosophila adult head tissues. We also examine gene expression in *doublesex* mutants to determine whether a gene with sex-differential expression is regulated by DSX isoforms and the mode by which DSX regulation produces sex-differential expression. The best known mode of

DSX regulation is the classic mode, in which DSX represses in one sex and activates in the other. However, there are multiple additional ways in which DSX regulation can produce sex-differential expression and we examine all possible modes in this study. Our results show that there is substantial flexibility in somatic regulation of sex-differential expression. The sets of genes with sexually dimorphic expression in each strain show remarkably little overlap. The presence and prevalence of different DSX modes also varies between strains, with large differences in the prevalence of different modes among genes with female biased expression. Despite these differences, the genes identified as regulated by DSX by analysis of *doublesex* mutations are enriched in each strain for known sites of DSX occupancy in the genome. Neither the observation of DSX binding in a gene's regulatory regions nor the specific mode of DSX regulation explain why some genes show robust sex-differential expression, while others differ between strains. Thus, regulation by DSX, does not appear to confer a robust pattern of expression with respect to strain differences. Finally, we find that in adult head tissues sex-biased genes in general are enriched on the X and highly enriched on the fourth chromosome in both strains and that the fourth chromosome is more specifically enriched with regions that are occupied by DSX isoforms. Overall these results provide insights into a more complete pool of potential DSX targets within the genome, as well as the molecular flexibility of DSX regulation.

D1434B Genetics, development and plasticity of metabolic performance in *Drosophila*. *K. L. Montooth*, C. R. Julick, O. B. Matoo, K. R. O'Brien. University of Nebraska-Lincoln, Lincoln, NE.

Development generates a dynamic internal environment that is predicted to impact the fitness effects of mutations that arise in populations. Moreover, the external environment in which development occurs can impact the expression of traits within and across life stages. We and others have shown that even fundamental properties of metabolism (e.g., the scaling laws that are thought the govern the relationship between metabolic rate and mass) can vary across development and as a function of the developmental environment (Greenlee, Montooth, Helm. 2014 ICB 54:307). For example, I will show that the scaling of metabolic rate as a function of mass in *Drosophila* depends on the developmental thermal environment, and that mitochondrial-nuclear genotype can significantly affect larval metabolic rate. This latter genetic effect is itself conditional on the developmental thermal environment, and we have found that interactions between genotype and developmental environment affect metabolic rate plasticity (i.e., the Q_{10} for metabolic rate) (Hoekstra, Siddiq, Montooth. 2013 Genetics 195: 1129). In addition, I will show that genetic variance in metabolic rate varies across larval development. To better understand the underlying mechanisms that govern the development of energetic processes, we have characterized larval metabolic rate and aspects of mitochondrial physiology across development for a number of natural *D. melanogaster* genotypes, as well as for mitochondrial-nuclear genotypes that generate energetic inefficiencies. To better understand how metabolic development and plasticity impacts organismal performance, I will relate these patterns to plasticity in development and survivorship in the presence of ethanol, an important ecological challenge and resource for *Drosophila* larvae.

D1435C Parthenogenomics: Assembly, annotation, and analysis of the facultative parthenogenetic fruit fly, Drosophila mercatorum. *C. E. Stanley*[1], D. E. Miller[2,3], T. A. Markow[4,5], R. S. Hawley[2,3], R. J. Kulathinal[1]. 1) Temple University, Philadelphia, PA; 2) Stowers Institute for Medical Research, Kansas City, MO; 3) University of Kansas Medical Center, Kansas City, KS; 4) 4Laboratorio Nacional de Genomica de la Biodiversidad, CINVESTAV, Irapuato, Guanajuato CP, Mexico; 5) 5Univserity of California San Diego, San Diego California, La Jolla, CA.

Parthenogenesis, or reproduction without fertilization, provides a "last resort" method of reproduction when the availability of males is low, resulting in impaternate offspring. While parthenogenesis is extremely rare among species, Drosophila mercatorum has been long-known to be facultative parthenogenetic. To elucidate the underlying genetic basis of parthenogenesis, we generated a draft genome of both sexual and parthenogenetic strains of D. mercatorum. Here, we characterize their genomes, identify genomic variants and genes exhibiting biased expression differentiating sexual and parthenogenetic strains, and discuss the potential contribution of these variants to the parthenogenetic process.

D1436A Partial loss of function in the *Drosophila melanogaster* septin gene *Sep5*. *R. S. O'Neill*, D. V. Clark. University of New Brunswick, Fredericton, New Brunswick, CA.

Gene duplication is a major evolutionary process. One mechanism of gene duplication, retroduplication, generates a retrogene via retrotransposition of a parent gene's mRNA. Retroduplication is thought to facilitate the evolution of novel functions by separating a parent gene's coding sequence from its untranscribed regulatory region. Septins are a family of cytoskeletal proteins that form heter-oligomeric, rod-like complexes which can further assemble into higher-order structures. The septin family is divided into subgroups. The general model for septin complex assembly is that each position in the complex is occupied by a member of a specific subgroup, and thus subgroup members are thought to be interchangeable within the complex. *Drosophila melanogaster* has five septin genes, including *Sep2* and its retrogene duplicate *Sep5*. *Sep2* and *Sep5* are the only *D. melanogaster* SEPT6 subgroup members. About 15% of amino acid sites in a multiple sequence alignment of Sep2 and Sep5 from 20 *Drosophila* species are conserved across orthologs but different between paralogs, suggesting functional diversification. We explored the functions of *Sep2* and *Sep5* to provide insight into the functional diversification of the complex-forming septin family. *Sep5* mutants have no obvious phenotype. About half of *Sep2* mutants die at the end of pupation when grown at 25°C, and those that emerge are sterile and have short eggs. About one fifth of *Sep2* mutant egg chambers are fusions containing multiple germline cysts, suggesting a role for *Sep2* in follicle cell encapsulation. A *Sep5* transgene fails to rescue the *Sep2* mutant egg chamber fusion phenotype, showing functional diversification of Sep2 and Sep5 proteins. *Sep2 Sep5* double mutants lack imaginal discs and die as prepupae. Mosaic analysis showed that double mutant follicle cells can encapsulate germline cysts but fail to proliferate and die at mid-oogenesis, whereas double mutant germline cysts appear normal. Thus, *Sep2* and *Sep5* are redundant for proliferation of some cell types. Sep2-GFP and Sep5-GFP localize

similarly, including as double flanking rings at the germline ring canals, and at the follicle cell cortex. Pnut localization, determined by immunostaining, is similar to Sep2-GFP and Sep5-GFP, and is maintained in both *Sep2* and *Sep5* single mutants but is lost in double mutants. The redundancy of *Sep2* and *Sep5* for Pnut recruitment suggests that they are interchangeable in and required for the formation of septin complexes. While we cannot rule out a unique function for *Sep5* in an untested context, we suggest that *Sep5* has undergone partial loss of its parent *Sep2*'s function; Sep5 has retained the ability to form part of the *D. melanogaster* septin complex, but has lost an ancestral follicle cell-specific function.

D1437B The effects of insulin signaling on sexually dimorphic gene expression in head tissues. *T. S. Howard*[1], R. Tzeng[2], M. N. Arbeitman[2], R. M. Graze[1]. 1) Auburn University, Auburn, AL; 2) Florida State University, College of Medicine, Tallahassee, Florida.

Insulin signaling is generally involved in nutrient sensing and growth and the pathway, overall, is highly conserved from fruit flies to man. In many organisms insulin signaling frequently plays a role in control and development of sexually dimorphic traits, including both differences in growth and in behavior. In Drosophila, this pathway plays a direct role in regulating body size dimorphism, activity level dimorphism and in female fertility and mating behaviors. This is consistent with direct sex specific regulation of the pathway, but the targets of this regulation and the downstream effects on expression in each sex are unknown. To understand how sex differences shape the regulatory effects of the insulin signaling pathway, we examined similarities and differences in the effect of perturbation of the pathway on gene expression in adult males and females. Expression of a dominant-negative *InR* transgene (InRDN) was driven by actin-5C-GeneSwitch controlled GAL4 in males and females. Expression was assessed by RNA-seq in replicate for each sex expressing InRDN and for genetically matched controls. By integrating perturbation data with genomic signatures of sex specific regulation, we are able to shed light on how the InR pathway is sex specifically regulated and on the indirect effects of that regulation.

D1438C How do polymorphic Y-chromosomes modulate genome-wide epigenetic states: analyses of a whole Y-chromosome dosage series. *B. Lemos*, A. T. Branco, L. DellBem. Harvard T. H. Chan School of Public Health, Boston, MA.

Heterochromatin remains a mysterious component of eukaryotic genomes. The amounts and kinds of repetitive elements within heterochromatin of a focal segment have emerged as potential determinants of gene expression across the genome (trans-regulation). Highly repetitive segments of heterochromatin represent one of the last frontiers of eukaryotic genomes and the mechanisms by which heterochromatin dosage exert their effects across the genome have remained elusive. Here we report two sets of results. First, we describe our efforts constructing a whole Y-chromosome dosage series with polymorphic Y chromosomes (XY, XYY, XX, XXY) in a homogeneous background of a autosomes and X chromosomes. Second, we report novel functional genome analyses across a number of attributes in these genotypes that help illuminate the impact of perturbing the nuclear environment with extra Y chromosomes. We discuss the results in view of several proposed models for heterochromatin action in trans, including a classical hypothesis known as the heterochromatin sink as well as others.

D1439A A Facilitated Diffusion Mechanism Establishes the Drosophila Dorsal Gradient. *G. T. Reeves*, S. N. Carrell, M. D. O'Connell. North Carolina State University, Raleigh, NC.

During the first three hours of Drosophila embryogenesis, the transcription factor Dorsal (homologous to NF- κB) patterns the dorsal-ventral axis. Dorsal is present in a nuclear concentration gradient with the highest concentration at the ventral midline and a steady decay to about 40% of the embryo's circumference. The Dorsal gradient is initialized on the ventral side of the embryo via Toll signaling, which phosphorylates the inhibitor protein Cactus (homologous to IκB), marking it for degradation. In the absence of Cactus, Dorsal can enter the nuclei and activate expression of target genes in a concentration-dependent manner. Recent work measuring the dynamics of the Dorsal gradient has shown that, while Dorsal nuclear levels are initially uniform, Dorsal protein diffuses towards the ventral midline, which causes the overall accumulation of a Dorsal gradient peak. To explain this accumulation phenomenon, which seems to act against standard Fickean diffusion, we hypothesize a facilitated diffusion, or "shuttling" mechanism. The Dorsal/Cactus system has each of the features required for facilitated diffusion: (1) Dorsal binds to a "carrier" molecule (Cactus) that protects it from capture; (2) the Dorsal/Cactus complex is diffusible; and (3) the complex is broken in a spatially-dependent manner.

After using a photoactivatable GFP to show that nucleus-to-nucleus diffusion of Dorsal occurs within the embryo, we extended a previous computational model of Dorsal/Cactus interactions. Our model generically predicts that shuttling occurs in the embryo, and that three experimental perturbations would reveal a shuttling-specific phenotype. First, embryos with a half dose of Dorsal develop gradients that are wider and flatter than normal. Second, slowing Dorsal or Cactus diffusion causes the gradient to widen. And third, expanding the spatial domain where Toll signaling causes Cactus degradation results in a widening or even splitting of the Dorsal gradient. We performed each of these model-guided experiments and observed the predicted phenotypes.

Our results suggest that Cactus plays multiple roles in dorsal-ventral axis specification. Besides its predominant role, which is to maintain Dorsal in the cytoplasm, a secondary, but important role is to shuttle Dorsal towards the ventral midline. Given that this mechanism has been found in other, independent systems, we suggest it may be more prevalent than previously thought.

D1440B Pax6 and the Polycomb group proteins promote eye formation by repressing alternate non-ocular fates. *J. Zhu*, A. Ordway, K. Buddika, J. Kumar. Indiana University Bloomington, Bloomington, IN.

The suppression of alternative tissue fates is important for the normal development of an organ. It has been shown that the Polycomb group (PcG) proteins, which are epigenetic regulators, are necessary for transcriptional repression of developmental regulated genes, such as Hox genes. Reductions in PcG protein levels can result in homeotic transformations of the wing, leg and antenna. Despite the importance of the PcG

complex in regulating Hox gene expression, its relationship to endogenous gene regulatory networks and its function in tissue/organ fate specification are not well understood. To address this question, we removed Polycomb (*Pc*) from the developing eye-antennal imaginal disc and observed ectopic expression of the Hox gene *Antennapedia* (*Antp*) and the wing selector gene *vestigial* (*vg*). These dramatic changes in gene expression accompanied a homeotic transformation of the eye into a wing. The mutant tissue also underwent hyperplastic growth and increased in size by several orders. However, knocking down other PcG proteins was insufficient to induce this phenotype. The Pax6 gene is required for eye formation in all seeing animals from Drosophila to humans. Although previous studies have revealed that *Drosophila* Pax6 homologs, *eyeless* (*ey*) and *twin of eyeless* (*toy*) are required for eye specification and head capsule development, the potential roles of Pax6 in the suppression of non-ocular tissue fates remain elusive. We discovered that simultaneous removal of PcG proteins and Pax6 could also induce the eye to wing transformation, indicating Pax6 and PcG proteins cooperate to control growth of the eye and to prevent the establishment of alternative tissue fates. Using different Gal4 drivers, we found that the tissue transformation only happened in the eye progenitor cells ahead of furrow where *ey* and *toy* are normally expressed. Removal of Pax6 and PcG proteins in the differentiated photoreceptor cells did not cause the tissue transformation. Moreover, *vg* was activated mainly in the dorsal part of the eye tissue, when Pax6 and PcG proteins were knocked down using *ey*-Gal4. This suggests that dorsal section of the eye disc is more capable to transform compared to the ventral domain. We found that the physical transformation of the eye to wing takes place in the third larval instar, when *vg* was activated ectopically in the eye imaginal disc. However, this transformation requires that PcG proteins and Pax6 are removed from the eye disc starting from the first larval instar stage.

D1441C SoxNeuro and Shavenbaby act cooperatively to shape denticles in the embryonic epidermis. *Nicholas P. Rizzo*, Amy Bejsovec. Duke University, Durham, NC.

During development, morphogenetic processes require the integration of numerous signals to properly shape cells and tissues. These signals are interpreted by cells to induce the precise transcriptional circuitry that controls morphogenesis. The cuticle pattern of the developing embryonic epidermis provides a valuable system to study how this process is executed. It is well established that the fly Wnt, *wingless* (*wg*), generates naked cuticle zones that separate the ventral denticle belts by repressing expression of *shavenbaby* (*svb*), which encodes a transcription factor required for denticle formation. What is not known is how Wg and Svb interact to produce the stereotyped diversity of denticle shapes within each belt. One possibility is that graded levels of Svb, responding to graded levels of Wg signaling, may determine denticle shape. Indeed, we found that the *svb* promoter responds differentially to altered Wg activity levels. However, artificially increasing the levels of ectopic *svb* does not produce morphologically distinct denticles, suggesting that additional factors may be involved. We have discovered that a second Wg-responsive transcription factor, encoded by *SoxNeuro* (*SoxN*), cooperates with Svb to shape the denticles. Co-expressing *SoxN* with *svb* in an ectopic location within the naked cuticle zone is sufficient to rescue shaping of the ectopic denticles. Strikingly, the expression of *SoxN* in *svb* null embryos produces rounded, remnant denticles resembling those present in *svb* null embryos, suggesting that SoxN activity in *svb* mutants promotes these remnant denticles. Consistent with this idea, *svb*;*SoxN* double mutant embryos secrete cuticles that completely lack ventral denticles and dorsal hairs. The lack of denticles in *svb;SoxN* embryos is not due to hyperactivity of Wg, because expression of the Wg target gene, *engrailed*, is not altered. We propose that Svb and SoxN together are required for proper denticle shaping, and we discuss target genes that show differential response to these transcription factors.

D1442A *eyeless* Participates in the Establishment and Maintenance of the Retinal Dorsal/Ventral Axis. *Luke R. Baker*, Justin Kumar. Indiana University, Bloomington, IN.

The eye of the adult *Drosophila* comprises 800 unit eyes known as ommatidia. Each ommatidium is composed of 8 photoreceptors and 12 accessory cells. Ommatidia are organized into dorsal and ventral chiral forms that are determined by their position relative to an equator that bifurcates the adult eye. This midline is established in larval development through the juxtaposition of independent dorsal and ventral compartments specified by differentially expressed and antagonistic gene networks. Here, I show that the Pax6 transcription factor, *eyeless* (*ey*), has a role in mediating the establishment and maintenance of the early DV patterning of the *Drosophila* eye. Flies harboring mutations in *ey* have either small or no eyes. I have examined the developing and adult *ey* mutants and have evidence that D/V patterning is disrupted. The developing eye shows an increase in the expression pattern of the dorsal selector gene *mirr* which suggests ventral eye tissue is reduced or lost. Consistently, the adult eye of *ey* mutants is composed solely of ommatidia of dorsal chirality. Additionally, the dorsal selector gene *wg* and the dorsal head capsule selector *otd* also show increased spatial expression in *ey* mutants, supporting the hypothesis that the loss of *ey* disrupts D/V patterning. The midline, which can be visualized by the expression of a *fj-lacZ* reporter, is shifted in accordance with the increased expression pattern of dorsal selector genes. Together, these data suggest that the loss of *ey* affects the formation of dorsal and ventral compartments in the developing eye. This represents a new role for Pax6 in eye development.

D1443B Role of axial patterning genes in growth regulation during eye development. *N. GOGIA*[1], M. KANGO SINGH[1,2,3], A. SINGH[1,2,3]. 1) Department of Biology, University of Dayton, 300 College Park Drive, Dayton, OH; 2) Premedical Program, University of Dayton,OH; 3) Center for Tissue Regeneration & Engineering (TREND), University of Dayton, 300 College Park Drive, Dayton, OH.

An important question in developmental biology is that how growth regulation and cell fate specification genes work together during organogenesis to form a three-dimensional organ. In any multicellular organism, organogenesis requires axial patterning to determine Antero-Posterior (AP), Dorso-Ventral (DV), Proximo-Distal (PD) axes. Any deviation in these axes during development leads to congenital birth defects. We use *Drosophila melanogaster* (a.k.a fruit fly), eye as our model. In *Drosophila,* Dorso-Ventral (DV) patterning marks first lineage restriction event where axial patterning genes, regulates the formation of dorsal, ventral compartments in the eye. We have identified *defective*

proventriculus (*dve*-a Homeobox gene), an ortholog of SATB homeobox 1 (special AT-rich sequence binding protein 1), as a new member of DV patterning gene hierarchy. We have shown that *dve* acts downstream of *pannier* (*pnr*, GATA-1 transcription factor), and upstream of *wingless (wg)* in dorsal gene hierarchy. Loss-of-function of *dve* or *pnr* results in dramatic dorsal eye enlargements, whereas gain-of-function suppresses the eye fate. We have demonstrated that Wg is a downstream target of Hippo growth regulatory pathway (highly conserved) in eye. Furthermore, Wingless (Wg), which acts downstream of *dve*, also exhibits similar eye enlargement and suppression phenotypes and has been shown to play a role in growth. Here, I present that DV patterning genes interact with Hippo signaling to regulate the common downstream target, Wg during growth and patterning of developing *Drosophila* eye. We are pursuing genetic epistatsis studies to determine how the members of these two highly conserved pathways regulate Wg signaling in the developing eye. Our data (using Gain-of-function studies) states that activation of Hippo signaling in *dve*, *pnr* expression domain results in change of fate. We have tested retinal determination fate markers in these backgrounds. This study will address an important question-if the axial patterning genes (*dve, pnr*) and Hippo pathway regulates patterning, growth independently or in-coordination with each other by regulating Wg signaling to form an eye/or any organ. Our study will have significant bearing on developmental mechanisms during organogenesis of the eye.

D1444C Defining the role of Glass, a zinc finger transcription factor, in eye development. *C. A. Morrison*, J. E. Treisman. New York University School of Medicine, New York, NY.

Cell fate specification is achieved through the combinatorial activity of transcriptional regulators, which activate the developmental program necessary to establish a cell's identity. The zinc finger transcription factor Glass (Gl) acts as a key determinant to establish photoreceptor identity in the *Drosophila* eye imaginal disc. In *gl* mutants, eye progenitor cells exhibit certain aspects of early neuronal differentiation and begin to organize into ommatidial clusters, but these cells fail to express photoreceptor-specific genes and display abnormal axon projections into the brain. It is thought that Gl directs the transition from an unspecified neuron to a photoreceptor identity by activating numerous downstream target genes. To determine if Gl is sufficient to induce any or all aspects of photoreceptor development we generated a UAS-*gl* transgenic line and performed misexpression experiments in neuronal and non-neuronal cells. We show that Gl misexpression in neuroblasts is sufficient to induce ectopic expression of the photoreceptor-specific gene *chaoptin* (Chp) in the larval brain. We also show that Gl is sufficient to induce Chp in non-neuronal cells of the larval wing and leg imaginal discs and that the Gl-expressing cells are not converted to a neuronal identity. Furthermore, Gl misexpression in imaginal discs or abdominal cells leads to ectopic eye pigment in the adult. We have performed RNA-seq in order to identify which genes can be ectopically induced by Gl in neuronal and non-neuronal cells. We find that some predicted Gl targets, including *PvuII-PstI homology 13* (*Pph13*) and *Eye-enriched kainate receptor* (*Ekar*), as well as *cardinal* (*cd*), which encodes a pigment biosynthetic enzyme, can be induced in both cell types, while others are induced only in either neuronal cells or non-neuronal cells. Surprisingly, we find that many genes predicted to be Gl targets because of the presence of Gl binding sites in their regulatory regions and the co-variation of their expression with Gl, such as *lozenge* (*lz*) and *kin of irre* (*kirre*), are not induced in either context. We are currently performing a promoter analysis of these genes in order to identify possible repressors of Gl function. Our misexpression data and RNA-seq analysis also suggest that Gl may promote cone cell and pigment cell specification in addition to photoreceptor identity. We are currently investigating this possibility using cell type-specific knockdown and rescue experiments. .

D1445A Zinc finger transcription factors, Teashirt and Tiptop: Their role in promoting early eye-antennal disc development and maintaining segregated eye-antennal fates. *Sneha Palliyil*, Justin Kumar. Dept. of Biology, Indiana University, Bloomington, IN.

How a small set of cells go on to become tissues and organs is one of the fundamental questions in the field of developmental biology. The eye-antennal imaginal discs give rise to the compound eye, ocelli, antennae, maxillary palps and the head capsule. Fourteen genes that form the retinal determination(RD) network are responsible for the proper specification of the compound eye and for many aspects of its development. Among them are the zinc finger proteins, Teashirt(Tsh) and its paralog,Tiptop(Tio). Understanding the specific functions of Tsh/Tio in the early eye-antennal imaginal disc development is the primary focus of my work. Tsh/Tio have redundant expression patterns in the larval third instar imaginal discs and are suggested to be functionally equivalent. Knockdown of each gene individually has very mild,if any, phenotype in the eye, while knocking down both genes simultaneously results in flies with small or missing eyes. We have evidence suggesting that *tsh*, functions with another RD gene *twin of eyeless*(*toy*),to maintain cells in a proliferative state. We determined that Tsh and Toy are required together during the embryonic and first larval instar stages. Simultaneous removal of both *tsh* and *toy* during these stages results in headless flies. We are examining how the loss of Tsh and Toy affects the expression of other RD network genes and whether the headless phenotype is due to increased cell death or a loss of cell proliferation. Also,I have evidence that Tsh/Tio play a part in antagonizing non-ocular fates.My results reveal that Tsh/Tio are capable of repressing *cut*, a key specification gene of the antenna and head epidermis when misexpressed in the antennal disc.Work from several labs has shown that the Sine Oculis(So) and Eyes Absent(Eya) proteins, which are also members of the RD network, function to repress the expression of gene regulatory networks that control surrounding non-ocular fates. My results suggest that the Tsh/Tio repress *cut* independent of the So-Eya complex. Finally,I have evidence that this Tsh/Tio require the co-repressor C-terminal Binding Protein(CtBP).

D1446B Cytoneme-mediated cellular synapsis for Hh signaling. *L. GONZÁLEZ-MÉNDEZ*, I. GUERRERO. CBMSO, MADRID, MADRID, ES.

Hedgehog (Hh) is a morphogen with a central role in development, and also implicated in other processes in the adult organism, including stem cells maintenance, cell migration, axon guidance and cancer. In many systems, Hh morphogen is secreted from a defined group of cells and specifically distributed to create a concentration gradient that drives differential genes expression and subsequent specification in target cells. The mechanism/s responsible for Hh gradient establishment through a tightly controlled dispersion of the morphogen remains

controversial. Increasing evidences support the role of specialized and highly dynamic filopodia (cytonemes) in the transport of morphogens during development, facilitating the concentration and spatial restriction of the signal. In this context, we have recently demonstrated that Hh transport via exosomes along cytonemes emanating from Hh producing cells is an essential mechanism for the restricted distribution of Hh in Drosophila epithelia development. It has recently suggested that signaling between epithelial cells occurs through direct cell-cell contacts even if they are separated by several cell diameters, in a similar manner to a synaptic connection. Currently, we are focusing on the study of the cytoneme-mediated communication between Hh producing and receiving cells during Drosophila wing disc patterning. In order to identify the physical interaction sites along these cytonemes, we use CD4-based GRASP technique combined with LexA/lexO and Gal4/UAS binary expression systems. We observe a strong connection between A and P compartments cytonemes at the basal surface of the epithelium. In addition, we study this interaction between Hh sending and receiving cytonemes during Hh reception by expressing some of the components of the Hh reception complex, such as Ihog/Boi, Patched (Ptc) and the proteoglycans Dally and Dlp. Interestingly, high levels of Dally, Dlp and Ihog accumulate at the contact sites along A and P cytonemes. Also, we have evidences for the presence of both Ptc (Hh receptor) and Hh at cytonemes emanating from Hh receiving cells. We find besides a recycling process of Ptc and Ihog to reach the plasma membrane as exosomes; Ptc and iHog colocalize with exosome markers, and different conditions (UAS-RNAi) that disturb the exosome formation in the Hh receiving cells lead to a block in Ptc recycling, modifying the Hh gradient. Our results agree with a cytoneme-mediated Hh release and reception, and suggest a mechanism of cell-cell signaling mediated by exosomes containing Hh and Ptc, resembling synaptic contacts.

D1447C Steep difference in Dpp signaling triggers JNK-dependent transcriptional activation of *reaper*. *H. Nojima*, JP. Vincent. The FRANCIS CRICK institute, London, GB.

Extensive evidence suggests that Dpp signaling controls patterning and growth in wing imaginal discs. Patches of cells undergoing excessive Dpp signaling trigger overgrowth while at the same time inducing JNK dependent apoptosis at their boundary. To investigate this process, we have developed several reporters of JNK signaling and pro-apoptotic gene expression. Using these tools, which we hope will be widely useful, we confirmed that JNK signaling is activated on both sides of the boundary. We also found that this leads to transcriptional activation of *reaper*, but not *hid*. Suppression of JNK signaling prevented *reaper* expression and led to a reduction in the number of apoptotic cells. Moreover, in the absence of *reaper*, apoptosis was no longer detected at the boundary of clones undergoing excess Dpp signaling. We conclude that morphogenetic apoptosis is mediated by JNK dependent activation of *reaper* transcription.

D1448A Trithorax Group proteins interact with Pax6 to specify proper organ number in the *Drosophila* eye-antennal disc. *A. J. Ordway*, G. M. Teeters, J. P. Kumar. Indiana University, Bloomington, IN.

The control of organ number is vital to the proper development of an organism. For example, the decision to make two lungs but just one heart allows vertebrate body to function correctly. My work is focused on understanding how this type of decision is made in *Drosophila* –in particular; I am interested in understanding how each eye-antennal disc produces a single adult antenna. I have uncovered a role for the Trithorax Group (TrxG) of epigenetic regulators in this decision. Reductions in some members of the TrxG result in an adult fly with four antennae instead of the normal two. In other cases, this antennal duplication requires the simultaneous reduction of a TrxG member and *twin of eyeless* (*toy*), a selector gene for eye fate and the *Drosophila* homolog of vertebrate Pax6. Data from our lab also shows that eliminating *toy* and a second Pax6 gene, *eyeless* (*ey*), during certain developmental windows causes identical antennal duplications. These results demonstrate novel roles for Pax6 in antennal development and for TrxG proteins in regulating organ number. There is precedent for communication between Pax proteins and TrxG members. It has been reported that vertebrate Pax2 physically interacts with PTIP (Pax Transcriptional Activation Domain Interacting Protein), a TrxG protein. To uncover how Pax6 and TrxG cooperate to control antennal numbers we are using candidate gene approach beginning with the Wingless (Wg) pathway. Prior studies have shown that some TrxG members regulate Wg signaling and that reductions in early Wg expression within the antennal field can lead to its duplication. In addition to its role in antennal development, Wg signaling is also necessary for preventing the initiation of ectopic furrows. We have observed ectopic furrows in discs with reduced levels of TrxG. Our model suggests that Pax6 and TrxG cooperate to regulate Wg signaling in the eye and early antennal discs. Disrupting this regulatory circuit results in ectopic furrows and an increase in the number of the antennal segments.

D1449B Computational analysis of spatiotemporally-patterned intercellular Ca^{2+} transients in the *Drosophila* wing imaginal disc. *P. A. Brodskiy*, Q. Wu, C. Narciso, J. J. Zartman. University of Notre Dame, Notre Dame, IN.

The calcium ion (Ca^{2+}) is a second messenger known to have important roles in regulating physiological processes such as proliferation, apoptosis and cell differentiation. However, how the spatiotemporal properties of Ca^{2+} transients reflect the underlying physiological state of tissues is still poorly understood. Here we use an established model system of an epithelial tissue, the *Drosophila* wing imaginal disc, to investigate how tissue properties impact the propagation of Ca^{2+} transients in simple epithelia. We recently observed oscillatory waves in cultured larval wing discs. A computational model of Ca^{2+} signaling was developed to explain these oscillatory Ca^{2+} waves. The computational model predicts that modulating the variance of phospholipase C (PLC) activity leads to multiple signaling regimes that transition from quiescence to coordinated long range waves at the tissue scale to noisy locally uncoordinated Ca^{2+} transients. As validation of this prediction we confirmed that these predicted regimes can be recapitulated experimentally through manipulating levels of serum-based stimulation. Imposing a pattern of Ca^{2+} signaling kinetics also explains relative differences in Ca^{2+} signaling frequencies between the anterior and posterior compartment of the wing disc. This model provides an important basis to computationally test mechanisms of Ca^{2+} regulation and function in organ development and homeostasis.

D1450C Rab11, a multi talented determinant of morphogenesis in *Drosophila*. *Jagat Kumar Roy*, Divya Singh, Praween Choubey, Nabarun Nandy. Banaras Hindu University, Varanasi, Uttar Pradesh, IN.

The small GTPase Rab11, a major regulator of endomembrane traffiking, has been linked to developmental defects. Using loss and gain-of-function approaches in *Drosophila,* new roles for Rab11 in mediating the process of myoblast proliferation, migration and differentiation during *Drosophila* indirect flight muscle development have been identified. Rab11 function in the developing IFMs is a prerequisite for the differentiation and *de-novo* development. It functions in the proliferating adult muscle precursors (AMPs) for normal division and for maintaining cellular contact between the neighbouring myoblasts, failure to which results in pre matured differentiation of myoblast. Genetic interaction studies show that Rab11 partners with Notch in patterning the IFMs, since expression of ligand independent Notch in Rab11 mutant background can rescue the muscle defects and restores the myoblast number. Rab11 is also involved in the morphogenesis of Malpighian tubules which is one of the important organs for excretion and osmoregulation in insects and escapes histolysis during metamorphosis. It has two cell types, the principal cells (PCs) and stellate cells (SCs). Rab11 downregulation in PCs by using Gal4c-42 leads to shortening of MTs due to reduced endoreplication. Also interestingly, the SCs do not show mesenchymal to epithelial transition and do not differentiate into characteristic star shaped cells during pupal stages, show altered physiological functions and individuals die at pharate adult stage. In another set of experiments we found Rab11 playing an instrumental role in epithelial morphogenesis of developing *Drosophila* embryos. We observed that embryos lacking a functional Rab11, fail to undergo Dorsal Closure and show improper cuticle synthesis. The epithelial cells of these embryos, lack proper cell-adhesions and show anomalous expression patterns of activated JNK, which interestingly, are quite similar to the cells which lose their apical-basal polarity, suggesting a putative interaction of Rab11 functions with the JNK pathway. We suggest that Rab11 mediated regulation of inter-cellular membrane trafficking may be an additional mechanism to regulate the intercellular signaling during *Drosophila* development..

D1451A *Macroglobulin complement-related* is required for border cell migration and proper egg shape during *Drosophila melanogaster* oogenesis. *H. Alhadyian*, R. Ward. The University of Kansas, Lawrence, KS.

Macroglobulin complement-related (*Mcr*) encodes an ~200 kDa protein with α-2-Macroglobulin and LDL receptor class A domains. We initially identified *Mcr* in a genetic screen of mutations that dominantly enhanced a malformed leg phenotype in *broad* mutant animals, suggesting a role for *Mcr* in imaginal disc morphogenesis. We subsequently determined that *Mcr* is a core component of epithelial septate junctions (SJs), which are analogous to the vertebrate tight junction in providing an essential occluding function to the epithelium. Interestingly, homozygous mutations in *Mcr* are embryonic lethal with defects in developmental process including head involution and dorsal closure that occur prior to the establishment of the SJ, suggesting a role in morphogenesis that is independent of its role in the occluding junction. To extend these studies we are investigating the role of *Mcr* during morphogenetic events that occur during oogenesis. First, we investigated the expression of Mcr in oogenesis, and determined that it is expressed in the germarium, where it is enriched in the germline stem cells. It is also expressed in follicle cells, with the strongest expression in the polar cells. We next used cell-type and stage specific Gal4 drivers and mosaic analysis to examine the function of *Mcr* during oogenesis. We find that reducing *Mcr* in border cells using *slbo-GAL4* to drive *Mcr-RNAi* results in 45% of the border cell clusters splitting apart. Knocking down *Mcr* in all the follicle cells including the follicle stem cells (*GR1-GAL4>Mcr-RNAi*) resulted in degeneration of middle stages egg chambers, whereas knocking down *Mcr* in all the follicle cells from stage 8 onwards (*c204-GAL4>Mcr-RNAi*) perturbs eggs elongation, resulting in stage 14 egg chambers that are significantly rounder than wild type egg chambers. Mosaic analysis using the strong loss of function allele *Mcr1* revealed that germline clones formed germ cell cysts that fail to separate from the germarium. In addition, *Mcr* clones in the anterior and posterior follicle cells, including stalk cells, results in rupture of the epithelium. Together, these observations suggest that *Mcr* plays an important role in multiple aspects of egg chamber morphogenesis during oogenesis.

D1452B Unstable enhancer activity during early development of Drosophila. *S. Casas-Tinto*, M. Arnés, A. Ferrús. Cajal Institute, Madrid, Madrid, ES.

Gene expression is a tightly regulated process that eventually determines cell fate. The regulation of this process relies on short gene regulatory sequences, enhancers, whose activity fluctuates until the on or off state is fixed. Based on the G-TRACE analysis system, we show here that a set of nervous system specific enhancers (elav, D42, OK6) have ectopic activity in epithelial tissues early in development. This ectopic activity is variable, unstable and mainly influenced by the primary sequence of the enhancer and the insertion site in the chromosome. In addition, the LN2 enhancer from the sex lethal (sxl) gene showed sex dependent features in its ectopic expression. Although variable and unstable, the non-canonical expression of enhancers seems to be regulated in terms of tissue and extent. The factors that determine enhancer activity are relevant for transgenic animal models and the engineering of biotechnology tools. As well as for the interpretation of many current developmental biology studies in which Gal4 lines are used. In addition, since all 12 neural enhancers analyzed here showed unstable expression, we argue that this general phenomenon may be relevant for evolutionary change.

D1453C The *Drosophila melanogaster tfiia-s-2* gene encodes a male germline-expressed homolog of the small subunit of the TFIIA general transcription factor. *M. Hiller*, E. Collins, J. Mohammadi. Goucher College, Baltimore, MD.

Eukaryotic General Transcription Factors (GTF) are protein complexes that help position RNA polymerase at promoters and initiate transcription. The general transcription factors TFIIA and TFIID are multi-subunit protein complexes that physically associate with each other and assemble on promoters early in the process of transcription initiation. TFIIA consists of three protein subunits. In *D. melanogaster*, a single gene, *tfiia-l*, encodes a 48 kD polypeptide that is proteolytically cleaved to form two proteins of 30 kD and 20 kD. *tfiia-s* encodes the small subunit of 14 kD. Both the large and small subunits are widely expressed in many tissues and cell types. A homolog of the small subunit, *tfiia-s-*

2 (CG11639), is expressed only in the male germ-line. We have shown that two transcripts are encoded by *tfiia-s-2*, and that both proteins are able to interact with the generally expressed large subunit when expressed in *E. coli*. Together, this suggests that three different forms of TFIIA might be present in the male germ-line. TFIID is comprised of TATA-binding protein (TBP) and up to fourteen TBP-associated factors (TAFs). Several testis-specific TAFs have been identified. Mutations in the testis-TAFs cause defects in transcription and block spermatid differentiation, however, there is no mutant allele of *tfiia-s-2*. We are investigating the possibility that the testis-specific TFIIA and TFIID homologs work together to during transcription initiation in the male germ-line. We are also characterizing the ability of complexes containing TFIIA-S-2 to physically associate with TFIID subunits and testis-expressed homologs of TFIID subunits.

D1454A Identification of transcriptional regulators and enhancer regions of the *Alk* locus in *Drosophila*. *P. Mendoza-Garcia*[1,2], F. Hugosson[1], K. Hens[3], K. Pfeifer[1], G. Wolfstetter[1], D. Popichenko[2], B. Deplancke[4], R. Palmer[1]. 1) Sahlgrenska Academy, Gothenburg University, Gothenburg, Sweden; 2) Molecular Biology, Umea University, Umea, Sweden; 3) Centre for Neural Circuits and Behaviour, University of Oxford, Oxford, United Kingdom; 4) Laboratory of Systems Biology and Genetics, Lausanne, Switzerland.

Specification of the *Drosophila* visceral trunk mesoderm occurs upon inductive signals from the ectoderm. This induces the transcription of some key regulators for visceral muscle differentiation such as Tinman, Bagpipe and/or Biniou. The **receptor tyrosine kinase (RTK)** Alk is expressed in the developing CNS but predominantly in the embryonic trunk visceral mesoderm (VM), where is activated in response to the secreted ligand Jelly Belly (Jeb). **Jeb/Alk signalling** is responsible for founder cell (FC) specification in the forming VM and for the subsequent fusion to the fusion competent myoblasts (FCMs) to form the functional larval midgut. In this study we have investigated the transcriptional control *Alk* expression in the embryonic VM. The *Alk* locus was examined by several approaches including functional enhancer activity in vivo, deletion analysis, yeast one-hybrid screening and *in silico* analysis of predicted transcription factors binding sites. Furthermore, we have studied *in vivo* relevance of several identified and *in silico*-predicted transcription factors that could modulate *Alk* gene expression by single or combinatorial effect. Here we describe the identification of *cis*-regulatory elements in the *Alk* gene active during early embryogenesis and sufficient for the embryonic expression of *Alk* gene in the VM. This regulatory region is highly conserved among different *Drosophila* species. We also show the role of some of the identified transcription factors and their potential regulation of *Alk* transcription during embryo development through the identified regulatory region.

D1455B Myb and Mip120: an oncogenic dyad that causes tumorigenesis in Drosophila 3rd instar larvae. *P. J. Vorster*, J. S. Lipsick. Stanford University, Stanford, CA.

The *Myb* proto-oncogene family is recurrently mutated in human leukemia, brain cancer, breast cancer, and cancer of the salivary gland. Whereas vertebrate animals have three different *Myb* genes, Drosophila has a single non-redundant gene. The Drosophila Myb protein regulates gene expression in concert with other proteins in the RBF E2F2 and Myb-interacting proteins (dREAM) complex. Apart from Myb, homologs of all proteins contained within the dREAM complex were identified by mutations in the group B synthetic multivulval (synMuvB) genes in *C. elegans*. In humans, the MuvB core associates either with Rb-E2F-Dp proteins or with Myb proteins. In the absence of Myb the MuvB core suppresses the transcription of other genes during G0/G1 of the cell cycle, while B-Myb is bound to the MuvB core during S/G2 of the cell cycle and activates transcription. The Myb-interacting protein of 120 kDa (Mip120, homologous to LIN54 in humans and *C. elegans*), is part of the MuvB core. While Myb and other components of the dREAM complex are misregulated or mutated in many human cancers, a role for Mip120 remains unclear. In the course of studying the epigenetic regulation of Drosophila eye development by the dREAM complex, we have discovered a new role for Mip120 in tumorigenesis. Dual expression of two members of the dREAM complex, Myb and Mip120, caused solid tumors in 3rd instar larvae, while expression of Myb or Mip120 alone did not have this effect. This result suggests that protein stoichiometry and abundance of interactors of the dREAM complex play a vital role in regulation of tumor development. Our work also highlights the role of Mip120 as a critical member of the Myb-MuvB/dREAM complex in oncogenesis.

D1456C Novel function of the class I bHLH protein Daughterless in postmitotic neurons. *E. A. Waddell*[1], E. L. Robinson[1], M. D'Rozario[1,2], D. R. Marenda[1,3]. 1) Drexel University, Philadelphia, PA; 2) Washington University School of Medicine, St. Louis, MO; 3) Drexel University College of Medicine, Philadelphia, PA.

Class I basic Helix Loop Helix (bHLH) proneural proteins are highly conserved transcription factors. Class I bHLH proteins are broadly expressed in multiple tissues and have critical roles in many developmental processes such as neurogenesis. However, little is known about how class I bHLH proteins function in mature, differentiated neurons. Class I bHLH proteins function during development by forming heterodimers with class II bHLH proteins to activate transcription or by forming homodimers to both activate or restrict transcription of target genes. Class I bHLH proteins can also heterodimerize with class V HLH proteins, preventing gene expression. Our laboratory has identified a novel role for the class I bHLH protein Daughterless (Da), the only class I bHLH protein in *Drosophila*. Neuromuscular junction dissections were performed on third instar larvae and mature motor neuron synapses were imaged from this tissue. We have shown that Da functions to restrict synaptic branching and synapse number in these postmitotic neurons. Furthermore, our laboratory has shown that Da accomplishes this in part through restricting the expression of Neurexin, a cell adhesion molecule required for synapse formation. Third instar larvae were dissected and direct immunohistochemistry was performed for α-Nrx1 to show Neurexin levels in Da knockdown and overexpression genotypes. The mammalian ortholog of *Da*, *Transcription Factor 4* (*TCF4*), is a well-identified risk factor for a number of neurodevelopmental disorders including Pitt-Hopkins syndrome and schizophrenia, both of which are characterized by defects in behavior, learning, and memory. It is hypothesized that defects in postmitotic neurons may contribute to the phenotypes associated with these neurodevelopmental disorders. Therefore, identifying

how Da functions to restrict synaptic branching and synapse number in postmitotic neurons will have a significant impact on our understanding of the etiology of these diseases.

D1457A Germline silencing of pUASt depends on the piRNA pathway. *YC. Huang*, H. Moreno, WM. Deng. Florida State Univ, Tallahassee, FL.

One of the widely used techniques in *Drosophila* is the Gal4/UAS system, which allows tissue-specific misexpression or knockdown of interested genes. The original UAS vector, the pUASt, can only be activated in somatic tissues, not in the germline. By replacing the hsp70 promoter and the SV40 3'UTR with the P transposase promoter and the K10 3'UTR, respectively, Rørth (1998) generated a modified UAS vector, called pUASp, which can respond to Gal4 in both somatic and germline tissues. However, the underlying mechanisms for UASt silencing in germline cells remained unclear. Here, we report that the piRNA pathway is involved in suppressing UASt expression in ovarian germline cells. When piRNA pathway components (Piwi, AGO3, Aub, Spn-E, and Vasa) were knocked down individually in germline cells, the UASt-RFP/GFP can be detected in germline cells in the ovary. To determine how piRNAs silence UASt-transgene expression, we performed RNA-seq analyses of small RNAs and found that the hsp70 promoter of pUASt is a potential piRNA target. Additionally, since the UASt vector also contains the SV40 3'UTR, which happens to be targeted by the Nonsense-mediated RNA decay (NMD) pathway. To find out whether NMD is also responsible for UAST silencing in the germline, we knocked down several NMD key components in ovarian germline cells, and observed a low frequency of UASt-RFP expression in germline cells with *Smg5* knockdown. Taken together, our findings suggest an important role of the piRNA pathway, and a potentially minor role of the NMD pathway in germline UASt silencing.

D1458B Transcriptome profile of abnormal testis reveals potential function for ceramidase in *drosophila melanogaster*. *M. Zhang*[1*], Z. Zhu[2]. 1) Zhejiang Univ., Hangzhou, Zhejiang, CN; 2) Zhejiang Univ., Hangzhou, Zhejiang, CN.

Sphingolipids are important components of eukaryotic cell membranes. Some sphingolipid metabolites, such as ceramide, sphingosine and sphingosine-1-phosphate, also act as signaling molecules to mediate various biological processes, like programmed cell death. However, little is known about the mechanisms responsible for the abnormality in testis development in ceramidase knock down strain. Genomic information for the phenotype is currently unavailable, therefore, to facilitate research on it, we present a method for *de novo* assembly of drosophila transcriptome using short read sequencing technology (Illumina) combined with a tag-based digital gene expression (DGE) system. Illumina sequencing generated the drosophila transcriptome from the reproductive organ of two phenotypes with normal and abnormal testes. In total, we obtained 46,498,038 uniquely mapped reads that covered 87.53% of the current annotated transcripts, which represented 16246 mRNA transcripts, across all the samples. Among them, 34 differentially expressed genes ($p < 0.05$, false discovery rate $q < 0.05$) between the normal and abnormal testes were revealed, and we confirmed their altered expression levels by quantitative real-time PCR (qRT-PCR). Gene ontology and KEGG pathway analysis demonstrated that the 34 differently expressed genes were enriched in specific biological processes with regard to actin filament-based process, oxidative phosphorylation, metabolic pathways, phenylalanine metabolism and ECM-receptor interaction ($p < 0.05$). The obtained transcriptome and DGE profiling data provided comprehensive gene expression information at the transcriptional level that could facilitate our understanding of the molecular mechanisms of the abnormal testis development.

D1459C *In vitro* characterization of Zelda zinc fingers – discovery of a new DNA binding activity. *N. C. Kirov*[1], H. Y. Liu[1], S. N. Higa[1], C. Y. Nien[1], D. Ouyang[1], A. Yang[2], T. Hughes[2], C. Rushlow[1]. 1) New York Univ, New York, NY; 2) University of Toronto, Toronto, ON.

The transcription factor Zelda (Zld) is essential for zygotic genome activation in Drosophila embryo. It is maternally deposited and activates groups of pre-blastoderm genes required for sex determination, cellularization and embryonic patterning, either alone or in combination with other transcription factors. Zld is a large DNA binding protein (1596 aa) containing six predicted C2H2 type Zn finger domains. Two of them (ZF1, ZF2) are located in the N-terminal half of the protein, while the others are clustered close to the C-terminal end. Zld cognate binding sites, CAGGTAG and related sites (TAGteam sites), are enriched in the regulatory elements of its target genes. *In vitro* binding experiments have shown that the C-terminal Zn fingers are required for binding to DNA, but it is not known how each of them is involved in the binding. The function of the N terminal Zn fingers is unknown. Here we use *in vitro* mutagenesis and DNA binding assays (gel shifts and protein binding microarrays) to further characterize the functional properties of Zld's Zn fingers. Surprisingly, we discovered a new DNA binding activity to G-rich sequences for ZF2 and adjacent conserved amino acids. We also quantified the contribution of the C-terminal cluster to the affinity and specificity of binding to different TAG team sites. We discuss the implications of these findings for Zld function in Drosophila embryos.

D1460A The circadian clock orchestrates *de novo* rhythmic expression of oxidative stress-response genes in aging *Drosophila*. *Rachael Kuintzle*, Eileen Chow, Tara Bonar, Jaga Giebultowicz, David A. Hendrix. Oregon State University, Corvallis, OR.

Maintenance of robust circadian rhythms is associated with healthy aging and delayed onset of age-related diseases. Disruption of these rhythms in flies increases susceptibility to oxidative stress and neurodegeneration. Loss of core clock gene function in mice similarly accelerates the onset of late life diseases and mental decline, indicating that the links between circadian desynchrony and neuronal aging are conserved from flies to mammals. However, the epigenetic mechanisms underlying this relationship have remained enigmatic. Here, we used RNA sequencing (RNA-seq) to compare gene expression in young and old *Drosophila melanogaster* heads at 4-hour intervals around the clock. Although attenuations of core clock gene expression were minor, we identified diverse age-induced transcriptional changes among oscillatory genes, including phase shifts and weakened or abolished rhythmicity. Remarkably, we also discovered a subset of mRNAs that adopted synchronous, *de novo* rhythmicity during aging. These genes were termed "Late Life Cyclers" (LLCs) and include, among others: small heat shock protein *Hsp22*, cytokine *bnl*, lactate dehydrogenase *ImpL3*, and Hsp40-like *CG7130*. Because the majority of LLCs were known to be

upregulated in oxidative stress, we used qRT-PCR to test their expression in heads of young flies challenged with hyperoxia. Interestingly, hyperoxic insult approximately phenocopied the aging effect by inducing rhythmic upregulation of the LLCs, supporting our hypothesis that increased oxidative stress during aging contributes to the LLC phenomenon. We also show that LLC expression was significantly reduced in the heads of Clk^{out} and cyc^{01} flies compared to controls with functional clocks, implicating the circadian transcription factors CLK and CYC as important regulators of LLC transcription. In addition, novel transcript assembly with our RNA-seq data uncovered many age-induced, unannotated genes, including several that exhibit LLC behavior. Besides providing a genome-wide, round-the-clock expression profile in heads of young and old *Drosophila*, our data more broadly offer a temporally unbiased measure of age-dependent differential expression. We have developed a web-based database to enable convenient viewing of these RNA-seq results for individual genes and isoforms. In summary, this study demonstrates a novel role for the circadian clock during aging and begins to uncover the mechanistic relationship between the senescent organism's timekeeper and its changing cellular environment.

D1461B Two temporal functions of Glass: ommatidium pattarning and photoreceptor differentiation. *X. Liang*, Simpla Mahato, Chris Hemmerich, Andrew Zelhof. Indiana University Bloomington, Bloomington, IN 47405, IN.

Much progress has been made in elucidating the molecular networks required for specifying retinal cells, including photoreceptors, but the downstream mechanisms that maintain identity and regulate differentiation remain poorly understood. Here, we report that the transcription factor Glass has a dual role in establishing a functional *Drosophila* eye. Utilizing conditional rescue approaches, we confirm that persistent defects in ommatidium patterning combined with cell death correlate with the overall disruption of eye morphology in *glass* mutants and reveal that Glass exhibits a separable role in regulating photoreceptor differentiation. In particular, we demonstrate the loss of photoreceptors in adult *glass* mutant retinas is due to a failure of photoreceptors to complete differentiation. Moreover, the late reintroduction of Glass in these developmentally stalled photoreceptors is capable of restoring differentiation in the absence of correct ommatidium patterning. Mechanistically, transcription profiling at the time of differentiation reveals that Glass is necessary for the expression of many genes implicated in differentiation, i.e. rhabdomere morphogenesis, phototransduction, and synaptogenesis. Specifically, we show Glass directly regulates the expression of *Pph13*, which encodes a transcription factor necessary for opsin expression and rhabdomere morphogenesis. Altogether, our work identifies a fundamental regulatory mechanism to generate the full complement of cells required for a functional rhabdomeric visual system and provides a critical framework to investigate the basis of differentiation and maintenance of photoreceptor identity.

D1462C Transcriptional regulation by Drosophila Suppressor of Hairy-wing: Investigating contributions of a newly discovered interacting protein HIPP1. *Steve Glenn*, Pamela Geyer. University of Iowa, Iowa City, IA.

Transcription is regulated by three classes of DNA regulatory elements: enhancers, silencers and insulators. Transcription factors bind these elements to coordinate gene expression across cell types and developmental stages. Most metazoan transcription factors carry Zinc finger (ZF) DNA binding domains, often with five or more ZFs. Many polydactyl transcription factors have distinct regulatory functions at different endogenous binding sites. How these activities are regulated is unclear. To better understand how a single transcription factor establishes enhancer, silencer and insulator functions, we study the Drosophila multi-functional twelve ZF insulator protein Suppressor of Hairy-wing [Su(Hw)]. Su(Hw) functions primarily as a repressor, and this activity is required in the ovary for female fertility. Su(Hw) is also important for male fertility through unknown mechanisms. We hypothesize that the diversity of Su(Hw) regulatory functions depends upon recruitment of partner proteins. Recently a novel Su(Hw) interactor was identified, called HP1 and insulator partner protein 1 (HIPP1). We find that HIPP1 is the major Su(Hw) interacting protein, localizing to more than 80% of Su(Hw) sites. HIPP1 is homologous to the vertebrate Chromodomain on Y (CDY), a transcriptional repressor that is required for spermatogenesis in mouse. These data suggest that HIPP1 may mediate Su(Hw) repressor function. To test this hypothesis, we undertook a genetic approach using genome editing to generate numerous *HIPP1* deletion mutants. We are currently using these mutants to determine the role of HIPP1 in Su(Hw) function, as well as defining its role in heterochromatin stability and function.

D1463A Split-ends is required for Ecdysone production during Larva development. *Sattar Soltani*, Qiuxiang Ou, Kirst King-Jones. Alberta, Edmonton, CA.

Steroid hormones coordinate many biological processes during development, metabolism and reproduction. *Drosophila* provides an excellent platform for studying steroid hormone regulation, since many studies have examined the role of ecdysone, the major insect steroid, and its roles during the development of the fly. Larval ecdysone production occurs in the prothoracic gland (PG) and is carried out by a group of well-examined enzymes that are encoded by the "Halloween" genes. Although the enzymatic reactions carried out by the Halloween enzymes are fairly well characterized, little is known about the molecular and genetic factors regulating this pathway. We report here that the *split-ends* gene is required for ecdysone regulation in the PG. *Split-ends* is a transcriptional co-repressor and that harbors three N-terminal RNA-binding motifs and a highly conserved C-terminal SPOC domain. PG-specific knock down of *split-ends* via RNAi resulted in developmental arrest during late third instar larvae, with no animals progressing to the pupal stage. Our data suggest that the down-regulation of *split-ends* affects ecdysone production due mainly to altering the expression level of Halloween genes. Furthermore, arrested animals can be rescued when fed with ecdysone or precursors thereof. Taken together, we provide new insights into how a co-repressor can modulate ecdysone production during *Drosophila* development.

D1464B Whole genome analysis of the transcriptional corepressor, Atrophin, reveals interactions with Trithorax-like and regulation of Dpp and Notch signaling. *K. Yeung*[1,2], D. Yap[3], P. H. Holmqvist[4], A. Boija[4], M. Moksa[5], S. Aparicio[3], M. Fanto[6], M. Hirst[5], M. Mannervik[4], H. McNeill[1,2]. 1) Lunenfeld-Tananbaum Research Institute, Toronto, CA; 2) Department of Molecular Genetics, University of Toronto, Toronto, CA; 3) Department of Molecular Oncology, BC Cancer Research Centre, Vancouver, CA; 4) Department of Molecular Biosciences, The Wenner Gren Institute, Stockholm University, Stockholm, Sweden; 5) Department of Microbiology & Immunology, University of British Columbia, Vancouver, CA; 6) MRC Centre for Developmental Neurobiology, King's College London, Guy's Campus, London, UK.

Atrophin (Atro, also known as Grunge) is a transcriptional corepressor. Mutation of a mammalian *Atro* homolog, *Atrophin-1*, causes a neurodegenerative disease called dentatorubral-pallidoluysian atrophy in humans, while mutation of the second mammalian *Atro* homolog, *Atrophin-2*, causes severe developmental defects. Although *Drosophila Atro* mutants have a large range of phenotypes including neurodegeneration, segmentation and planar polarity defects, very little is known about Atro's binding partners and downstream targets. We present the first genomic analysis of Atro using ChIP-seq against Atro. Our Atro ChIP-seq identified 1300 potential targets of Atro; these include *engrailed*, and components of the *dpp* and *Notch* signaling pathways. Using *Atro* mutant clones, we show that Atro regulates *dpp* signaling and the expression of Engrailed in imaginal discs. Interestingly, Atro mutant imaginal disc clones have similar phenotypes to the ones caused by loss of Notch signaling. In addition, our bioinformatic analyses, sequential ChIP and coimmunoprecipitation experiments show that Atro and Trithorax-like (Trl, *Drosophila* GAGA factor) physically interact and bind to the same loci. *Atro* and *Trl* also interact genetically. We propose that Atro and Trl function together as a complex to regulate transcription.

D1465C Characterization of a *grainyhead* neuroblast enhancer. *Thomas Brody*, Alexander Kuzin, Svetlana Smith, Ward Odenwald, Neural Cell-Fate Determinants Section. NINDS/NIH, Bethesda, MD.

Analysis of *cis*-regulatory sequences using comparative genomics reveals that enhancers consist of clusters of conserved sequence blocks (CSBs) that are made up of unique and repeat sequence elements; both often consist of identifiable motifs corresponding to binding sites of known transcription factors. Our goal has been to address aspects of enhancer structure, including the basis for spatial and temporal regulation of gene expression and the functions of the large number of CSBs in neural enhancers. We have identified a late temporal network enhancer of *grainyhead*. The enhancer, *grh-15* contains two separable activities, one that drives expression in the brain and another in the ventral cord. We have systematically truncated, rearranged and mutated each of the nine CSBs present in the brain-specific portion of *grh-15*, expressed in a ~12 embryonic brain neuroblasts and in ~15 larval neuroblasts and their lineages. While our results indicate that information regulating enhancer expression is carried in a highly redundant fashion, individual CSBs convey expression in subsets of larval lineages. We also show that the *grh* enhancer is co-expressed within a subset of cells that express the temporal determinants Cas and Pdm, that it marks a subset of both type I and type II neuroblasts and their lineages in the larval brain, and that it is expressed in only some of the Grh^{+} lineages. These studies highlight the advantages of using evolutionary conservation as a guide to the analysis of *cis*-regulatory sequences.

D1466A Fiber-specific Troponin C isoform switching in Drosophila thoracic muscles. *M. Chechenova*[1], S. Maes[2], S. Oas[2], C. Nelson[2], A. Bryantsev[1], R. Cripps[2]. 1) Kennesaw State University, Kennesaw, GA; 2) University of New Mexico, Albuquerque, NM.

During development and differentiation, structural tissue-specific proteins undergo isoform switching. Although instances of multiple isoform expression have been described for all multicellular organisms, particular mechanisms of isoform switching in many cases still remain unclear. Among the five Drosophila Troponin C isoforms, *TpnC4* is predominantly expressed in the fibrillar-type fibers of the indirect flight muscle, whereas *TpnC41C* is the main isoform of the tubular-type fibers of jump muscle. In our study, we show that these two isoforms are essential for the functioning of thoracic muscles, and can mutually replace each other when the expression of each is down-regulated.

To analyze functional importance of the two TpnC isoforms, we created genetic lines with single gene deletions for either *TpnC4* or *TpnC41C*, and a line with a double deletion for both genes. We found that the removal of one of the isoforms resulted in reciprocal activation of expression of the other isoform in both fiber types. Moreover, minimal enhancers of *TpnC4* and *TpnC41C* can be activated in both fiber types, suggesting that normal isoform expression pattern is rather a result of transcriptional repression in non-native muscles. However, functionally these two isoforms were not equivalent. Although *TpnC4* expressed in jump muscles was able to support effective jumping, *TpnC41C* expressed in flight muscles could not sustain flight. Flies with the *TpnC4/TpnC41C* double deletion showed flightless and jumpless phenotypes. Similar data were obtained in experiments with RNAi knockdown of these genes. Analysis of the ultrastructural muscle organization in the flies with the double deletion revealed defects in myofibril alignment and Z-line integrity.

Our study provides insight into isoform switching mechanisms for muscle genes, and defines the importance of TpnC for normal muscle assembly.

D1467B The activity of the *en* imaginal disc enhancers is dependent on chromatin structure. *Y. Cheng*, J. Kassis. Eunice Kennedy Shriver NICHD, NIH, Bethesda, MD.

engrailed (*en*) is a gene important for many different aspects of development including embryonic segmentation and formation of the posterior compartment in imaginal discs. *en* and the co-regulated, redundant gene *inv* reside in a 113 kb domain covered with tri-methylated histone H3 (H3K27me3), the distinctive mark of genes regulated by the Polycomb group proteins. We have been identifying *en* enhancers that drive its complex expression during development. We previously reported that a 79kb genomic *en* construct (*HA-en79*) contains enhancers for both embryonic and wing imaginal disc (WD) expression, and rescues a chromosomal deletion of the *inv/en* domain. Interestingly, even though the WD enhancers are present in the transgene, their ability to drive HA-*en* expression is subject to *en* protein (EN) auto-repression; in the presence of endogenous EN, HA-en is only expressed in subsets of the wild type domain. In contrast, the endogenous *en* gene is not repressed

by the presence of the *HA-en79* transgene. Further, reporter constructs that contain the imaginal disc enhancers driving lacZ show lacZ expression only in the anterior compartment; our data strongly suggest that EN silences *lacZ* expression in the posterior compartment. These data indicate that removing the imaginal disc enhancers from the *inv/en* domain alters their activity, rendering them sensitive to repression by EN. Chromatin-immunoprecipitation experiments suggest that EN binds directly to a DNA fragment that contains one of the imaginal disc enhancers. We suggest that when this imaginal disc enhancer is within the *inv/en* domain, its activity is high, and it cannot be repressed by EN, but when this same enhancer is taken out of the domain, EN is able to repress it. Experiments to examine the chromatin marks present in the endogenous locus and the small and large transgene are in the planning stages.

D1468C Concentration Dependent Activity of the Bicoid Transcriptional Activator. *Colleen Hannon*, Shelby Blythe, Eric Wieschaus. Princeton University/HHMI, Princeton, NJ.

In order for embryonic development to proceed correctly and reproducibly, the expression of genes in individual cells must be coordinated with precision. In *Drosophila*, graded expression of the maternal transcription factor Bicoid (Bcd) provides positional information to pattern the anterior-posterior (AP) axis of the developing embryo. Bcd is known to bind hundreds of sites in the genome, activating target genes at different positions along the AP axis. To measure Bcd binding states at specific concentrations along its gradient, we have developed a series of transgenic lines that express defined uniform concentrations of Bcd. Using chromatin immunoprecipitation for Bcd followed by high throughput sequencing in these transgenic embryos, we group Bcd-bound target regions into several "affinity" classes based on their *in vivo* occupancy by Bcd at different concentrations. We find that the occupancy of a given target sequence for Bcd is dependent not just on the biochemical affinity of its Bcd binding sites, but its genomic context. Further, we find that some low affinity target regions are dependent on Bcd for maintaining an open chromatin state. This suggests a model in which Bcd is able to influence chromatin structure to gain access to low affinity targets at high concentrations. In contrast, high affinity targets are more accessible either through their native chromatin structure or as a result of other chromatin modifying factors.

D1469A Expression of reciprocal antagonists Mirr and Mid is regulated by localized input from EGFR, JAK/STAT, and Dpp signaling pathways. *Scott De Vito*[1], Mariana Fregoso Lomas[1], Jean François Boisclair Lachance[2], Josée Houde[1], Laura Nilson[1]. 1) Department of Biology, McGill University, Montreal, Quebec, CA; 2) Ben May Department for Cancer Research, University of Chicago, Chicago, Illinois, USA.

EGFR signalling is central to tissue patterning. In Drosophila ovarian follicular epithelium, EGFR signalling is activated by Grk, a ligand secreted by the oocyte. Localized secretion of Grk leads to localized EGFR signalling, which in turn specifies distinct cell fates at different stages . In early oogenesis, Grk/EGFR signalling at the posterior induces a posterior fate characterized by expression of the paralogous T-box transcription factors Mid and H15. In later stages, dorsal anterior Grk/EGFR signalling induces dorsal anterior fates characterized by the expression of the transcription factor Mirr. These fates contribute to structure of the eggshell. Patterning of this epithelium thus involves activation of the same signalling pathway leading to different outcomes in different regions of the tissue. Here we show that EGFR signalling outcome is determined by spatially localized input from other signalling pathways. Here we show that at the anterior of the epithelium, Dpp signalling cooperates with Grk to induce expression of Mirr while also repressing Mid and H15. At the posterior of the epithelium, JAK/STAT signalling is required for expression of Mid and H15 while also repressing Mirr. Moreover, we show that Mid and Mirr mutually repress each other, contributing to the complementary expression of Mirr in the dorsal anterior and Mid at the posterior. Input from Dpp and JAK/STAT signalling thus defines whether EGFR activity will induce expression of Mirr or expression of Mid/H15, and this choice is refined by the mutual repression between Mirr and Mid/H15. The components comprise a molecular switch where graded inputs are converted into bistable outcomes.

D1470B Methionine Sulfoxide Reductase expression in response to anoxic stress conditions in *D. melanogaster*. *E. Rakitina*, D. Binninger. Florida Atlantic University, Boca Raton, FL.

Anoxia is the condition of extreme oxygen deprivation. It presents real danger to the viability of tissues, subjected to inadequate oxygen supply. Different organisms have various degrees of susceptibility to anoxic stress conditions. Thousands of human deaths each year are attributed to the events of induced anoxic conditions – ischemic strokes and heart attacks being one the most numerous. But whereas mammals tolerate anoxic stress very poorly, *D. melanogaster* is known to develop a special protective mechanism – spreading depression, allowing it to withstand hours of oxygen deprivation. Period following reintroduction of oxygen is the most dangerous consequence of anoxia and is characterized by the abundance of ROS (Reactive Oxygen Species), which oxidize vital molecules in cells rendering them non-functional. Methionine is exceptionally susceptible to oxidation by ROS, but it can be catalytically restored by the enzyme Methionine Sulfoxide Reductase (Msr). Two forms of Msr are known – MsrA and MsrB, which act upon two different epimers of oxidized methionine. Currently, little is known of the relationship between Msr gene activity and anoxic stress recovery in *Drosophila*. Activity of the Msr-encoding genes in response to anoxia is the subject of the proposed study. We use anoxia chamber to induce comma in flies, followed by recording recovery times. Preliminary results show, that single mutant flies do not take significantly longer than wildtype to recover from spreading depression. However, double mutants take significantly longer to recover and greater number of Msr-deficient flies die as a result of anoxia. Failure to recover becomes more pronounced as animals approach senescence. These studies offer insight into the role of oxidative damage during reperfusion period following cardiac stroke.

D1471C CLAMP: Sex Specific or Global Transcription Factor. *W. Jordan*, J. Johnson, C. Doherty, E. Larschan. Brown University, Providence, RI.

Dosage compensation is a mechanism by which gene dosage of X-linked genes between males and females is equalized. In Drosophila, the Male Specific Lethal Complex (MSL) regulates this process. This complex is responsible for the upregulation of a single X-chromosome in males (XY) so that expression of male X chromosome genes is equal to those on the female (XX). MSL complex also includes two non-coding RNAs called roX (RNA on the X) that are important for targeting of the complex. The protein, Chromatin-Linked Adaptor for MSL Proteins, CLAMP, is directly responsible for mediating the interaction between MSL and DNA elements called MSL Recognition Elements (MRE) that are two-fold enriched on the X chromosome compared with autosomes. While much of what we currently know about CLAMP is in the context of its function during X chromosome dosage compensation, CLAMP is localized to similar MRE-like DNA sequences in all regions of the genome. Therefore, we used CRISPR to knockout the gene encoding CLAMP to determine how it functions in vivo. We determined that in the absence of CLAMP males die earlier than females but there are no viable flies of either sex. Also, CLAMP functions as a repressor of transcription of the roX RNAs in females to assure that aberrant dosage compensation does not occur. Future experiments include retargeting CLAMP and roX RNAs to determine which factors are sufficient for X chromosome identification.

D1472A An integrated causality-based regulatory network for Drosophila S2 cells. *Hangnoh LEE*[1], Yijie Wang[2], Michael Buckner[3], Quentin Gilly[3], Dong-Yeon Cho[2], Stephanie Mohr[3], Norbert Perrimon[3], Teresa Przytycka[2], Brian Oliver[1]. 1) National Institute of Diabetes, Digestive, and Kidney Diseases, National Institutes of Health, Bethesda, MD 20892; 2) National Center for Biotechnology Information, National Institutes of Health, Bethesda, MD 20892; 3) Drosophila RNAi Screening Center, Department of Genetics, Harvard Medical School, Boston, MA 02115.

Reconstruction of regulatory networks and prediction of biological interactions are important aims of network biology. Advances in high-throughput genomics technologies have accelerated the building of improved network models. However, delineation of the overall network topology requires further effort because many of current network models are based on correlation, rather than causation. In order to overcome this limitation, and to generate a comprehensive network based on causality, we depleted 483 transcription factors (TFs) expressed in S2 cells, and profiled gene expression changes upon knockdown by sequencing a total of 1,920 RNA-Seq libraries. Our knockdown reduced transcript level in approximately 98% of target genes and significantly induced changes in gene expression in more than 40,000 non-target genes. Based on these observations, we described 25 different modules of genes affected by different combinations of TFs. We then integrated chromatin Immunoprecipitation data for 137 TFs and histone marks from the same cell line as well as 1,264 TF binding motifs and implemented a mathematical modeling approach. Our network model predicted more than 70,000 gene interactions that a few of which were previously known, but primarily these were novel predictions. The known interactions include regulatory pathways that govern sex determination. The novel ones largely describe cell cycle progression of the proliferative cells. Our result modeled a regulatory network based on causality and provided a testable catalog of genetic interactions.

D1473B Competitive binding of transcription factors drives dominance in regulatory genetic pathways. *A. H. Porter*[1], N. A. Johnson[1], A. Y. Tulchinsky[2]. 1) Univ Massachusetts, Amherst, MA; 2) SUNY New Paltz, New Paltz, NY.

We report a new mechanism for allelic dominance in regulatory genetic interactions and its sensitivity to genetic background. We investigated a biophysical model of gene regulation, where the fractional occupancy of a transcription factor (TF) on the *cis*-regulated promoter site it binds to is determined by binding energy (*–ΔG*) and TF concentration. Transcription and gene expression proceed at the regulated *cis* site while the *trans*-acting TF is in the bound state. In diploids, individuals may be heterozygous at the *cis*-site promoter, at the TF's coding region, or at the TF's own promoter, which determines allele-specific TF concentration. We find that when the TF's coding region is heterozygous, TF alleles compete for occupancy at the *cis* sites and the tighter-binding TF is dominant in proportion to the difference in binding strength. When the TF's own promoter is heterozygous, the TF produced at the higher concentration is also dominant. *Cis*-site heterozygotes have additive and therefore codominant phenotypes. While this dominance is inevitable at the molecular level, it may be difficult to detect in the phenotype under some biophysical conditions, more so when TF concentration is high. In three-locus linear pathways of loci A->B->C where A and B are TF's, dominance propagates down the pathway: locus A can show dominance with respect to expression at locus C. This dominance is attenuated at the phenotypic level such that only low-expression A alleles appear recessive, especially when TF concentration is high at the B locus. Two types of genetic background effects occur. In the proximal background of the two-locus interaction, where a TF is heterozygous in both its promoter and coding sites, their effects on competitive binding interact to increase, decrease or even reverse dominance of the other; heterozygosity in the *cis*-site promoter has no effect. In more distant interactions of three-locus pathways, locus A's dominance with respect to C-locus expression can be modified by allelic variation at locus B, especially at its coding site. Many empirical findings of dominance in TF and *cis*-site interactions in the literature can be explained by this simple mechanism of competitive binding.

D1474C Patterns of gene expression variation in a natural population of *Drosophila melanogaster* provide evidence for GRN robustness through compensatory *cis trans* interactions. *J. Fear*[1,2], L. León-Novelo[3], A. Morse[1,2], A. Gerken[1,2], K. Van Lehmann[5], J. Tower[4], S. Nuzhdin[4], L. McIntyre[1,2]. 1) Molecular Genetics and Microbiology University of Florida, Gainesville, FL; 2) Genetics Institute University of Florida, Gainesville, FL; 3) Department of Biostatistics; University of Texas Health Science Center at Houston-School of Public health, Houston, TX; 4) Molecular and Computation Biology Program, Dornsife College of Letters, Arts and Sciences, University of Southern California, Los Angeles, CA; 5) Memorial Sloan Kettering Cancer Center, 1275 York Avenue, New York, NY.

Regulatory variation in gene expression can be described by *cis* and *trans* genetic components. Here we use RNA-seq data from a panel of *Drosophila melanogaster* test crosses to compare allelic imbalance (AI) in female head tissue between mated and virgin flies, an environmental

change known to affect transcription. Indeed, 3,048 exons (1,610 genes) are differentially expressed in this study. We use a Bayesian model for the detection of AI and control type I error with an intersection test. There are ~200 genes with AI exclusively in mated or virgin flies and on average 34% of genes within a cross, and 54% of all genes across the entire panel show evidence for genetic regulation of transcription. Nearly all differentially regulated genes are affected in *cis*, with an average of 63% of expression variation explained by the *cis* effects. *Trans* effects explain 8% of the variance in AI on average and the interaction between *cis* and *trans* explains an average of 10% of the total variance in AI. In both environments c*is* and *trans* effects are compensatory in their overall effect, with the opposite signs of effects of the allele coupled 63% of the time. There is a negative association between *cis* and *trans* effects (85%) across lines. We hypothesize that the gene expression level perturbed by *cis*-regulatory mutations is compensated through *trans*-regulatory mechanisms, e.g. *trans* and *cis* by *trans* factors buffering *cis*-mutations. In addition, when AI is detected in both environments, *cis-mated, cis-virgin,* and *trans-mated-trans-virgin* estimates are highly concordant. We conclude that the GRN are robust and that *trans* buffering explains robustness.

D1475A A novel Smad/Su(H)-target enhancer drives *hedgehog* expression in a signaling hole of the posterior wing disc compartment. *Timothy Fuqua*, Elizabeth Stroebele, Christian Noblett, Albert Erives. Department of Biology, University of Iowa, Iowa City, IA, 52242-1324, USA.

Developmental patterning involves dynamic integration of signals from the BMP, Notch, Wnt, Hedgehog and other signaling pathways. These signals are integrated by transcriptional enhancers in a manner that is customized for each target gene. To advance our understanding of this signal integration, we identified regulatory belts that are conserved across the *Drosophila* genus and contain binding sites for the Notch-signaling effector Su(H), the Dpp/BMP effectors Mad:Medea, and the LIM-homeodomain selector Apterous (Ap). We report identifying a novel wing imaginal disc enhancer for *hedgehog* driving an interesting expression pattern. While the *hedgehog* gene is normally expressed only in the posterior compartment of the wing imaginal disc, this novel enhancer, "*hh-E*", drives twin spots of expression on either side of the Dpp expression stripe in the dorsal-proximal region of the columnar epithelial side of the wing disc. Of these twin spots of *hh-E* driven expression, one (ectopic) spot is located in the anterior compartment and the other (normal) spot is in the posterior compartment. While the *hh-E* expression pattern is consistent with a Dpp-readout licensed in part by Ap, it is not consistent with it being a canonical Notch/Su(H) target. To understand the role of the conserved Su(H) site in *hh-E*, we mutated this site and found that it functions as a dedicated repressor in the peripodial membrane of the wing disc. Mutated *hh-E* continues to drive twin spots of expression in the dorsal-proximal regions of both the anterior and posterior wing disc compartments. Thus, *hh-E* likely features a dedicated Su(H) repressor binding site that is refractive to Notch-induced activation. To understand what must be silencing the ectopic spot of anterior expression driven by *hh-E*, we "restored" anterior silencing in an expanded *hh-DEF* fragment. One of these flanking regions,"*hh-F*", is another Su(H) binding site containing enhancer driving posterior-compartment specific expression in the distal regions of the wing disc, including the wing pouch. A combined *hh-DEF* enhancer with a mutated *hh-F* Su(H) site has attenuated wing pouch expression without diminishing the posterior spot of dorsal proximal expression driven by the embedded *hh-E* enhancer. In summary, the modular *hh-DEF* enhancers, which are different from the previously identified *hh-ABC* regulatory modules, are each responsible for various signaling holes in the wing disc and collectively piece together the full *hedgehog* expression throughout the posterior compartment. We conclude that some Su(H)-targeted enhancers may function independently of Notch signaling at unexpected loci and do so via additional unknown contextual cues present in these enhancers.

D1476B Strong interactions between copies of *spineless* drive interchromosomal communication independent of homologous chromosome pairing. *K. C. Viets*, R. J. Johnston. Johns Hopkins University, Baltimore, MD.

Fifty years ago, Nobel laureate Ed Lewis observed that two mutant alleles of a gene, one lacking a functional regulatory region and one lacking a functional protein-coding region, can interact in *trans* to rescue gene expression. This process, which he called transvection, requires homologous chromosome pairing and is disrupted by chromosomal rearrangements. With only a handful of DNA elements linked to transvection and chromosome pairing since Ed Lewis's initial discovery, many questions remain in the field. What role do these phenomena play in regulating gene expression in the wild? Does crosstalk between alleles always require chromosome-wide pairing? What DNA elements are necessary for gene copies to locate each other in the genome, and are these elements similar between genes? Our work seeks to answer these fundamental questions using stochastic gene expression in the *Drosophila* retina as a model.

In the retina, the gene *spineless* (*ss*) is expressed in a random on/off manner in 67% of R7 photoreceptors. A transvection-like mechanism known as Interchromosomal Communication (InterCom) allows cross-regulation of expression states between *ss* alleles within each R7. InterCom is one of the only known examples of transvection in a biological context, acting to average the expression frequencies of functional, naturally derived *ss* alleles. Using a recently described DNA FISH technique called DNA Oligopaints, we have developed a system to study *ss* pairing and InterCom in a quantitative manner. With this system, we have determined that InterCom requires copies of *ss* to pair. We have also found that, unlike classical transvection, pairing and InterCom can occur between copies of *ss* located in heterologous genomic locations, independent of homologous chromosome pairing. Pairing and InterCom of *ss* loci requires surprisingly minimal regions of homology: a *ss* transgene of only 110 kb can drive pairing between non-homologous chromosomes. Additionally, fragments of *ss* as small as 46 kb can pair and perform InterCom with endogenous *ss* when inserted 0.4 or 4.6 Mb away on the same chromosome arm, indicating that even small portions of the gene can mediate interactions. Our data suggest that strongly interacting loci such as *ss* may hold chromosomes together at specific nodes, rather than chromosome-wide homology driving tight pairing along the entire chromosome.

D1477C The developmental effects of germline ablation contribute more strongly to somatic gene expression than the maternal effects of piRNA. *Alexandra A. Erwin*, Justin P. Blumenstiel. University of Kansas, Lawrence, KS.

piRNAs are key regulators of transposable elements (TEs) that have been also shown to have strong effects on gene expression. Since piRNAs are transmitted maternally, they play a key role in maintenance of genome defense across generations. The degree to which they contribute to variation in gene expression across generations is poorly known. Here, using a syndrome of hybrid dysgenesis in *D. virilis*, we evaluate how gene expression profiles differ in progeny whose mothers greatly differ in their piRNA profile. Moreover, because gonadal atrophy occurs in about 50% of progeny of the dysgenic cross, we can contrast the maternal effects of a divergent piRNA pool with the effects on gene expression that arise from loss of the germline. We have evaluated these contrasting effects by performing RNA-seq on head and thorax tissue of reciprocal males and females, with and without atrophied gonads. We find that differences in maternal piRNA contribution have little to no effect on gene expression in the heads and thorax of progeny. However, when we compare expression profiles of flies with ovaries to genetically identical flies that lack ovaries, but share the same maternal piRNA profile, we find that germline ablation results in changes in the expression of metabolic and neuronal genes in tissues distant from the germline. This indicates that the effects of germline ablation contribute more strongly to somatic gene expression than the maternal effects of piRNA. Interestingly, we do not find significant differential gene expression of genetically and epigenetically identical males with and without testes. This indicates that maintenance of male sex organs in *D. virilis* has little consequence on gene expression of somatic tissues outside of the abdomen.

D1478A Development and optimization of light-dependent switches for spatiotemporal control of gene expression. *L. De Mena*, P. Rizk, C. A. Cruz, Y. Zhang, P. Fernandez-Funez, D. E. Rincon-Limas. University of Florida, Gainesville, FL.

Tools that enable manipulation or perturbation of gene function in a spatiotemporal manner are critical to define its contribution to normal development and disease. Unfortunately, current inducible expression systems preclude accurate spatiotemporal control of gene expression and involve steroid hormones, antibiotics, heavy metals, or heat shock, which can induce toxicity or pleiotropic effects. What if transgene expression could be rapidly activated and immediately reversed with a switch triggered by light? Here we present the generation and implementation of a new genetically encoded light-dependent expression system in animal cells based on the fast, reversible photoactivation of Phytochrome B (PhyB) from plants. Phytochromes are light activated biological switches that control plant growth and development. In response to red light, PhyB is activated and moves to the nucleus, triggering a cascade of signal transduction events. Under far-red light, it returns to the inactive state, promptly ending signaling. This system, which we have called PhotoGal4, possesses all the elements required for the formation of active phytochromes in animal cells, including genes essential for chromophore formation as well as important motifs required for transcriptional activity. Our hypothesis is that this system will serve as a high-resolution device to sculpt gene expression in Drosophila with agile on-off control and with unprecedented precision and resolution. Finally, we anticipate that this system will have a variety of applications in many areas of biomedical research, from the development of new therapeutic strategies, to the analysis of complex and multi staged biological processes such as embryogenesis, neurodegeneration and cancer.

D1479B Investigating Effects of TDP-43 on Metabolic Gene Expression in a Drosophila model of Amyotrophic Lateral Sclerosis. *J. Barrows*, E. Manzo, A. Joardar, A. Coyne, D. C. Zarnescu. University of Arizona, Tucson, AZ.

Amyotrophic lateral sclerosis (ALS) is a neurodegenerative disease that primarily affects motor neurons, disrupting muscle function, which eventually leads to death by respiratory failure. TDP-43, a DNA/RNA binding protein that plays numerous roles in RNA processing, has been associated with RNA stress granule pathology in over 95% of ALS cases. TDP-43 has also been linked to dysregulation of specific mRNA targets at both the transcriptional and translational levels. Metabolomic analyses demonstrated that several metabolites in glycolysis and the TCA cycle are altered in *Drosophila* larvae expressing human TDP-43 compared to controls, suggesting that enzymes within these metabolic pathways are being affected in ALS. To confirm this hypothesis, we are using the GAL4-UAS system in *Drosophila* to express TDP-43 specifically in the motor neurons or glia. Indeed, transcriptional profiling shows that phosphofructokinase (PFK; Pfk in *Drosophila*) and glucose-6-phosphate dehydrogenase (G6PD; Zw in *Drosophila*) expression levels are altered in the context of TDP^{WT} or disease associated TDP^{G298S}. These findings are consistent with increased glycolysis and high levels of pyruvate identified using metabolomics in TDP-43 expressing flies. Current experiments are aimed at identifying additional transcriptional and translational alterations in metabolic pathways that control cellular energetics. Next, we will use genetic approaches to reduce (in the case of upregulation) or increase (in the case of downregulation) the expression levels of metabolic genes in the context of TDP-43. These experiments will determine whether restoring specific targets can rescue TDP-43 dependent phenotypes. This combination of molecular and genetic analyses will establish physiologically significant targets of TDP-43 that can be used for developing novel therapeutic strategies in the future.

D1480C Sex chromosome-wide transcriptional suppression and compensatory *cis*-regulatory evolution mediate gene expression in the *Drosophila* male germline. *Emily L. Landeen*[1], Christina A. Muirhead[1], Lori Wright[1], Colin D. Meiklejohn[2], Daven C. Presgraves[1]. 1) Univ. of Rochester, Rochester, NY; 2) Univ. of Nebraska Lincoln, Lincoln, NE.

The evolution of heteromorphic sex chromosomes has repeatedly resulted in sex chromosome-specific forms of regulation, however how the X chromosome is regulated in the *Drosophila* male germline has been unclear. In *Drosophila melanogaster* expression of transgenes driven by spermatogenesis-specific promoters show significantly lower expression on the X chromosome compared to the autosomes. The ~3-fold or greater difference in X-autosome expression is established premeiotically, suggesting that this regulatory process is distinct from canonical sex chromosome dosage compensation or meiotic sex chromosome inactivation. We use transgenes and chromosomal transpositions to compare X and autosomal expression across multiple tissues and find that both non-specific and testis-specific endogenous X-linked genes are

transcriptionally suppressed ~2-4-fold specifically in male germline cells. However, in wildtype testes, this sex-chromosome transcriptional suppression is undetectable, as it is effectively compensated by the evolution of strong promoters at X-linked genes. We identify one promoter element sequence motif, in particular, that is enriched immediately upstream of transcription start sites of testis-specific genes, evolutionary conserved across species, associated with increased expression in the testes, and overrepresented on the X. We transgenically validate that this promoter element and show via site-directed mutagenesis that it results in 2-4-fold increased expression in the testes, effectively offsetting X suppression.. Our results help clarify how the X chromosome is regulated in the *Drosophila* male germline and show that global expression of X-linked genes reflects a balance between chromosome-wide epigenetic transcriptional suppression and long-term compensatory evolution. Our results have broad implications for the evolution of gene expression in the *Drosophila* male germline and for genome evolution.

D1481A The insect specific Drosophila gene *banshee* (*bshe*; *CG8878*), a putative protein kinase, has an acid-rich region inserted within the catalytic domain. *J. Locke*, L. Canham. Univ Alberta, Edmonton, AB, CA.

Changes in chromatin structure can occur through histone modification, such as phosphorylation. Changes in chromatin structure can also be detected by mutations that suppress or enhance of the phenotypic expression of easily visible marker loci, such as *white*, as observed in Position Effect Variegation (PEV). Seven mutations in *banshee* (*bshe*, *CG8878*) were recovered in a genetic screen for dominant enhancers of PEV. The predicted amino acid sequence of BSHE suggests a protein kinase within the CK1 protein kinase family. Phylogenetic analysis of *Drosophila melanogaster* BSHE with sequences from other Dipterans, insects, and arthropods shows that BSHE represents a type of protein kinase that is insect specific, unlike the other groups within the CK1 family. The closest protein kinase sub-family to BSHE is *ballchen*, a vaccinia related kinase (VRK), which is known to modify histone proteins. BSHE is unusual in that it has an acid-rich amino acid stretch inserted within the predicted kinase catalytic domain. I-TASSER 3D structure predictions of BSHE put the insert stretch in a position that retains the catalytic site 3D structure and thus its predicted enzyme activity. The length of the insert varies among insect families with Drosophila species having the longest inserts. BSHE appears to play a role in changing chromatin structure, possibly via its kinase activity.

D1482B Investigations into the action of the CHD1 remodeler on chromatin across a transcriptionally active gene in larval salivary glands. *J. A. Armstrong*, M. A. Erb, L. Bugga, C. Kim. Claremont Colleges, Claremont, CA.

CHD1 (chromodomain, helicase, DNA-binding domain) is a conserved member of the SWI2 family of chromatin remodeling factors. While not an essential gene, *Chd1* is important for male and female fertility and wing development. CHD1 stoichiometrically co-localizes with elongating RNA Polymerase II (Pol II) on polytene chromosomes from salivary glands of third instar larvae, suggesting that CHD1 may be important to allow or facilitate the passage of Pol II through chromatin. However, CHD1 is not required for persistence of elongating Pol II on polytenes. Instead, we observed that CHD1 is important for genome-wide deposition of H3.3, a histone variant enriched at transcriptionally active genes, suggesting that CHD1 may be important for the deposition of new or recycled nucleosomes in the wake of Pol II. These findings are consistent with studies of the Chd1 remodeler in mammalian cell lines and yeast. To investigate the function of CHD1 across active genes in a metazoan, we have used both native and cross-linked chromatin immunoprecipitation (ChIP) to investigate changes in nucleosome composition across the transcriptionally active *CrebA* gene in salivary glands of third instar larvae. The use of salivary glands allows us to correlate our ChIP results with our low-resolution immuno-staining of polytene chromosomes. Consistent with prior immuno-staining results, we observe that CHD1 is enriched at *CrebA* relative to the transcriptionally inactive *white* gene, and the remodeler is not required for transcription of *CrebA* in salivary glands. Using both native and cross-linked ChIP, we investigate changes in H3/H3.3, H3K36me3, H3K56Ac and H3K9me2 across the *CrebA* gene in salivary glands lacking CHD1.

D1483C Determining how chromatin structure impacts DNA replication and cell cycle progression. *Robin L. Armstrong*, Robert J. Duronio. University of North Carolina at Chapel Hill, Chapel Hill, NC.

Temporal control of DNA replication is essential for maintenance of cellular proliferation and homeostasis, where loss of control can result in genomic instability, developmental abnormalities, and cancer. Origins of replication act in cis to establish temporal control of DNA replication through cell cycle-controlled recruitment of trans-acting factors. Metazoan studies have yet to find a consensus sequence associated with origins where, instead, origin definition is suggested to be strongly influenced by chromatin architecture, comprised of both nucleosome density and histone tail post-translational modifications (PTMs). PTMs modulate nucleosome density along a DNA molecule, establishing chromatin states that are either “open” or “closed” to protein complexes required for DNA replication.

Chromatin PTMs that contribute to heterochromatin formation and those associated with early origin firing and replication timing are being investigated to address central questions including whether specific histone PTMs are required for origin definition and replication timing, whether PTMs that define heterochromatin are required to create conditions permissive for heterochromatin replication during late S-phase, and whether specific PTMs function in cell cycle regulation. Using a *Drosophila melanogaster* histone replacement platform, we show that specific histone PTMs function in cell cycle control, regulation of DNA replication, and concentration of *trans*-acting factors.

D1484A Characterizing the role of HP1 proteins in aging. *Tandy Dolin Petrov*, Nicole Riddle. University of Alabama at Birmingham, Birmingham, AL.

Aging organisms show declines in both physical and mental abilities. Epigenetic processes, such as those that control chromatin structure, have been associated with these age-related declines. The highly conserved chromosomal proteins of the Heterochromatin Protein 1 (HP1) family have a variety of functions, including in maintenance of chromatin structure, in transcription regulation, and in DNA repair. Disruption of HP1 localization is often associated with aberrant gene transcription, which can contribute to disease. In *Drosophila melanogaster,* there are

three somatic HP1 proteins: HP1a, HP1B, and HP1C. These three proteins share a subset of binding sites despite the fact that initial reports suggest that HP1a localizes mainly to heterochromatin, HP1C localizes mainly to euchromatin, and HP1B localizes to both heterochromatin and euchromatin. Published data suggest that HP1a is redistributed during aging: while young individuals show a clear distinction between heterochromatin and euchromatin, this distinction disappears in older individuals. However, HP1a protein levels do not change with increased age. Moderate overexpression of HP1a in Drosophila increases lifespan (~23%), and under starvation conditions, flies lacking HP1B have a longer median lifespan (~24%) than control flies. These findings suggest that HP1 proteins impact longevity and health span. In order to address the roles of HP1 proteins in aging, we are investigating the HP1 distribution during aging and evaluating cognitive performance. In control, HP1a overexpressing, and Su(var)3-9 overexpressing Drosophila strains, the distribution of HP1a throughout lifespan will be determined via ChIP-seq. Using classical conditioning techniques with y-mazes, aversive and appetitive olfactory memory throughout lifespan will be assessed. HP1a overexpressing lines that show increased maximum lifespan will be tested to determine if memory is improved due to increased HP1a levels. Performance indices will be calculated from the behavior assay results, which will be analyzed via ANOVA and Chi-Square tests.

D1485B An RNA Topoisomerase Complex Interacts with RNAi Machinery to Promote Heterochromatin Formation and Transcriptional Gene-silencing. *Seung Kyu Lee*, Weiping Shen, Yutong Xue, Yongqing Zhang, Muzammil Ahmad, Yuyoung Joo, Supriyo De, Elin Lehrman, Kevin Becker, Sige Zou, Weidong Wang. National Institute on Aging / NIH, Baltimore, MD.

Topoisomerases resolve topological problems generated during DNA metabolism (Wang et al. NRMCB 2002), but the roles of topoisomerases in RNA metabolism remain unclear. Our prior study has identified human Topoisomerase 3b (Top3b) as the first RNA topoisomerase in eukaryotes (Xu et al. 2013), whereas another study has linked *Top3b* gene deletion to schizophrenia and intellectual disability (Stoll et al. 2013). Mechanistically, Top3b forms a stoichiometric complex with TDRD3 (Tudor domain containing 3); and a fraction of this complex associates with FMRP (Xu et al. 2013), an RNA-binding protein known to regulate translation of mRNAs important for synapse development and autism. FMRP is encoded by the *fmr1* gene, which is inappropriately silenced in the Fragile X mental retardation syndrome, a leading cause of autism. Using *Drosophila* as a model, we showed that *Top3b* genetically interacts with *fmr1* to promote synapse formation.

Increasing evidence has shown that *Drosophila* FMRP is a component of the RNAi-induced silencing complex (RISC), which includes AGO2, p68 helicase, and Vig. Mutations in *fmr1*, other components of RISC, as well as *Dicer-2* (*Dcr-2*; a protein essential for siRNA biogenesis), disrupt heterochromatin formation, transcriptional gene silencing, and repression of transposable elements. Here, we show that similar to FMRP, the *Drosophila* Top3b-TDRD3 complex also stably associates with RISC; and mutation of *Top3b* disrupts heterochromatin formation and transcriptional silencing in Position Effect Variegation (PEV) reporter assays. In addition, *Top3b* genetically interacts with *AGO2, p68,* and *Dcr-2* in PEV assays, indicating that Top3b works coordinately with the siRNA machinery to facilitate heterochromatic gene silencing. Moreover, an epigenetic marker of heterochromatin, H3K9me2, displayed abnormal distribution in *Top3b* mutant flies. Furthermore, microarray and RT-qPCR analyses revealed that *Top3b* mutant flies exhibit global derepression of many genes in the pericentric heterochromatin region, as well as in other regions of different chromatin states. Finally, several transposable elements are de-silenced in the *Top3b* mutant flies. Together, our data suggest that Top3b interacts with the siRNA machinery to promote heterochromatin formation and transcriptional silencing.

D1486C Comparative Genomics Analysis of *Drosophila ficusphila* heterochromatic chromosome 4 contig 5. *D. Schiller*, Paula Croonquist. Anoka Ramsey Community College, Coon Rapids, MN.

The Drosophila chromosome 4, known as the “dot chromosome” or Müller F element is predominantly heterochromatic. There is evidence however that 80 genes are actively transcribed in this region. The mechanism by which active transcription is carried out in this environment is under investigation. It is hypothesized that chromosome 4 genes share common elements in their transcriptional start sites that may explain their levels of transcription in this highly compacted environment similar to the other euchromatic autosomes. As part of the Genomics Education Partnership (GEP) undergraduate research initiative, the goal of this study was to annotate all features in Contig 5 of *Drosophila ficusphila* chromosome 4 utilizing a comparative genomics approach and several bioinformatics tools including the Basic Local Alignment Search Tool (BLAST), the UCSC Genome Browser, and gene predictors such as GENSCAN and N-SCAN, as well as RNA-Seq data and TopHat junctions. The *Drosophila melanogaster* genome was used as a reference for gene orthology. It was found that three genes, *pan, ank, and ank2*, with orthologs in *D. melanogaster* are located in contig.5. Gene models were proposed based on all gathered evidence that allowed for annotation of exact coordinates for each intron and exon of all isoforms for each gene homolog. We are currently analyzing the transcriptional start sites that may shed light on how these genes can be expressed in such a highly heterochromatic environment.

D1487A Investigating the molecular basis of dominant male sterility associated with X-autosome translocations in *D. melanogaster* using RNA-seq and cytological analyses. *J. H. Wong*, J. A. Kennison. Eunice Kennedy Shriver National Institute of Child Health and Human Development, National Institutes of Health, Bethesda, MD.

Dominant male sterility in *D. melanogaster* has been associated with approximately 75% of translocations between the sex chromosomes and autosomes. The current model for male infertility suggests condensation of the sex chromosomes directed by an element in the centric heterochromatin silences X-linked genes earlier than the autosomes during spermatogenesis. By generating a collection of X-ray-induced translocations between the autosomes and X-chromosomes, we will locate breakpoints to map the heterochromatin site responsible for X chromosome regulation and use RNA-seq to determine if there are altered expression levels of either X-linked or autosomal genes during spermatogenesis. This will allow us to test the current models for sterilizing effects involving the X-autosome translocation and to further understand the underlying factors in male infertility.

D1488B Rapidly Evolving Stonewall maintains Germline Stem Cells and regulates Transposons. *Daniel Zinshteyn*, Daniel Barbash. Cornell University, Ithaca, NY.

Germline stem cells (GSCs) are the progenitor cells for the entire population of an organism's germline. In *Drosophila*, these cells reside in a well-defined cellular niche that is required for both their maintenance (self-renewal) and differentiation (asymmetric division resulting in a daughter cell that differs from the GSC). Dozens of genes have been implicated in both maintenance and differentiation and most of them are required for production of viable gametes. The critical function of these genes suggests that they should be highly conserved across *Drosophila* taxa. However, population genetic analyses have shown that many of them have undergone adaptive evolution within the *D. melanogaster* lineage. One possible cause of this evolutionary signature is the critical role that many of these genes play in regulating genomic parasites, particularly transposons. It may be that some of these genes are locked in a dynamic arms-race with rapidly evolving selfish elements.

The stem-cell maintenance factor Stonewall (Stwl) is a particularly intriguing candidate, as it has undergone adaptive evolution and has been implicated in heterochromatin maintenance. We hypothesized that Stwl is required for regulating transposons in *D. melanogaster*. We performed RNA-seq on *stwl* mutant ovaries and testes to assay the transcript abundance of transposable elements in the absence of a functional Stwl. We find that mutant *stwl* ovaries show significant de-repression of many transposon families. Surprisingly, heterochromatic genes are not preferentially misregulated relative to euchromatic genes. These data suggest that Stwl may be required for regulation of transposons via a mechanism other than general heterochromatin maintenance. Our findings support the hypothesis that Stwl is a target of positive selection as a response to rapidly evolving TEs.

D1489C Characterization of essential domains in the BEAF-32B insulator protein. *S. V. Satya Prakash Avva*, Craig M. Hart. Louisiana State University, Baton Rouge, LA.

Like enhancers and promoters, insulators (or boundary elements) are a specialized class of regulatory DNA sequences. Insulators are defined by their ability to function in transgene assays to limit enhancer-promoter communication when placed between a promoter and an enhancer. They are also known to function as barrier elements that protect transgenes from chromosomal position effects. Two of the first insulator elements to be identified are the scs and scs' sequences which bracket two *Hsp70* genes at the *87A* locus of *Drosophila*. BEAF-32 was identified as a Boundary Element-Associated Factor of 32 kDa that binds to the scs' insulator, and was subsequently shown to immunolocalize to hundreds of sites on polytene chromosomes, suggesting that BEAF-dependent insulators are a common feature in the *Drosophila* genome. This is substantiated by genome-wide mapping experiments, which have identified from 1800 to 6000 binding regions. The *BEAF-32* gene encodes two isoforms, 32A and 32B, that differ only in their amino-terminal 80 amino acids. Both of these regions include a different atypical zinc-finger DNA binding domain. The remaining 200 amino acids are identical. BEAF-32 can form homo- and hetero- dimers, trimers and possibly also larger oligomers with varying ratios of 32A to 32B through interactions mediated by the sequences in the carboxy-end of the proteins. Yet transgene rescue experiments utilizing a lethal null *BEAF-32* mutation found that *32B* is essential, while *32A* is not. In order to understand BEAF-32 better, we have used a combination of *in vivo* and *in vitro* experiments to map essential domains in the common portion of the proteins.

D1490A Boundary elements-anchored chromatin loops may facilitate genome rearrangement. *Zhibo Ma*, Matthew Romine, Haini Cai. University of Georgia, Athens, GA.

Genomic architecture lays the physical foundation of gene regulation. Interactions between chromatin boundary elements anchor chromatin loops, which can modulate enhancer-promoter interactions and the extent of active or repressive domains. We have been using the Drosophila ftz gene region as a model to study how chromatin boundaries regulate local gene expression. In Drosophila, the ftz gene is nested within the regulatory sequences of the Scr Hox gene. We have recently shown that SF1 and SF2, two boundary elements flanking the ftz region in D. melanogaster, form a stage-specific chromatin loop. This loop insulates the ftz gene from the interference by the surrounding Hox enhancers and the PcG-mediate repression. SF1 and SF2 cancel their enhancer-blocking activity when arranged in tandem. This is an indication of their pairing in vivo, which is consistant with our 3C data, providing a mechanism for the distal Scr enhancer to bypass their blocking. The ftz gene region is highly conserved among Drosophila species. However, it is found in an inverted orientation in several Drosophila species as compared to D. melanogaster. We found that SF1 and SF2 are located immediately outside the "flipped" ftz gene region in all 12 sequenced Drosophila species. Similar boundary-flanked and inverted intervals are found at multiple locations in the Drosophila Hox complexes. We hypothesize that boundary-anchored chromatin loops facilitate genomic rearrangement and buffer the pressure of misregulation caused by these rearrangement. To test this, we have cloned SF1 and SF2 homologs from D. wilistoni and D. virilis, two species with inverted ftz. We found that all these elements contain strong enhancer-blocking activities, as assayed in transgenic D. melanogaster. Importantly, they cancel each other when arranged in tandem. This suggests that SF1 and SF2 loop with each other in D. wilistoni and D. virilis. New data to extend our preliminary findings will be discussed.

D1491B Characterization of the SCS' insulator. *M. Maharjan*, C. Hart. Louisiana State University, Baton Rouge, LO.

DNA insulator elements are thought to affect gene regulation at least in part by influencing chromatin structure and nuclear organization. Insulator function is determined by sequence-specific DNA binding proteins that bind to them. The insulator protein BEAF-32 usually binds near transcription start sites, suggesting it might play a direct role in promoter function. One example is the scs' insulator, which contains divergently transcribed promoters with a BEAF-32 binding site by each. Identifying protein partners of BEAF-32 through a detailed analysis of the scs' insulator would provide insight into the role of BEAF-32 in the insulator and promoter activity of scs'. Half of scs' retains insulator activity, and this is lost if the BEAF-32 binding site is mutated. Through a linker scanning analysis of this half of scs', we found that mutation of a

20 bp sequence decreases the insulator activity of the BEAF-32 binding site. Additional mutations are being tested to determine if other sequences also play a role. These variations are also being tested for effects on promoter activity to determine whether or not insulator and promoter activity can be separated. For instance, promoter activity is impaired if the BEAF-32 binding site or 20 bp sequence is mutated. In addition, we are using DNA affinity chromatography to purify proteins that bind to the identified sequence with the goal of identifying proteins by mass spectrometry. Characterization of minimal scs' sequences required for insulator and promoter activity, and identification of proteins that bind these sequences, will provide insight into BEAF-32 function.

Progress on this project to identify proteins that work together with BEAF-32 for proper insulator and promoter function will be presented..

D1492C The *Dm*-Myb oncoprotein coordinates higher-order chromatin structure to potentiate expression of target genes as well as stabilize facultative heterochromatin. *Juan Santana*, Mrutyunjaya Parida, Abby Long, Joshua Wankum, John Manak. Univ of Iowa, Iowa City, IA.

Myb is a proto-oncogene that when mutated causes leukemias and lymphomas in birds and mammals. Vertebrates contain three representatives of the *Myb* gene family consisting of A-, B- and c-*Myb*, all of which encode DNA-binding factors that are important for the proper expression of genes. Several studies have described Myb's primary function as a factor that upregulates transcription by binding to promoter regions, thus controlling the expression level of genes adjacent to these sequences. In flies, this regulation has been shown to be accomplished epigenetically such that *Dm*-Myb is only required after initial activation of a gene in order to potentiate this distinct transcriptional state. Here, we further characterize the potentiator role of Myb and show that its absence leads to a reduction in H3K4me3 along promoters, and RNA polymerase occupancy across gene bodies, resulting in downregulation of transcription. However, up to now, no other mechanisms have been proposed that account for the thousands of genes whose expression is altered in the absence of dMyb, including those that appear to be "repressed" by Myb, or lie a distance away from any Myb binding sites. Here we uncover a novel and critical role of Myb in demarcating and maintaining silent chromatin domains, as well as promoting intra-chromosomal interactions which can influence gene expression at sites distal from Myb binding regions. We observe that Myb demarcates and stabilizes H3K27me3 domains associated with silent genomic regions, and in its absence, these domains become reduced in length and less enriched for this chromatin mark, promoting an enrichment of H3K4me3 and subsequent derepression of the genes within these domains (including transcription factors). Notably, the genes whose expression levels change in the absence of Myb (~2,000 genes) are directly influenced or regulated by Myb, with virtually no genes showing altered expression through secondary consequences of aberrant transcription factor upregulation, thus providing strong evidence for a chromatin "buffering" effect in cells that helps prevent misprogramming. .

D1493A Don't Steer Me Wrong: Rustling for Connections Between BEAF Insulator Protein, PBAP Chromatin Remodeler and Gene Expression. *Jamie L. Wood*[1], S. V. Satya Prakash Avva[1], M. Maharjan[1], J. Keller McGowan[1], Fabiana M. Duarte[2], Jacob M. Tome[2], John T. Lis[2], Craig M. Hart[1]. 1) Louisiana State University, Baton Rouge, LA; 2) Cornell University, Ithaca, NY.

Our understanding of gene regulation has grown to include the role of chromatin in managing where and when genes are expressed. Chromatin, the organizational framework that packages DNA into the nucleus, affects the access of specific regulatory proteins to DNA sequences. As part of the regulatory structure, chromatin is divided into domains. Specific sequences of DNA called insulators, which are bound by proteins called insulator binding proteins (IBPs), assist in establishing these domains. We are interested in how the *Drosophila melanogaster* IBP Boundary Element Associated Factor (BEAF) acts within the chromatin landscape to control gene expression. Previous data shows BEAF localizes to hundreds of promoter regions within the genome, often at housekeeping genes. This may indicate a role in promoter function, a non-traditional role for an IBP. We have evidence to suggest a positive interaction of BEAF with the Polybromo-associated Brahma (PBAP) chromatin remodeling complex, specifically the Polybromo subunit. We are probing the nature of this interaction using animal and cell culture experiments to determine the effect of this association on transcription. We have tested for genetic interactions using our rough eye screen and have dissected Polybromo to determine which domains specifically interact with BEAF. We have also used the high through-put techniques PRO-seq and MNase-seq after RNAi mediated knockdowns of BEAF and Polybromo in S2 cells. Progress in analyzing the relationship between BEAF and PBAP will be presented.

D1494B Analysis of *Sex combs reduced* HOX gene cis-regulatory elements. *M. T. Cooper*, J. A. Kennison. Eunice Kennedy Shiver National Institute of Child Health and Human Development, Bethesda, MD.

The Drosophila *Hox* gene, *Sex combs reduced* (*Scr*), is required for patterning the first thoracic segment. The *Scr* transcription unit spans 35 kb, with at least 35kb of upstream cis-regulatory sequences. Transcriptional silencing of *Scr* in the second and third thoracic segments requires the Polycomb group genes. We have identified several *Scr* genomic fragments as Polycomb group response elements (PREs).

D1495C Maintenance of tissue pluripotency by epigenetic factors. *D. Huang*, D. Sadasivam. Academia Sinica, Taipei, Taiwan, TW.

Pluripotent stem cells often adopt a unique developmental program while retaining certain flexibility. The molecular basis of such properties remains unclear. Using differentiation of pluripotent *Drosophila* imaginal tissues as assays, we examined the contribution of epigenetic factors in ectopic activation of Hox genes. We found that over-expression of Trithorax H3K4 methyltransferase can induce ectopic adult appendages by selectively activating the Hox genes Ultrabithorax and Sex comb reduced in wing and leg discs, respectively. This tissue-specific inducibility correlates with the presence of paused RNA polymerase II in the promoter-proximal region of these genes. Although the *Antennapedia* promoter is paused in eye-antenna discs, it cannot be induced by Trx without a reduction in histone variants or their chaperones, suggesting additional control by the nucleosomal architecture. Lineage tracing and pulse-chase experiments revealed that the active state of Hox genes is

maintained substantially longer in mutants deficient for HIRA, a chaperone for the H3.3 variant. In addition, both HIRA and H3.3 appeared to act cooperatively with the Polycomb group of epigenetic repressors. These results support the involvement of H3.3-mediated nucleosome turnover in restoring the repressed state. We propose a regulatory framework integrating transcriptional pausing, histone modification, nucleosome architecture and turnover for cell lineage maintenance.

D1496A A genetic screen for Polycomb group mutants. *J. A. Kennison*, M. T. Cooper. NIH, Bethesda, MD.

Genetic studies first identified the Polycomb group genes by their defects in transcriptional silencing of the homeotic genes. To identify new Polycomb group genes, we have developed a transgene assay using pairing-sensitive silencing of the mini-white reporter gene caused by a Polycomb Group Response Element (PRE) from the Sex combs reduced homeotic gene. Recessive mutations that disrupt silencing are recovered in mitotic clones in heterozygous flies. We have screened about 98% of the genome and isolated mutations in most of the known Polycomb group genes. We have also isolated mutations in several new genes required for silencing. Using a combination of meiotic recombination mapping, deletion mapping, and whole genome sequencing, we have identified the transcription units corresponding to most of these new silencing genes.

D1497B The chromatin remodeling protein Kismet regulates synaptic pruning by controlling steroid hormone receptor expression. *N. K. Latcheva*[1,2], D. Melicharek[4], D. R. Marenda[1,2,3]. 1) Department of Biology, Drexel University, Philadelphia, PA; 2) Molecular Cell Biology and Genetics Department, Drexel University College of Medicine, Philadelphia, PA; 3) Department of Neurobiology and Anatomy, Drexel College of Medicine, Philadelphia, PA; 4) Fox Chace Cancer Center, Philadelphia, PA.

Epigenetics relies in large part on histone modifications and the proteins which make and recognize these modifications. Chromatin readers are a family of proteins which recognize different histone modifications and coordinate the appropriate chromatin rearrangements. A subset of chromatin readers are chromodomain containing proteins that are thought to recognize methylated histone tails, though how they influence gene expression remains largely unknown. One such chromatin reader is encoded by the *kismet* (*kis*) gene in *Drosophila melanogaster*. Decreased *kismet* function leads to defects in axonal guidance and pruning in mature neurons. The Kismet protein shares homology with the mammalian Chromodomain Helicase DNA binding (CHD) subgroup III family of proteins, including CHD7, an ATP-dependent chromatin remodeling protein. Haploinsufficiency of the *CHD7* gene leads to CHARGE syndrome, a congenital neurodevelopmental disorder that affects approximately 1 in 10,000 individuals worldwide. Here we show that axon pruning defects are present in both *kis* mutants and flies expressing RNAi mediated knockdown of *kismet*. Further, we show the pruning defects are due to a decrease in expression of the steroid hormone receptor Ecdysone Receptor isoform B1 (EcR-B1) in the mushroom body Kenyon cells. Supplementing with exogenous EcR-B1 rescues pruning defects in two *kis* mutant backgrounds. Additionally, knocking down *kismet* leads to a global decrease in H3K4me3, a histone modification associated with actively transcribed chromatin. Elucidating the mechanism of Kismet-mediated *EcR-B1* expression will provided greater insight into the epigenetic regulation of neuronal gene expression in general, and will be crucial to further the understanding of neurodevelopmental events that lead to CHARGE syndrome. .

D1498C The recognition of target gene transcriptional state by epigenetic regulators and establishment of Polycomb-group-mediated repression. *P. Ye*, E. Ghotbi Ravandi, J. AlHaj Abed, J. Benes, R. Jones. Southern Methodist University, Dallas, TX.

Polycomb group (PcG) proteins are conserved epigenetic transcriptional regulators that maintain the transcriptional repression of silenced genes. *giant* (*gt*), a PcG target gene, is a zygotic gap gene involved in the development of the head and abdominal regions in *Drosophila*. We have generated a genetic system, triple mutant embryos (*bcd osk tsl*), in which maternal *hunchback* (Hb) is expressed ubiquitously but zygotic Hb expression is absent, resulting in the ubiquitous repression of *gt* by PcG proteins. Chromatin immunoprecipitation (ChIP) experiments on these embryos is being carried out at multiple developmental stages to determine the timing and locations of binding by transcription factors, PcG proteins, and deposition of histone modifications. We have initiated studies to (a) identify the roles of individual proteins in recruitment of PcG complexes and (b) determine the mechanisms by which PcG proteins distinguish between repressed and active target genes. Progress on these studies will be presented.

D1499A Stuxnet Facilitates the Degradation of Polycomb Protein during Development. *Alan J. Zhu*, Juan Du, Junzheng Zhang, Tao He. Peking University, Beijing, CN.

Polycomb-group (PcG) proteins function to ensure correct deployment of developmental programs by epigenetically repressing target gene expression. Despite the importance, few studies have been focused on the regulation of PcG activity itself. Here, we report a novel *Drosophila* gene *stuxnet* (*stx*) that controls Pc protein stability. We find that heightened *stx* expression reduces *Pc* activity, leading to de-repression of PcG targets and homeotic transformation. Conversely, *stx* mutants display developmental defects associated with hyper-activation of *Pc*. Apart from its role on classical PcG targets, this Stx-controlled Pc activity is required for Notch signaling. Mechanistically, Stx facilitates Pc degradation in the proteasome independent of ubiquitin modification. Furthermore, this mode of regulation is conserved in vertebrates. Mouse *stx* promotes degradation of Cbx4, an orthologous Pc protein, in vertebrate cells, rescues *stx*-associated Notch defects and induces homeotic transformation in *Drosophila*. Our results highlight an evolutionarily conserved mechanism of regulated protein degradation on PcG homeostasis and epigenetic activity.

D1500B Mechanisms of epigenetic gene regulation by the Drosophila COMPASS-like complex. *C. B. Zraly*[1], M. G. Slattery[2], A. K. Dingwall[1]. 1) Loyola Univ Chicago-Stritch School of Medicine, Maywood, IL; 2) University of Minnesota Medical School, Duluth, MN.

The highly conserved COMPASS-like complexes recognize/bind specifically modified histone tails and carry out enzymatic histone modifications (methylation and demethylation of lysine residues). The complexes perform many essential functions in epigenetic gene control, including histone reader, writer and eraser functions, allowing for either gene activation or repression. The complexes are essential, with mutations in the fly and mammalian components directly linked to signaling pathway and stem cell defects, developmental and neurological disorders as well as a multitude of cancers. The COMPASS-like complexes are enriched on active, primed and poised enhancers and gene promoters to monomethylate lysine 4 of histone 3 (H3K4me1), considered the hallmark of transcriptional enhancers throughout the genome. We determined the COMPASS-like complex patterns of chromatin binding at various developmental stages in Drosophila using ChIP-seq analyses and identified potential transcription factors including nuclear receptors that collaborate with the complex in enhancer regulation. Genetic interaction studies incorporating null mutant alleles and RNAi combined with RNA-seq and gene specific ChIP analyses were used to examine effects of losing the complex on gene regulation and epigenetic modification. Our analyses revealed that the EcR hormone receptor is pre-engaged on the chromatin prior to ligand binding and that this engagement requires the stabilization by the COMPASS-like complex. Upon stimulation with hormone, the epigenetic modifications change in a precise manner representative of activation then enhancer 'closing' or poising for a subsequent round of activation, representing a form of enhancer pioneering.

D1501C The RNA paradox: can small RNA increase gene expression? *Nikita Deshpande*, Victoria Meller. Wayne State University, Detroit, MI.

Many species have dissimilar sex chromosomes. Dosage compensation is an essential process that modulatesexpression to equalize the ratio of X:A gene products in both sexes. Drosophila melanogaster achieves dosage compensation by transcribing male X-linked genes at twice the rate as females. This is accomplished by the Male Specific Lethal (MSL) complex, which binds the X, modifies chromatin and increases expression. The siRNA pathway contributes to X-localization of the MSL complex, but no RNAi components directly interact with the MSL complex. This suggests that the siRNA pathway acts through a novel and indirect mechanism. For example, an Ago2-containing complex could bind nascent RNAs from the X chromosome and recruit activities that alter epigenetic marks or chromatin architecture. This might facilitate MSL recruitment and spreading along the X-chromosome. To test this model, we used publically available databases to assemble a network of proteins that interact with Ago2. These formed the basis of a targeted screen that has identified several Ago2-interacting proteins that contribute to dosage compensation. Some of these are known to modify chromatin. I then used Chromatin ImmunoPrecipitation(ChIP) to demonstrate that members of the Ago2-interaction network maintain chromatin marks on the X chromosome. This analysis is now being extended to examine the interacting proteins themselves. This study addresses the molecular mechanism by which Ago2 contributes to X-recognition and will provide a useful model for how small RNA contributes to coordinated regulation of broad chromosomal domains in eukaryotes.

D1502A Exploring the chromatin regulation of an inner nuclear membrane Speg (CG9723). *C. Kuok*[1,2], H. Hou[1,3], R. Rosenfeld[1,2], Y. Tsatskis[2], A. Soltyk[4], T. Westwood[4], M. Wilson[1,3], H. McNeill[1,2]. 1) Department of Molecular Genetics, University of Toronto, Toronto, Canada; 2) The Lunenfeld-Tanenbaum Research Institute, Mount Sinai Hospital, Toronto, Canada; 3) Genetics and Genome Biology Program, SickKids Research Institute, Toronto, Canada; 4) Department of Biology, University of Toronto Mississauga, Mississauga, Canada.

Previously, we identified Speg (CG9723) as an inner nuclear membrane protein required for proper testis development. In *speg* mutants, flies have small testes that lack proper cyst structure and produce few late stage germ cells. To explore if *speg* functions in nuclear or chromatin organization, we examined *speg* null testes and enGal4-driven *speg* RNAi in wings with NLS-GFP. The nuclear envelope appears normal in *speg* mutants. Interestingly, heterochromatin protein 1 (HP1) is decreased in both *speg* mutant testes and wings. H3K4me3, H3K9me3, H3K27me3 and core histones are also decreased in *speg* mutant wings, suggesting a general requirement of *speg* for chromatin organization. We then performed DamID chromatin profiling in Kc cells. Bioinformatics analyses suggested that there are continuous Speg-associated domains spreading along *Drosophila* genome. The majority of Speg-associated domains are Black chromatin. Gene set enrichment analysis suggested that a subset of Speg-associated genes are significantly enriched in testis.

D1503B Regulation of metazoan DNA replication fork progression, stability and composition. *J. T. Nordman*[1], T. L. Orr-Weaver[2]. 1) Vanderbilt University, Nashville, TN; 2) Whitehead Institute; Massachusetts Institute of Technology, Cambridge, MA.

Genome duplication requires exquisite regulation to ensure accurate transmission of genetic information and to prevent chromosomal abnormalities associated with several diseases, including cancer. Further complicating the genome duplication process is the fact that replication forks, the molecular machines responsible for replication of the genome, must be able to stably navigate a dizzying array of replication impediments and chromatin subtypes that pose structural challenges to replication fork progression and stability. Very little is known, however, about how replication forks are able to facilitate progression through difficult-to-replicate regions of the genome present in all eukaryotic cells.

Purification of replication forks from distinct developmental contexts and identification of components provides a means to define plasticity at the fork, an approach for which Drosophila is ideal. In early Drosophila embryos, S phase is three to four minutes in length. Following the maternal-to-zygotic transition, S phase lengthens to approximately one hour. These rapid embryonic S phases are in contrast to the 10-12 hour S phase length in differentiated cell types. Importantly, rapid embryonic S phases of the Drosophila embryo are driven by increased numbers of replication forks per cell. We have developed an iPOND approach, coupled to quantitative mass spectrometry, to enrich and characterize

replication forks from Drosophila embryos. This methodology has identified factors that could be important for controlling replication fork progression and activity in development.

One example of how replication fork composition and activity can be modulated during development is the Suppressor of Underreplication protein, SUUR[1]. In Drosophila polyploid cells, DNA replication is repressed within specific regions of the genome, which results in chromosome fragility. SUUR mediates repression of DNA replication through direct inhibition of replication fork progression. SUUR is not always associated with replication forks, rather it is recruited to active replication forks in specific genomic regions to inhibit their progression. Given that SUUR associates with replication forks in specific developmental contexts, it provides an example of how replication fork composition and activity can be altered during development.

D1504C Evaluation of genes required for telomere maintenance on *HipHop* dependent suppression of cell lethality after telomere loss. *Christopher Hendrix*, Miriam Snider, Ashley Hanson, Daniel Beck, Rebeccah Kurzhals. Southeast Missouri State University, Cape Girardeau, MO.

The telomere cap is a complex of proteins and nucleic acids found at chromosome ends which prevents the DNA terminus from being seen as a double strand break in need of repair. HP1, HOAP, HipHop, Ver, and Moi are components of the capping complex. In most cells the absence of a single telomere cap is sufficient to trigger apoptosis. Cells that do not die are likely to experience end-to-end fusions of uncapped ends, leading to gross chromosomal rearrangements and genomic instability. The apoptotic response to telomere loss or dysfunction is mediated by the DNA damage response pathway. However, even in a wildtype background, a small fraction of such cells manage to evade this apoptotic response.

We developed a technique that allows for controlled loss of a single telomere during development. We wish to understand how some cells survive telomere loss. Immunostaining for the telomere cap component HOAP revealed that in some somatic cells, non-telomeric ends can be healed by the addition of a new cap. To characterize this process, we misexpressed genes required for telomere maintenance, while simultaneously inducing telomere loss. We found that misexpression of *HipHop*, or its paralog *ms(3)K81*, resulted in increased survival of cells that lost a telomere. However, misexpression of *cav,* the gene encoding HOAP or *Su(var)205*, the gene encoding HP1, or *ver*, did not significantly increase cell survival. We suggest that HipHop has the ability to seed formation of new telomeres in somatic tissue.

In order to determine if proteins required for telomere maintenance are limiting for HipHop to suppress of cell death after telomere loss, we misexpressed *hiphop* while simultaneously inducing telomere loss in flies that are heterozygous for mutations in *tefu, mre11*, *nbs*, and *cav.* Initial results suggest that these genes do not significantly affect cell survival following telomere loss. We are currently testing other genes required for telomere maintenance. In the absence of misexpression of *hiphop*, cell survival is not significantly different in flies that are heterozygous for mutations in *tefu*, *mre11*, *nbs*, *cav*, *hiphop,* or *Su(var)205* following telomere loss. The telomere cap components tested to date do not appear to be limiting for HipHop's role in suppressing cell lethality after telomere loss.

D1505A Tip60/HDAC balance promotes neuroprotection of cognitive function in the neurodegenerative *Drosophila* brain. *Priyalakshmi Panikker*, Felice Elefant. Drexel University, Philadelphia, PA.

Appropriate histone acetylation homeostasis is critical for neural health and function and is maintained by the antagonistic activity of histone acetlytransferase (HAT) and histone deacetylases (HDAC). Disruption of this fine tuned epigenetic balance involving reduced levels of histone acetylation in the brain causes significant cognitive deficits that are a debilitating hallmark of most neurodegenerative disorders, including Alzheimer's disease (AD). Nevertheless, the HATS that generate these neuroepigenetic marks and their mechanisms of action remain largely unclear. We recently made the exciting discovery that Tip60 is critical for cognitive processes based on its role in neural epigenetic cognition gene control and remarkably, promotes neuroprotection for multiple cognitive neural circuits impaired in the brain during early AD associated neurodegenerative progression. Our findings support a model by which Tip60 promotes neuroprotection by epigenetically reprogramming gene sets that together protect and/or promote cognitive function. To test this model, we performed a gene expression analysis screen on 15 Tip60 cognition-linked target genes that have human homologs. Notably, we found that while expression for all 15 genes was repressed in the AD associated APP neurodegenerative fly brain, expression of 10 of these genes was restored by increasing Tip60 levels in the brain. We next tested possible epigenetic-based mechanisms for Tip60 transcriptional rescue under APP neurodegenerative conditions. Recent compelling studies show reduced histone acetylation levels and enhanced repressor HDAC2 activity in a variety of AD models and in the human AD brain. Thus, we selected 5 of the Tip60 rescued cognition genes and assessed levels of histone acetylation, Tip60 and HDAC2 enrichment using ChIP analysis with Abs to Tip60, Rpd3 (HDAC2), and acetylation marks at histone H4K5,12,and 16 in fly brains expressing APP versus APP and excess Tip60 levels. We found that all histone acetylation marks were reduced in the APP neurodegenerative fly brain and restored by increasing Tip60 levels. Conversely, repressor HDAC2 binding enrichment at these 5 cognition genes was enhanced in the APP fly brain and remarkably, significantly reduced in 3 out of the 5 genes tested upon increased Tip60 levels. Together, our results support a model by which increasing Tip60 in the neurodegenerative fly brain restores Tip60 binding and acetylation levels at cognition gene loci by displacing inappropriate HDAC2 binding, thus activating Tip60 cognitive gene expression to promote neuroprotection.

D1506B Regulation and scaling of developmental time during *Drosophila* embryogenesis. *C. Amourda*[1], J. Chong[1], T. E. Saunders[1,2,3]. 1) Mechanobiology Institute, Singapore; 2) Department of Biological Sciences, NUS, Singapore; 3) IMCB, A-star, Singapore.

Embryogenesis is a precisely regulated process that requires tight coordination of events in space but also in time. Despite being exposed to both endogenous and exogenous cues, embryos reliably develop to their final shape within a predictable timeframe. Perturbations have

subsequently little effect on embryonic development; i.e. the process of embryogenesis is able to account and to correct for environmental and intra-embryo noise. Despite the observation that development happens in a highly temporally coordinated manner there is little work focusing on how embryos are temporally robust.

Here, we develop procedures to analyze temporal robustness at the whole organism level. Using *Drosophila* embryos maintained at precise temperatures, we simultaneously image up to 60 embryos from early embryogenesis until larvae hatching. We time the stage of embryogenesis by identifying developmental landmarks. Due to the large embryo number and controlled environment, our setup enables us to study intra- and inter- embryo temporal variations. We analyzed temporal variation at temperatures from 16 to 30°C and found that there exists an optimal developmental temperature (21°C) at which the temporal variation between embryos is minimal. Furthermore, we show that temporal paths are highly correlated at high (>25ºC) and low (<19ºC) temperature (*i.e.* an embryo that develops quickly at early stages is also fast developing at later stages and *vice versa*).

In accordance with previous studies, embryos develop faster at higher temperatures, though with increasing temporal variability. Whilst this observation can be explained by the faster kinetics of various processes at increasing temperature, we are now investigating whether active temporal regulators are present and coordinate tissue growth with developmental time. Coupled with microarray analysis, our setup offers the unique opportunity to discover such unknown regulators. We performed miRNA arrays and we found that 22 miRNAs are differentially regulated at varying temperature during embryogenesis. These miRNAs have a broad spectrum of action. Despite being expressed during embryogenesis their absence does not prevent hatching. Hence, they may have a subtler role, possibly ensuring coordination between developmental processes. We are currently using miRNA knockout and miRNA overexpression to further understand their role in controlling developmental time.

Our work represents the first quantitative analysis of temporal variation in embryogenesis and the setup we have developed enables us to explore if – and if so, how – time is effectively regulated during embryogenesis.

D1507C RNA helicase Belle/DDX3 regulates transgene expression in Drosophila. *YC Huang*, PK Lo, WM Deng. Florida State Univ, Tallahassee, FL.

Belle (Bel), the Drosophila homolog of the yeast DEAD-box RNA helicase DED1 and human DDX3, has been shown to be required for oogenesis and female fertility. Here we report a novel role of Bel in regulating the expression of transgenes. Abrogation of Bel by mutations or RNAi induces silencing of a variety of P-element-derived transgenes. This silencing effect depends on downregulation of their RNA levels. Our genetic studies have revealed that the RNA helicase Spindle-E (Spn-E), a nuage RNA helicase that plays a crucial role in regulating RNA processing and PIWI-interacting RNA (piRNA) biogenesis in germline cells, is required for loss-of-bel-induced transgene silencing. Conversely, Bel abrogation alleviates the nuage-protein mislocalization phenotype in spn-E mutants, suggesting a competitive relationship between these two RNA helicases. Additionally, disruption of the chromatin remodeling factor Mod(mdg4) or the microRNA biogenesis enzyme Dicer-1 (Dcr-1) also alleviates the transgene-silencing phenotypes in bel mutants, suggesting the involvement of chromatin remodeling and microRNA biogenesis in loss-of-bel-induced transgene silencing. Finally we show that genetic inhibition of Bel function leads to de novo generation of piRNAs from the transgene region inserted in the genome, suggesting a potential piRNA-dependent mechanism that may mediate transgene silencing as Bel function is inhibited.

D1508A The activation of new *lawc* transcripts after the homologous long double-stranded RNA treatment in *Drosophila.* *O. Simonova*, R. Cherezov, J. Vorontsova, I. Mertsalov, D. Kulikova. Koltzov Institute of Developmental Biology, Moscow, RU.

The increasing of gene expression by small RNAs and long non-coding RNAs homologous to promoter or 3'-UTR gene region (RNA activation, RNAa) is opposite to phenomenon of RNA-interference (RNAi). Being opened in the human cell culture (Li et al., 2006) RNAa is considered to be an evolutionary conserved, but in ***Drosophila*** it has not been yet described although it is one of the most convenient model organism to study. Early we have discovered that long double stranded RNAs homologous to ***leg-arista-wing complex*** (***lawc***) gene Open Reading Frame caused activation of ***lawc*** gene expression in ***Drosophila melanogaster*** (Cherezov et al., 2013). Now we confirmed our finding in ***Drosophila*** Schneider 2 (S2) cell culture. We have cloned activated ***lawc*** RNAs and its subsequent analysis revealed that the activated RNAs were new long non-coding ***lawc*** transcripts. The mechanism of new ***lawc*** transcripts activation remained unclear but we proposed that in normal conditions its expression could be suppressed by a new set of microRNAs previously unstudied (Schertel et al., 2012).

D1509B Clueless is a ribonucleoprotein that binds the ribosome at the mitochondrial outer membrane. *R. T. Cox*, A. Sen. Uniformed Services University, Bethesda, MD.

Mitochondrial function is critical for cells. These organelles are central for many cellular functions, including synthesizing ATP, steroid biosynthesis, fatty acid beta-oxidation and apoptosis. Drosophila mitochondria contain their own DNA, mtDNA, that encodes the same suite of products as human mtDNA. However, the vast majority of proteins used in the many biochemical pathways carried out by mitochondria are encoded in the nucleus and must be imported. Since respiration is a source of reactive species that can cause mtDNA damage, it is important for the cell to be able to maintain mitochondrial quality control. Because loss of mitochondrial function gives rise to specific mitochondrial diseases as well as is common in neurodegenerative disease, we are identifying proteins responsible for supporting mitochondrial function.

Towards this end, we have characterized the protein Clueless (Clu). Clu is a large, multi-domain protein that is highly conserved. We showed loss of Clu causes a drop in ATP, increased oxidative stress, short life lifespans, mislocalized mitochondria and sterility. Clu peripherally associates with mitochondria because it can form a complex with the Translocase of the Outer Mitochondrial membrane (TOM) 20, as well as Porin. In addition, we showed that Clu genetically and physically interacts with the PINK1-Parkin quality control mitophagy complex. These

associations place Clu at the mitochondrial outer membrane and indicate that Clu's affect on mitochondria is direct. Recently, we have found that Drosophila Clu is a ribonucleoprotein that binds mRNA, and that the tetratricopeptide repeat domain is largely responsible for this. In addition, Clu is able to bind both large and small ribosomal proteins, and does so at the mitochondrial outer membrane. Mitochondrial protein import can occur either post- or co-translationally, however the mechanisms controlling co-translational import have not been well characterized. Our data support a model by which Clu binds mRNAs, the ribosome, and the outer membrane translocase to facilitate co-translational import, which we are now testing.

How would Clu's roles in protein import and mitochondrial quality control work together? We propose that Clu functions in protein import when mitochondria are healthy, but when the organelle is stressed and import no longer occurs, Clu contributes to PINK1-Park induced mitophagy in order to cull damaged mitochondria. By mediating both pathways, Clu may act as a sensor for mitochondrial quality.

D1510C Investigating a link between methyl-6 adenosine RNA and the dNab2 RNA binding protein in *Drosophila melanogaster*. *B. Jalloh*[1], R. Bienkoski[1], C. Rounds[1], C. Pak[2], S. Kelly[3], A. Corbett[1], K. Moberg[1]. 1) Emory University, Atlanta, GA; 2) Stanford University, CA, USA; 3) College of Wooster, OH, USA.

Intellectual disability is the most common developmental disorder, with an estimated worldwide prevalence of 1%. Although in many cases the causes of intellectual disability are complex, a number of types of intellectual disability are caused by mutations in a single gene. Loss of the *ZC3H14* gene, which encodes an evolutionarily conserved polyadenosine RNA binding protein, leads to a form of inherited autosomal recessive intellectual disability. Loss of the fly ZC3H14 ortholog, dNab2, within *Drosophila* neurons impairs behavior, short-term memory, and alters patterns of axon guidance in the brain. Intriguingly, these brains exhibit longer poly (A) tails and increased levels of m^6A (methylation of position-6 in the RNA base adenosine) expression as compared to control flies. The m^6A mark is an abundant and reversible RNA modification linked to post-transcriptional gene regulation of mRNA with poorly understood biological relevance. Biochemical data suggest that ZC3H14/dNab2 may interact physically with a metabolic enzyme known to deaminate adenosine monophosphate (AMP), leading to the hypothesis that this enzyme could act on m^6A in RNA as well. Our preliminary data reveal strong genetic interactions between dNab2 and the AMP deaminase in a retinal model (GMR-dNab2). These preliminary studies will be followed-up with biochemical and genetic experiments to test the hypothesis that dNab2 controls m^6A levels and expression of specific neuronal target RNAs by interacting with an AMP deaminase. These experiments could provide novel insight into how loss of ZC3H14 impairs brain function.

D1511A Investigating a link between methyl-6 adenosine RNA and the dNab2 RNA binding protein in *Drosophila melanogaster*. *B. Jalloh*[1], R. Bienkoski[1], C. Rounds[1], C. Pak[2], S. Kelly[3], A. Corbett[1], K. Moberg[1]. 1) Emory Universit, GA, USA; 2) Sanford University, CA, USA; 3) Wooster, OH, USA.

Intellectual disability is the most common developmental disorder, with an estimated worldwide prevalence of 1%. Although in many cases the causes of intellectual disability are complex, a number of types of intellectual disability are caused by mutations in a single gene. Loss of the *ZC3H14* gene, which encodes an evolutionarily conserved polyadenosine RNA binding protein, leads to a form of inherited autosomal recessive intellectual disability. Loss of the fly ZC3H14 ortholog, dNab2, within *Drosophila* neurons impairs behavior, short-term memory, and alters patterns of axon guidance in the brain. These experiments could provide novel insight into how loss of ZC3H14 impairs brain function.

D1512B The level of nuclear 80S ribosomes increases during cell stress. *A. S. Abdullahi*[1,2], S. Brogna[2]. 1) Umaru Musa Yar'adua University Katsina, Katsina, NG; 2) University of Birmingham, Edgbaston, Uk.

A hallmark of translation initiation is joining of the small and large ribosomal subunits on the mRNA. Although the 40S and 60S subunits are synthesized and assembled in the nucleolus in eukaryotes, it is believed that there are mechanisms that kept them inactive, preventing 80S assembly and translation in the nucleus. The consensus is that translation occurs only in the cytoplasm. Contrary to this view, we have recently reported that translating 80S ribosomes are also present in the nucleolus and other nuclear sites in *Drosophila* (1). By employing our 80S reporter technique coupled to flow cytometer analysis of *Drosophila cells*, we have observed that nuclear 80S are most apparent during S phase. Furthermore, increased levels of nuclear 80S were observed upon serum starvation and other forms of cellular stress. Our observations suggest a role for nuclear translation during cellular stress.

1: Al-Jubran et al. Visualization of the joining of ribosomal subunits reveals the presence of 80S ribosomes in the nucleus. RNA. 2013.

D1513C Tet and epitranscriptomics in Drosophila. *F. Wang*[1], B. Delatte[2], S. Minakhina[1], F. Fuks[2], R. Steward[1]. 1) Waksman Institute, Piscataway, NJ; 2) Université Libre de Bruxelles, Brussels, Belgium.

The three vertebrate TET genes encode 5-methylcytosine (5mC) hydroxylases that catalyze the transition of 5mC to 5hmC, resulting in the elimination of the methyl mark on DNA. DNA methylation in Drosophila is controversial and recent genome-wide bisulfide sequencing did not uncover any methylated cytosine. However, Drosophila has one essential TET homolog that modifies RNA. We show that

hydroxymethylcytosine preferentially marks polyadenylated RNAs and is deposited by Tet in Drosophila. The transcriptome-wide hydroxymethylation landscape revealed hydroxymethylcytosine on transcripts of many genes expressed during neuron development. Tet and hydroxymethylated Cytosine mRNAs 5hmrC are most abundant in the larval brain, and Tet-deficient larvae have impaired locomotion behavior and brain development, accompanied by decreased RNA hydroxymethylation. This study highlights the distribution, localization, and function of cytosine hydroxymethylation and identifies central roles for this modification in Drosophila. Our findings open new research prospects in an emerging realm of biological regulation: epitranscriptomics.

D1514A The m^{6}A RNA modification controls neurogenesis and sex determination in *Drosophila* via its nuclear reader protein YT521-B. *T. Lence*[1], Junaid Akhtar[1], Marc Bayer[1], Katharina Schmid[2], Laura Spindler[3], Cheuk Hei Ho[4], Nastasja Kreim[1], Miguel A. Andrade-Navarro[1], Burkhard Poeck[3], Mark Helm[2], Jean-Yves Roignant[1]. 1) Institute of Molecular Biology, Mainz, DE; 2) Institute of Pharmacy and Biochemistry, Johannes Gutenberg University of Mainz, 55128 Mainz, Germany; 3) Institute of Zoology III (Neurobiology), Johannes Gutenberg University of Mainz, 55128 Mainz, Germany; 4) Kimmel Center for Biology and Medicine of the Skirball Institute, NYU School of Medicine, Department of Cell Biology, 540 First Avenue, New York, NY 10016.

N^6-methyladenosine RNA (m^{6}A) is the most abundant mRNA modification in vertebrates. While its functions in the regulation of posttranscriptional gene expression are beginning to be unveiled, precise roles of m^{6}A during development of complex organisms remain unclear. Here we carry out a comprehensive molecular and physiological characterization of the individual component of the m^{6}A methyltransferase complex as well as of the YTH reader proteins in *Drosophila melanogaster.* Components of the complex are ubiquitously expressed but show significant enrichment in the nervous system, which is consistent with the high level of m^{6}A in this tissue. Transcriptome wide m^{6}A profiling reveals that the modification is conserved, yet some unique features distinguish *Drosophila* from vertebrates. Surprisingly, mutant flies for the catalytic subunits are viable, but suffer from severe locomotion defects due to impaired neuronal functions, demonstrating the essential importance of m^{6}A in the *Drosophila* nervous system. Components of the m^{6}A methyltransferase complex also control the female-specific splicing of *Sex lethal* (*Sxl*) transcript and of its downstream targets, revealing a role for this modification in sex determination and dosage compensation. Remarkably, knock out (KO) of the nuclear m^{6}A reader YT521-B resembles the loss of the catalytic subunits, implicating this protein as a main effector of m^{6}A functions *in vivo*. Lastly, a screen to identify novel m^{6}A players revealed few conserved candidates that regulate m^{6}A levels and m^{6}A-dependent RNA processing, suggesting their role as *bona fide* components of the methyltransferase complex. Altogether, our study substantially extends our knowledge on m^{6}A biology, revealing the existence of novel components of the complex and demonstrating the crucial roles for this RNA modification in fundamental processes within the context of the whole animal.

D1515B Regulated epithelial microenvironment chip for whole organ studies in *Drosophila*. *C. Narciso*, N. Contento, T. Storey, D. Hoelzle, J. Zartman. University of Notre Dame, Notre Dame, IN.

The genetic mechanisms that lead to the precise size and pattering of tissues is an important question that has long fascinated researchers. Although the roles of many chemical signaling pathways have been elucidated, much work remains to understand the overall systems-level network that defines how basic cellular logic is determined as a result of both chemical and environmental factors in a tissue. More specifically, the impact of exogenous forces, such as mechanical compression, on the regulation of these genetic mechanisms to effect basic cellular processes such as proliferation and apoptosis remains unresolved. Although the mechanisms of regulation are unknown, mounting experimental evidence has increasingly implicated mechanical forces in the regulation of cell cycle and cell survival. However, probing these relationships experimentally remains problematic, owing to the unique challenges involved in mechanically manipulating tissues both *in* and *ex vivo*. Here we describe the fabrication and implementation of a scalable microfluidic culture chip (the **R**egulated **E**pithelial **M**icroenvironment **Chip**) for studying the impact of exogenous forces on development and gene expression in the *Drosophila* wing imaginal disc. The device consists of individually addressable culture chambers. Each chamber allows control over the chemical perfusion of culture media, in addition to the precise application of compressive forces exerted on the disc via a pneumatically operated membrane on the chamber's ceiling. Our results demonstrate that Ca^{2+} signaling is inhibited during mechanical compression, but once compression is removed a Ca^{2+} wave cascades throughout the disc. This response is dependent on the presence of specific serum conditions indicating synergy between chemical and mechanical factors. The observed wave is also qualitatively similar to observed waves of Ca^{2+} *in vivo* that are likely the result of larval motion. A quantitative understanding of how genetic and environmental factors interact is essential to decoding how basic cellular processes are dynamically regulated and can lead to cessation of growth and homeostasis.

D1516C Persistence of RNAi-mediated knockdown in *Drosophila* complicates mosaic analysis yet enables highly sensitive lineage tracing. *J. A. Bosch*, T. S. Sumabat, I. K. Hariharan. University of California - Berkeley.

RNA interference (RNAi) has emerged as a powerful way of reducing gene function in *Drosophila melanogaster* tissues. By expressing synthetic short hairpin RNAs (shRNAs) using the Gal4/UAS system, knockdown is efficiently achieved in specific tissues or in clones of marked cells. Here we show that knockdown by shRNAs is so potent and persistent that even transient exposure of cells to shRNAs can reduce gene function in their descendants. When using the FLP-out Gal4 method, in some instances we observed unmarked "shadow RNAi" clones adjacent to Gal4-expressing clones, which may have resulted from brief Gal4 expression following recombination but prior to cell division. Similarly, Gal4 driver lines with dynamic expression patterns can generate shadow RNAi cells after their activity has ceased in those cells. Importantly, these effects can lead to erroneous conclusions regarding the cell autonomy of knockdown phenotypes. We have investigated the basis of this phenomenon and suggested experimental designs for eliminating ambiguities in interpretation. We have also exploited the persistence of shRNA-mediated knockdown to design a sensitive lineage-tracing method, i-TRACE, which is capable of detecting even low levels of past

reporter expression. Using i-TRACE, we demonstrate transient infidelities in the expression of some cell-identity markers near compartment boundaries in the wing imaginal disc.

D1517A A *Drosophila* RNAi library modulates Hippo pathway-dependent tissue growth. *J. H. A. Vissers*[1,2], S. A. Manning[1,3], A. Kulkarni[1,2], K. F. Harvey[1,2,3]. 1) Peter MacCallum Cancer Centre, East Melbourne, Melbourne, Victoria, AU; 2) Sir Peter MacCallum Department of Oncology, University of Melbourne, Parkville, Melbourne, Victoria, AU; 3) Department of Pathology, University of Melbourne, Parkville, Melbourne, Victoria, Australia.

Libraries of transgenic *Drosophila melanogaster* carrying RNA interference (RNAi) constructs have been used extensively to perform large-scale functional genetic screens *in vivo*. For example, RNAi screens have facilitated the discovery of multiple components of the Hippo pathway, an evolutionarily conserved growth-regulatory network. Here we investigate an important technical limitation with the widely used VDRC KK RNAi collection. We find that approximately 25% of VDRC KK RNAi lines cause false-positive enhancement of the Hippo pathway, owing to ectopic expression of the Tiptop transcription factor. Of relevance to the broader *Drosophila* community, ectopic *tiptop (tio)* expression can also cause organ malformations and mask phenotypes such as organ overgrowth. To enhance the use of the VDRC KK RNAi library, we have generated a *D. melanogaster* strain that will allow researchers to test, in a single cross, whether their genetic screen of interest will be affected by ectopic *tio* expression.

D1518B Hemophilia, direct diagnosis in Cuba suporting genetic counseling. *N. González*[1], M. Ramírez[2], Y. Cordero[2]. 1) Ramón González Coro hospital, Havana, Havana, CU; 2) National Center of Medical Genetics, Havana, Havana, CU.

Hemophilia A (HA) is an inherited bleeding disorder linked to the X chromosome caused by mutations in the gene for clotting factor VIII. Prenatal diagnosis in female carriers from families with hemophilia is vital to reduce the incidence of the disease. The main objective of our work is to describe the characteristics of a family with HA in which it was impossible to know the phase linkage and genetic counseling in the prenatal stage was conducted empirically. Subsequently, it could make a direct diagnosis confirmed the hypothesis for the advice and validated the decisions made by the couple together specialists.

D1519C Efficient targeted editing of genes with a modified Crispr/Cas9 strategy. *D. Li-Kroeger*[1,3], Y. He[3,4], H. Bellen[1,2,3,4]. 1) Department of Molecular and Human Genetics, Baylor College of Medicine, Houston, TX; 2) Department of Neuroscience, Baylor College of Medicine, Houston, TX; 3) Neurological Research Institute, Houston, Texas; 4) HHMI, Baylor College of Medicine.

Here we present a Knock-in/Knock out approach to Crispr/Cas9 gene editing in *Drosophila* that allows simple dominant marker-based screening to delete DNA regions of interest. The insert cassette is engineered to allow precise and efficient replacement of the deleted segment with any DNA, allowing scarless swapping of engineered sequences for downstream applications. We created a modular toolkit for tagging any gene. We demonstrate the utility of these tools by creating dominantly marked loss-of-function alleles of several genes including the neuronal maintenance factor Nicotinamide Adenylyl Transferase (Nmnat). We then show using the Nmnat allele that we can efficiently swap the inserted cassette by creating Nmnat:GFP:Nmnat fusion proteins with either wild-type or mutated sequences. We find using multiple replicates of injection that greater than fifteen percent of vials from injected (G0) larvae contain Knock-in genes with seamless cassette swapping. In summary, we have created a toolkit and supporting reagents that allow genomic editing in *Drosophila* and permits scarless modification of regions of interest for downstream applications.

D1520A Curation of transcript models with all available public sequencing reads. *ZX Chen*, B. Busby, J. Fear, H. Yang, B. Oliver. National Institute of Health, Bethesda, MD.

A complete reference genome and accurate gene annotations are essential for all genetics and genomics research. The Berkeley *Drosophila*Genome Project (BDGP) release 6 of *D. melanogaster* genome has significantly improved completeness of the genome, especially for the Y chromosome and other heterochromatic regions. However, the current annotations were lifted over from release 5 and remain incomplete. To address this issue, we are taking a deeply data-driven approach to update the gene annotations. Here we use 13,020 runs of publically available RNA-seq data, with a total of 186 billion reads or 17 terabases from Sequence Read Archive (SRA) to re-construct gene models. Furthermore, we extracted associated metadata from SRA, Biosample, Gene Expression Omnibus (GEO), and publications to annotate each sample with tissue, sex, stage, genotype, cell-type and sample-type information. The samples come from a variety of tissues (whole organism [5,158], head [4,859], ovary [1,023], brain [121], testis [69]), stages (adult [8,896], embryo [2,422], larva [973], pupa [243]) and cell type (mix [10,889], S2 [1,122], Kc167 [150], OSC [118], neuroblast [57]). With a study of this scale we need to not only assess the quality of the individual samples, but also verify associated metadata. We subjected each of these datasets to a strict set of quality control metrics. First, all samples were mapped to the *D. melanogaster* BDGP release 6 genome with HISAT2. Alignments were used to measure strandedness, mappability, 5' or 3' bias, RNA integrity and gene expression abundance. For gene model annotation we selected only stranded libraries, for a total of 47 billion mapped reads. This dataset shows an expanded signal to noise ratio compared to single datasets such as modENCODE, that allows for better distinctions between intronic and exonic segments of gene models and provides clearer splicing evidence. Current FlyBase annotations are very good with only 13% of stranded SRA runs having more than 5% uniquely mapped reads in intergenic regions. However, there are still cases of unannotated genes, UTR extensions, novel splicing events, and antisense transcripts. For example, we found extended 5' UTR of the protein-coding gene *cut (ct)*, and an unannotated antisense transcript in 5' region of another protein-coding

gene *bazooka (baz)*. These results indicate that published sequencing data are rich resources for the curation of transcript models that will validate many of the outstanding current transcript models and add to the transcriptional complexity of the annotation.

D1521B Highly contiguous de novo genome assembly of a non-model metazoan using PacBio long reads. *Patrick F. Reilly*, Julie Z. Peng, Peter Andolfatto. Princeton University, PRINCETON, NJ.

Background: With the advent of population and comparative genomics research in non-model organisms, a highly contiguous and accurate reference genome has become paramount in assuring the validity of conclusions from such genome-wide analyses. In the last two years, the references assemblies of two model eukaryotes have been significantly revised using PacBio long read sequencing technology (*Saccharomyces cerevisiae* and *Drosophila melanogaster*). Here we extend these methods to a non-model Drosophilid, *D. yakuba*, in order to assess the practicality of PacBio long read assemblies for non-model metazoans, with the particular aims of rectifying previously characterized misassemblies, and producing a whole chromosome arm genome assembly for an insect genome within a reasonable budget.

Methods: We obtained ~100x of long reads from 20 SMRT cells, performed de novo assembly of the PacBio long reads using Celera Assembler and FALCON, meta-assembled these assemblies, and re-incorporated read information thrown out by the assemblers. Using an existing linkage map, we scaffolded the contigs into full chromosome arms.

Results: We generated meta-assembled contigs with an N50 of 12.2 Mb, three of which spanned at least 90% of a chromosome arm. Minimal scaffolding was necessary to generate chromosome arms (on the order of tens of contig joins across the genome). The contigs also corroborated evidence of and fixed two major (5 Mb and 3 Mb) misassemblies in the existing *D. yakuba* reference genome.

Significance: We have shown that PacBio-only assembly can generate a highly accurate whole chromosome arm genome sequence for non-model metazoans, a necessary prerequisite for reliable genomics analyses.

D1522C Library preparation effects on estimating satellite DNA abundance from short-read sequencing. *Sarah E. Sander*, Kevin H.-C. Wei, Andrew G. Clark, Daniel A. Barbash. Cornell University, Ithaca, NY.

Tandem repetitive DNA, also known as satellite DNA, is a major component of most eukaryotic genomes, including Drosophila and humans. Satellite DNAs can exist as selfish genomic parasites that propagate in the genome at the expense of the host, but can also form essential chromosome structures including centromeres, telomeres, and sub-telomeric regions. Despite these roles in chromosome structure, satellite DNA sequences differ widely in sequence, location, and abundance in the genome, even between closely related species. There is a basic molecular and theoretical understanding of how repetitive DNA can expand or contract within a genome. However, few studies test these models using genome-wide data, because the repetitive part of the genome is difficult to sequence accurately and to quantify with current technology.

Here we describe the effects of using newly developed PCR-free library preparation methods on the assessment of satellite DNA abundance from Illumina sequencing reads. We performed Illumina sequencing on replicate libraries constructed with PCR-free, 8 cycle PCR, and 12 cycle PCR methods from a single DNA extraction. We quantify satellite abundance from raw sequencing reads using our kmer-based algorithm, k-Seek. We then compare satellite abundances across library preparations using correlations, principal components analysis (PCA), and discriminant analysis of principal components (DAPC). We find that the different preparation methods produce libraries that are distinctly different from one another and that much of the differences between libraries are driven by satellite sequences that are underrepresented in conventional PCR-based library preps, such as the highly abundant AATAT satellite. These satellites are much better represented in sequencing reads derived from PCR-free libraries. Despite the PCR-induced bias, which skews absolute abundances, the bias appears to be quantitatively stable, so that contrasts across lines whose libraries are all constructed in the same way can still be reliable. Nevertheless, PCR-free methods are clearly preferred if there is interest in quantitative assessment of repeat composition.

D1523A Highly sensitive measurement of poly(A) tail by TAIL-seq2 reveals dynamic gene regulation via cytoplasmic polyadenylation during oogenesis. *Ahyeon Son*[1,2], Jaechul Lim[1,2], Mihye Lee[1,2], Hyeshik Chang[1,2], V. Narry Kim[1,2]. 1) Center for RNA Research, Institute for Basic Science, Seoul, KR; 2) School of Biological Sciences, Seoul National University, Seoul, KR.

The tail of eukaryotic mRNA is subject to intensive modifications and critically influences mRNA stability and translatability. To investigate RNA tails at the genomic scale, we previously developed a method called TAIL-seq, but its low sensitivity precluded its applications to minute amounts of biological materials. In this study, we present a new version of TAIL-seq (TAIL-seq2) by incorporating splint ligation, which strongly enhances the sequencing depth for mRNAs (~1000 fold compared to that of the previous version). The improved method enabled us to investigate the regulation of poly(A) tail in oocytes and embryos. We discover that the cytoplasmic polyadenylation takes place mainly during late oogenesis in Drosophila, prior to fertilization. Mutation of wispy, a noncanonical poly(A) polymerase, abolishes polyadenylation, indicating that Wispy is likely to be the major, if not the sole, poly(A) polymerase in oocytes. Only ~5% of maternal transcripts (~143 genes) escape from cytoplasmic polyadenylation. By comparing with ribosome profiling data, we further find that mRNAs with elongated poly(A) tail become translationally active upon egg activation. Thus, the dynamic control of poly(A) tail in maturing oocytes pre-shapes the translatomic landscape of initiating embryos.

D1524B Improving Genome Annotation across the Drosophila Clade. *T. D. Murphy*, the Eukaryotic Genome Annotation Team. NCBI/NLM/NIH, Bethesda, MD.

Comparative genomics research in the Drosophila clade has advanced considerably in the last decade with the availability of dozens of whole genome assemblies for various Drosophila species. However, many of these genomes have either old annotations that pre-date the use of RNA-seq evidence, or are from different pipelines that may complicate their use in cross-species analyses. The NCBI Eukaryotic Genome Annotation Pipeline (www.ncbi.nlm.nih.gov/genome/annotation_euk/) has been used to annotate over 300 organisms, ranging from Insects to Plants and Mammals. The pipeline generates alignment evidence including RNA-seq and cross-species protein alignments to predict gene models with Gnomon, an alignment- and HMM-based gene prediction program developed at NCBI. The pipeline also includes robust tracking logic to preserve gene, transcript, and protein identifiers with an annotation update, even with an update in the assembly.

We have used this pipeline to re-annotate many species in the Drosophila clade. In collaboration with FlyBase, these annotations have been used to update eight of the reference Drosophila annotations. This poster will discuss details of NCBI's pipeline, summarize details of the new annotation sets, and provide details on NCBI's future plans for providing annotations of other Drosophila assemblies currently available in GenBank. Some details of this presentation will also be covered in an NCBI workshop on the Saturday morning session.

D1525C Ilastik- and Matlab-based computational tools to analyze biological tubes in 3-D. *Ran Yang*, Eric Li, Madhav Mani, Greg J. Beitel. Northwestern University, Evanston, IL.

The architecture of biological tubes must be tightly regulated for an organism's survival. Understanding the mechanisms of tube size control requires the ability to quantify many aspects of tube structure such as tube length and diameter and cell shape. Our objective was to develop computational tools that could robustly measure differences in morphology of the Drosophila trachea, using open source and generally accessible software. Although programs to measure planar epithelia exist, few are able to process the more complex problem of a 3-D tube and measure cells on a highly curved surface. We acquired confocal images of the tracheal dorsal trunk and segmented the apical surface and overlying cells using Ilastik, an open source image analysis tool funded by the HHMI and Heidelberg Collaboratory for Image Processing. The segmentation data were imported to Matlab, where we used a marching cubes algorithm to create a tube skeleton, automatically detected branches, and mapped apical cell outlines on the tube surface. From this data, many features of interest can be calculated. Those that we focused on include tube length, luminal volume, cross-sectional regularity, and cell size and orientation relative to the local trunk axis. We are still optimizing and validating our code, but preliminary analysis of *src42A*$^{26\text{-}1}$ mutants, which have tube length defects and increased variation in cell orientation, produced results comparable to the previous studies done by Nelson et al. (2012) and Förster and Luschnig (2012). The major cell axes of *src42A*$^{26\text{-}1}$ mutants tend to be orthogonal to the tube axis, resulting in shorter dorsal trunks.

D1526A *REDfly*: The Regulatory Element Database for *Drosophila*. *M. S. Halfon*[1,2,3], M. Zia[1,2], S. M. Gallo[1,2]. 1) University at Buffalo, Buffalo, NY; 2) New York State Center of Excellence in Bioinformatics & Life Sciences, Buffalo, NY; 3) Roswell Park Cancer Institute, Buffalo, NY.

The REDfly database is a curated portal for *Drosophila cis*-regulatory data containing records for empirically validated *cis*-regulatory modules (CRMs, "enhancers") and transcription factor binding sites (TFBSs) reported in the published literature. REDfly's goal is to include all functionally tested sequences regardless of whether they have observable regulatory activity or have activity redundant with other, shorter regulatory sequences. Graphical views show the position of each CRM within its genomic locus, and the location of each CRM with respect to its associated gene is provided. Curation of TFBSs includes sites identified by electrophoretic mobility shift assay (EMSA, "gel shift"), DNAase I footprinting, and high-throughput yeast one-hybrid assays. REDfly currently covers more than 680 publications and contains more than 11,600 records of reporter constructs regulating over 550 genes, including over 5600 "minimal" CRMs, as well as over 2000 TFBSs. Extensive abilities exist for database searching and results filtering. In 2015 we released REDfly v4 including updates to release 6 genome coordinates, an option to download sequences in BED format, and numerous behind-the-scenes improvements. REDfly v5.0 was released in Spring 2016 with fully updated genome annotations and anatomical descriptions. Search has been updated to optionally retrieve all annotated CRMs within a user-defined distance of a locus, not just CRMs explicitly associated with a specific gene. Additional improvements scheduled for release in 2016 include further improved search and download capabilities, addition of ChIP-derived TFBSs, predicted CRMs, integration with Galaxy, and substantial new curation. REDfly provides a comprehensive source of *Drosophila cis*-regulatory data and is a powerful platform to facilitate high-throughput experimental and computational studies of gene regulation. REDfly is freely accessible at http://redfly.ccr.buffalo.edu and can be followed on Twitter at @REDfly_database.

D1527B DRSC Informatics Tools for Functional Genomics Studies, 2016 Update. *Claire Hu*, Arunachalam Vinayagam, Ankita Nand, Aram Comjean, Benjamin Housden, Ian Flockhart, Charles Roesel, Lizabeth Perkins, Norbert Perrimon, Stephanie Mohr. Harvard Medical School, Boston, MA.

A set of online informatics tools has been developed at *Drosophila* RNAi Screening Center (DRSC) to help scientists identify genes, select RNAi reagents, analyze high-throughput datasets and validate results. Here, we present recent updates to existing tools and new tools. DIOPT (flyrnai.org/diopt) was developed for query of predicted orthologs among common model systems by integrating 10 ortholog prediction approaches. We added Rat recently beside the 8 species we previously support. Our CRISPR sgRNA tools include a resource of pre-computed *Drosophila* sgRNA designs viewed in a genome browse context, as well as annotation of potential off-target locations and predicted efficiency. We recently added a Frameshift score, which predicts the likelihood of a frameshift mutation when repairing a CRISPR cut.

We launched three new resources. 1.) GLAD is a resource of high quality lists of functionally related *Drosophila* genes, e.g. based on protein domains (kinases, transcription factors, etc.) or cellular function (e.g. autophagy, signal transduction). 2.) DGET stores and facilitates search of

RNA-Seq based expression profiles available from the modEncode consortium and other public data sets for *Drosophila* genes. Using DGET, researchers are able to look up gene expression profiles, filter results based on threshold expression values, and compare expression data across different developmental stages, tissues and treatments. In addition, at DGET a researcher can analyze tissue or stage-specific enrichment for an inputted list of genes (e.g. 'hits' from a screen) and search for additional genes with similar expression patterns. 3.) MIST is a comprehensive resource of molecular interactions. MIST currently supports several species, including yeast, frog, worm, fly, fish, mouse and human. At MIST, users can mine known physical interactions and infer interactions using other supportive evidence as well as similar genes by correlation analysis. The web interface allows users to retrieve interacting or similar genes in table format as well as visualize these interactions as networks.

D1528C Model organism analysis using InterMine. *Rachel Lyne*[1,2], Karen Christie[5], Paul Davis[4], Jeff De Pons[7], Todd Harris[4], Kalpana Karra[3], Sheldon McKay[4], Howie Motenko[5], Paulo Nuin[4], Leyla Ruzicka[6], Julie Sullivan[1,2], Jennifer Smith[7], Sierra Taylor Moxon[6], Edith Wong[3], Mike Cherry[3], Joel Richardson[5], Mary Shimoyama[7], Lincoln Stein[4], Gos Micklem[1,2], Monte Westerfield[6,8]. 1) Cambridge Systems Biology Centre, University of Cambridge, Cambridge, UK; 2) Department of Genetics, University of Cambridge, Cambridge, UK; 3) Department of Genetics, Stanford University, Stanford, CA; 4) Ontario Institute for Cancer Research, Toronto, ON, Canada; 5) The Jackson Laboratory, Bar Harbor, ME; 6) ZFIN, University of Oregon, Eugene, OR; 7) Human and Molecular Genetics Center, Medical College of Wisconsin, Milwaukee, WI; 8) Institute of Neuroscience, University of Oregon, Eugene, OR.

Ultimately the aim of studies in model organisms is to further understanding of human biology and disease and eventually facilitate the translation of research into clinical practice. The InterMOD consortium provides a framework for accessing model organism data through the InterMine data integration system (http://intermine.org). InterMine-based databases have been developed for budding yeast (http://yeastmine.yeastgenome.org), rat (http://www.ratmine.org), zebrafish (http://zebrafishmine.org), nematode (http://im-dev.wormbase.org/tools/wormmine), mouse (http://mousemine.org) and fruitfly (http://flymine.org) (known as the MOD-InterMine databases) together with a complementary InterMine database containing human data (http://humanmine.org). The result is a unified interface for data access, search and exploration, through which data from different model organism can be related to each other and to human data through orthology, and likewise model organism data can become more accessible to medical researchers.

The web interface includes a useful identifier resolution system, sophisticated query options and interactive results tables that enable powerful exploration of data, including summaries, filtering, browsing and support for lists. Graphical analysis tools provide a rich environment for data investigation including statistical enrichment of sets of genes or other biological entities.

The powerful, scriptable web service API includes client libraries in multiple widely used languages, including Python, Perl, Ruby, Java and JavaScript, allowing programmatic access to data and facilitating creation of bioinformatic workflows.

Building on this framework, and as part of the NIH BD2K program, we are creating tools that will interrelate human genes and their MOD orthologs, allowing users to examine similarities and differences across the range of model organisms, and therefore increasing the ease with which biomedical researchers can exploit MOD data. A pilot Gene Ontology Analysis tool will be presented. Please come by for a demonstration to the poster/exhibition hall, to booth 403..

D1529A Enhanced orthology data in FlyBase. *Steven Marygold*[1], David Emmert[2], Victor Strelets[3], Josh Goodman[3], Jim Thurmond[3], Claire Hu[4], Thom Kaufman[3], the FlyBase Consortium. 1) University of Cambridge, Cambridge, UK; 2) Harvard University, Cambridge, MA; 3) Indiana University, Bloomington, IN; 4) Harvard Medical School, Boston, MA.

FlyBase has recently incorporated orthology data from the DRSC Integrative Ortholog Prediction Tool (DIOPT). This dataset integrates ortholog predictions between 8 species (*D. melanogaster*, *H. sapiens* and 6 other model organisms) from 10 individual tools (Compara, Homologene, Inparanoid, Isobase, OMA, OrthoDB, orthoMCL, Phylome, RoundUp and TreeFam). The DIOPT approach provides a comparison of orthology predictions originating from different algorithms based on sequence homology, phylogenetic trees or functional similarity. DIOPT data are now searchable directly in FlyBase through the new 'Orthologs' tab of our QuickSearch tool, and are shown explicitly within the 'Orthologs' section of *D. melanogaster* Gene Reports.

The new Orthologs QuickSearch tool is quick and intuitive to use: simply select an input species, enter one or more gene symbols/IDs, then select one or more output species. When the input species is *D. melanogaster*, there is a choice between searching the new DIOPT data or our existing OrthoDB-derived orthology calls. The OrthoDB-specific dataset comprises ~40 species, biased towards those that are closely related to *D. melanogaster*, and will be particularly relevant to researchers interested in orthology relationships between *Drosophila* species or related Diptera, for example.

The results page of a QuickSearch Orthologs search shows the list of ortholog predictions arranged by species, and includes links to report pages at the relevant species databases, NCBI, Ensembl and/or OMIM. For DIOPT-based searches, the number and list of individual ortholog prediction tools that support a given orthologous gene-pair relationship is given; links are also provided to an alignment between orthologous gene-pairs on the DIOPT site, and to FlyBase Gene Reports where a non-*Drosophila* gene has been expressed transgenically in flies. A similar presentation is used for DIOPT-based data within the 'Orthologs' section of *D. melanogaster* Gene Reports.

In addition to serving the core *Drosophila* community, our new orthology search tool will provide a convenient portal to FlyBase data for non-*Drosophila* researchers - they can search with a human/mouse/worm (etc) gene of interest and quickly access the available knowledge and reagents for the fly ortholog(s). The provision of extensive links within the results page to orthologous gene reports at external websites will further aid inter-species/database navigation.

D1530B *flyDIVaS*: A database for genus- and genome- wide divergence and selection in Drosophila. *C. E. Stanley*, R. J. Kulathinal. Temple University, Philadelphia, PA.

Almost a decade ago, the 12 Drosophila Genomes project and the associated development of community-based resources including the AAA site (Assembly/Alignment/Annotation), transformed D. melanogaster into a premiere comparative model (Clark et al. 2007). However, the analysis sets made available for evolutionary inference and biological discovery have become outdated. Here, we provide an updated and upgradable comparative genomics resource of Drosophila divergence and selection, flyDIVaS, based on the latest genomic assemblies, curated FlyBase annotations, and recent OrthoDB orthology calls. flyDIVaS is an online database containing D. melanogaster-centric orthologous gene sets, sequence alignments, divergence estimates (% gaps, dN, dS, dN/dS), and codon-based tests of positive selection. Out of 14K protein-coding D. melanogaster genes, ~80% have one aligned ortholog in the closely related species, D. simulans, and ~50% have 1-1 alignments in the original 12 sequenced species. Genes and their orthologs can be chosen from four taxonomic datasets differing in phylogenetic depth and coverage density, and visualized via interactive alignments and phylogenetic trees. Computationally-savvy users can also batch download entire comparative datasets. A preliminary functional survey finds conserved mitotic, cell cycle, and neural genes, highly diverged immune and reproduction-related genes, strong signals of divergence across tissue-specific genes, and an enrichment of positive selection among highly diverged genes. We encourage researchers to regularly use this resource as a tool for biological inference and discovery, as well as in their classrooms to help train the next generation of biologists to creatively use such genomic big data resources in an integrative manner. flyDIVaS will be annually updated and is freely available at www.flydivas.info.

D1531C A Comprehensive and Precise Genome Duplication Kit in *Drosophila melanogaster*. *G. Mardon*, M. Fa, Y. Tan, R. Chen. GenetiVision Corporation, Houston, TX.

We have generated a new set of transgenic fly stocks that carry >80 kb BAC genomic clones tiling the majority of the autosomal portion of the *Drosophila melanogaster* genome. As a new fly stock collection carrying molecularly-defined genomic duplications, it is a very useful tool for rescue and complementation testing, genetic fine mapping, and can form the basis for further genomic engineering. Specifically, a set of about 1,200 overlapping BACs that tile the entirety of chromosomes 2 and 3 was selected and inserted using site-specific integration. This collection covers >99% of the genes in the autosomal genome. Together with the existing genomic duplication collections for the X and 4th chromosomes, the vast majority of the *Drosophila* genome is now covered. Due to the precise nature of this new collection where the end points of each BAC and the genomic insertion site are precisely known, additional applications are enabled, such as clonal analysis. Furthermore, this collection can serve as the starting point for other manipulations such as gene tagging, generating point mutations, and structure-function analyses. Transgenic stocks are now available through a web-based searchable database (http://genetivision.com/duplication.html).

D1532A Do not let your money fly away: Cost-effective strategies for new investigators operating a fly lab. *A. Auge*, W. J. Kim. University of Ottawa, Ottawa, ON, CA.

According to the NIH director, early-career researchers in the biomedical sciences currently face the worst financial environment of the past half century. Thus, the cost-effective use of start-up packages is extremely important. Here, we present our experience from the past year in setting up a new low-cost fly lab in Canada.

General strategies: Be creative; traditional purchasing techniques are not the most cost-effective.
1) Ask the experts in your department for used items: incubators, microscopes and Petri dishes. Collaborate with facility managers who know about abandoned equipment. Having certain items manufactured at a local machine shop saves money. Our custom fly pads—which are bigger than commercial fly pads—were made in this fashion, at a similar cost.
2) Take advantage of sales that vendors offer to new investigators.
3) Buy scientific supplies at non-scientific stores. Amazon.com, eBay, and dollar stores offer similar supplies for a lower price
4) Sign up for a lab account with vendors and don't forget to negotiate before you regularly order in bulk. Vendors usually offer a lower price than what they advertise. Below are strategies we followed to establish four fly stations and one fly cooking room and a description of how we saved money maintaining twelve trays of stock fly lines with weekly experiments at a low cost.

Equipment:
1) Use websites such as LABx.com for trading used items. There, cheap equipment can be purchased on sale.
2) Browse Amazon.com for cooking room supplies (oven plate, pots, spoons, scoops and strainers), fly station materials (tubing, connectors, paintbrushes and spatulas), general lab equipment (carts and bag holders), and immunostaining items (glass well dishes, Pyrex dishes, micro scissors, and tweezers).
3) Organizers, containers, and storage boxes can be purchased at dollar stores and department stores. For example, purchasing gooseneck lamps from IKEA instead of a vendor's microscope lighting will save 200 CAD per unit.

Consumables:
1) Most fly-food ingredients can be found at a local grocery or bulk food store.
2) Vials, bottles and plugs should be negotiated as regular bulk orders for a discount with sales representatives. For small-scale and short-term use, for example, cotton balls from Amazon.com fulfill the same purpose as conventional plugs.

In **summary**, by setting up a fly lab using these cost-effective methods, new researchers can obtain supplies of equal or higher quality. We saved 2,500 CAD per fly station and 1,000 CAD on the cooking room compared to purchasing from conventional vendors. A further 20,000 CAD per year is saved on consumables (vials, food, bottles, plugs) for maintaining and experimenting with flies. Don't let your money fly away.

D1533B A New Protocol to Visualize Dopamine in Whole Mount *Drosophila* Brains. *Y. Liu*[1], K. Cichewicz[1], E. Garren[1], J. Hirsh[1], A. Tito[2], S. Zhang[2]. 1) University of Virginia, Charlottesville, VA; 2) University of Texas Health Science Center at Houston, Houston, TX.

Dopamine is a neurotransmitter critical in mediating reward pathways, locomotion, and learning and memory. Dopamine visualization is crucial for studying dopamine localization, release, and subcellular quantitation in the brain. We have developed a new immunostaining protocol to directly detect dopamine (DA) in brains of *Drosophila melanogaster* with high signal to noise ratio. The DA antibody stains dopamingergic neurons and terminal projections in wild-type flies while DA deficient brains lack staining, showing specificity of the antibody. The common method to infer DA in the brain utilizes immunostaining of tyrosine hydrolyase (TH), the rate limiting enzyme for DA synthesis. Here, we show the flaw in using this marker, since detectable levels of TH produced by poorly translated TH protein can produce normal amounts of dopamine. Reduced DA staining in the terminal region of a vesicular transporter mutant tell us that stained dopamine is contained in vesicles. This new immunodetection protocol will allow accurate and direct visualization of changes in subcellular localization of DA as a function of other genetic and behavioral state alterations.

D1534C What's new at the Bloomington Drosophila Stock Center. *A. L. Parks*, K. Matthews, K. R. Cook. Bloomington Drosophila Stock Center, Indiana University, Bloomington, IN.

The Bloomington Stock Center added over 5200 stocks in 2015, bringing our total number of stocks to almost 59,000. In 2015 we added >1600 TRiP RNAi stocks, >1000 Mi{MIC} stocks and we began acquisition of the InSITE collection. InSITE insertions, like Mi{MIC}s, carry attP sites that allow you to swap in cassettes carrying your DNA of choice. We also brought in a variety of other exciting new stocks, including UAS-mir and UAS-mir-sponge stocks, Rab knockout lines, transcriptional calcium sensors, Mi{MIC}-based Recombinase-Mediated Cassette Exchange lines expressing tagged fusion proteins under their own power and more. We will provide an overview of these and other new acquisitions and highlight some important sets of pre-existing useful stocks. As always, we hope we will give you ideas for experiments or new ways to explore biological processes. We welcome all suggestions and questions so come by and see us!

Poster Session Abstracts

M5001A Oncogenic Role of BRE (BRCC45) by USP7-mediated CDC25A Deubiquitylation. *K. Biswas*[1], S. Philip[1], S. Chang[1], B. Martin[1], S. Burkett[1], S. North[1], S. Sharan[1]. 1) National Cancer Institute, Frederick, MD; 2) National Cancer Institute, Frederick, MD; 3) National Cancer Institute, Frederick, MD; 4) National Cancer Institute, Frederick, MD; 5) National Cancer Institute, Frederick, MD; 6) National Cancer Institute, Frederick, MD; 7) National Cancer Institute, Frederick, MD.

BRCA2 has an essential role in DNA repair, and therefore primary cells exhibit severe proliferation defect or fail to survive in its absence. Yet, *BRCA2*-deficiency results in tumorigenesis. It is believed that mutations in genes like *TP53* contribute to the viability of *BRCA2*-deficient cells that subsequently undergo neoplastic transformation due to their unstable genome. To identify other genes that contribute to cell survival in the absence of *BRCA2*, we have undertaken an insertional mutagenesis screen using the Murine Stem Cell Virus (MSCV). Here we describe one of the genes identified in the screen, brain and reproductive organ expressed (TNFRSF1A modulator) (*BRE*), also known as BRCC45. BRE is a component of the BRCA1-complex that specifically recognizes the Lys-63-linked ubiquitinated histones H2A and H2AX at the site of DNA damage. We found that overexpression of BRE can rescue the lethality of *Brca2* null mES cells. Furthermore, our findings revealed that its overexpression results in perturbation of DNA damage induced degradation of CDC25A phosphatase, a key cell cycle regulator and an oncogene, by facilitating deubiquitylation through ubiquitin specific peptidase 7 (USP7). The oncogenic role of BRE is demonstrated by its effect on the growth of BRCA2-deficient tumor cells in mice and the positive correlation between BRE overexpression and CDC25A levels is confirmed in human breast tumors. Altogether, our findings demonstrate a novel oncogenic role for BRE that is independent of its known role in BRCA1-mediated tumor suppression.

M5002B Genes, Orthologs, and Human Diseases: How Model Organism Databases and the Gene Ontology Empower Knowledge Discovery. *J. A. Blake*. The Jackson Laboratory, Bar Harbor, ME.

The Model Organism Databases (MODs) and the Gene Ontology (GO) systems are core data resources for the study of human biology and disease. The MODs having been continuously funded by since the initiation of the Human Genome Project in recognition of the power inherent in the use of these key model organisms for knowledge discovery. They provide gold standard integration of multiple genetics and genomics data, and have been instrumental in the rapid advances in our understanding of the how biological systems work and how genetic variation impacts human biology and contributes to human diseases. The 2016 TAGC meeting brings together communities from Ciliates, Yeast, Mouse, Zebrafish, Drosophila and *C. elegans* to share genetics discovery stories and advance our common objectives.

I will discuss how the MODs and GO communities work together in their common objectives to capture and integrate genetics and genomics data at surprising depth and complexity. I will demonstrate how these communities provide these data to a variety of research communities. I will use the Mouse Genome Database and the Gene Ontology Consortium as the primary examples of how the shared and complementary efforts of experimental scientists, bioinformatics analysts, and bioinformatics specialists together advance science in our current research environment that features very large heterogeneous data sets and rapidly advancing technologies that build on existing understanding of biology and disease.

This work is funded by NIH grants HG 000330 to the Mouse Genome Database (PIs, JA Blake, CJ Bult and JT Eppig) and HG 002273 to the Gene Ontology Consortium (PIs JA Blake, JM Cherry, SE Lewis, PW Sternberg and PD Thomas).

M5003C Neonatal Exposure to UV-Radiation and NER Pathway Deficiencies Enhance Melanomagenesis In A Novel Transgenic K5-*Edn3* Mouse Model. *D. Cardero*[1*], A. P. Benaduce[1], D. Batista[1], G. Grilo[1], K. Jorge[1], C. Milikowski[2]. 1) Florida International University , Miami, FL; 2) University of Miami, Miami, FL.

Melanoma is the most aggressive form of skin cancer and results from transformed melanocytes. Melanomagenesis is influenced by both genetic and environmental factors. Exposure to Ultra Violet Radiation (UVR) is accepted as one of the most common environmental factors leading to melanomagenesis. The Nucleotide Excision Repair (NER) pathway is very significant during UVR exposure because it is responsible for repairing UVR-induced DNA damage. Xeroderma Pigmentosum (XP) is an autosomal recessive disorder resulting from deficiencies in any of the eight XP complementation group genes, which code for many proteins indispensable to the NER pathway. XP patients exhibit extreme sensitivity to UVR and a high predisposition to developing skin cancers, including melanoma. Upon being exposed to UVR, *Xpa*^{tm1Tnka}-deficient mice, which share many characteristics of XP patients, develop skin cancers, but not melanoma. The endothelin 3 (Edn3) pathway is critical for the development, proliferation, survival and migration of melanocyte precursor cells. The aim of this study was to develop a novel transgenic UVR-induced melanoma mouse model deficient in XPA in conjunction with overexpression of the EDN3 pathway. Three groups of transgenic mice that overexpress the EDN3 pathway under control of the keratin 5 promoter Tg(KRT5-rtTA)1Glk Tg(tetO-Edn3,-lacZ)Kosl (aka K5-Edn3) and have *Xpa*^{tm1Tnka} heterozygous or homozygous mutations (*Xpa*-/- K5-Edn3, *Xpa*+/- K5-Edn3 and *Xpa*+/+ K5-Edn3) were either exposed to a single suberythemal neonatal dose of UVR at 3.5 days, two doses of UVR (at 3.5 days and 6 weeks), or a single dose of UVR at 6 weeks during adulthood. Only transgenic K5-Edn3 mice developed melanomas, and animals exposed to one dose of UVR at 6 weeks of age did not develop any melanomas. *Xpa*-/- K5-Edn3 mice showed increased penetrance (60%, n=10) and earlier disease appearance, when compared to *Xpa*+/- K5-Edn3 (46%, n=13) and *Xpa*+/+ K5-Edn3 (*19%, n=16*). These results suggest that neonatal UVR exposure along with the over-activation of the EDN3 pathway is sufficient for melanomagenesis in mice, and is enhanced by deficiencies in the NER pathway.

M5004A *In Vivo* Modeling of Heritable Dopamine Transporter Dysfunction Associated with Neuropsychiatric Disorders. *G. L. Davis*[1,2], R. D. Blakely[2]. 1) Graduate Neuroscience Program, Vanderbilt University, Nashville, TN; 2) Department of Biomedical Sciences, Florida Atlantic University, Jupiter, FL.

Attention-Deficit Hyperactivity Disorder (ADHD) is the most common childhood psychiatric disorder, and one that, left untreated, is associated with low socio-economic status, addiction and/or incarceration. Our lab has created a construct valid mouse model based on the

Slc6a3^{tm1Rbl} (DAT Val559) coding variant to elucidate neurobiological mechanisms supporting ADHD and other DA-linked comorbid disorders. With these 129;B6-*Slc6a3*^{tm1Rbl} animals and their wildtype adolescent littermates, we sought evidence for cognitive, attention and impulsivity alterations using the 5 choice serial reaction time task (5-CSRTT) and used progressive ratio and sucrose preference tasks to examine changes in motivation and hedonic valuation. In the 5-CSRTT, mice were trained to a baseline performance with a 5 second delay followed by a 2 second stimulus presentation. Premature, incorrect, and correct responses were recorded, as well as, omissions. Once animals met predetermined criteria for task completion, the paradigm was manipulated to probe for different aspects of attention and impulsivity. This effort consisted of increasing the delay between the start of the trial to the presentation of the stimulus from 5 seconds to 15 seconds. Mice were also tested under a variable delay condition where four different delay times (2, 5, 10, and 15 seconds) were used throughout the session in a randomized order. DAT Val559 mice showed several key differences in the task, including faster acquisition of the task, increased impulsivity under the long delay condition, yet improved performance with a variable delay. We hypothesize that with the proper motivation, DAT Val559 may hyperfocus on the parameters driving task acquisition and differentially utilize the temporal information presented during training sessions, being less reliant on absolute timing expectations. An enhancement in motivation for reward in the DAT Val559 mice was suggested by an increase in the progressive ratio break point. Interestingly this response became dysregulated under a devalued condition (i.e. DAT Val559 mice will continue to nose-poke for reward despite home cage satiation). This alteration is likely not due to a difference in hedonic valuation as we found no genotype difference in sucrose preference. Ongoing studies seek to determine the cellular and circuit level plasticities that derive from lifelong expression of the DAT Val559 variant and that lead to the observed changes in impulsivity and motivation. Supported by NIH Awards MH107132-02 (GLD) MH105094 (RDB).

M5005B KDM1A inhibition may contribute to MAPT (tau)-mediated neurodegeneration in Alzheimer's disease. *A. K. Engstrom*, R. A. Moudgal, M. A. Christopher, D. A. Myrick, B. G. Barwick, A. I. Levey, D. J. Katz. Emory University, Atlanta, GA.

Alzheimer's disease (AD) is an irreversible, progressive brain disorder caused by massive neuronal cell death in the frontal and temporal cortices and the hippocampus. AD is associated with the accumulation of β-amyloid plaques and neurofibrillary tangles of hyperphosphorylated MAPT (tau) (NFTs). However, how NFTs contribute to neuronal cell death remains unclear. Recent data from our lab has demonstrated that the histone demethylase KDM1A(LSD1) is mislocalized with NFTs in AD cases. In addition, loss of LSD1 systemically in adult mice is sufficient to recapitulate many aspects of AD. These data raise the possibility that neurofibrillary tangles contribute to neuronal cell death, in AD, by interfering with the continuous requirement for LSD1 to repress inappropriate transcription. Here we further test this model by removing one copy of *Kdm1a* from Tg(Prnp-MAPT*P301S)PS19Vle (P301S Tau) mice, which contain a human transgene overexpressing an aggregation-prone mutant of tau. Our preliminary results show these mice exhibit a much faster and more severe neurodegeneration phenotype. This suggests that aggregated tau functions genetically through the loss of LSD1. As a result, it may be possible to target this step therapeutically to block the progression of AD.

M5006C Degenerative transformations in the Liver and Gonads of male Wister albino rats by *Irvingia gabonensis* (Aubery-Lecomte ex O'Rouke) Seed extract. *H.Edim Etta*[1*], E. Victor Ikpeme[2], C. Chinomsos Olisaeke[1], E. Eneobong Eneobong[2]. 1) Cross River University of Technology, Calabar, Cross River, Nigeria; 2) University of Calabar, Calabar, Cross River State, Nigeria.

The effect of seed extract of *Irvingia gabonensis* -African Bush Mango (ABM)- seeds, on the liver and gonads of male Wister albino rats (*Rattus norvergicus*), was investigated. This investigation was prompted by the increasing international acceptance of the seeds of the ABM (test substance) as being an effective weight reducing herbal medication. Male Wister albino rats, were treated with 50mg/kg bw, 100mg/kg bw and 150mg/kg bw of ABM seed extract. The extract was administered by oral intubation for fourteen (14) days, after which the organs, to be investigated were collected for histological processing. Photomicrographs of organs showed mild to severe degenerative effects on the histology of the organs investigated. The seed extract of *Irvingia gabonensis* had a dose-dependent effect on the organs. Some of the histopathological effects observed in the liver were, sinusoidal dilations (SD), hemorrhaging of the central vein (HCV), inflammation (I) and abnormal distribution of hepatocyte (ADH). Others were, macrosteatosis(M) and macrovesicular fatty infilterations (MFI). In the testes, arrested spermatogenesis (AS), degenerated germinal epithelium (DGE), absent interstitial cells (AIC), hardened basal cells (HBC) and empty seminiferous tubules(EST) were some of the effects of the seed extract observed. This indicates that seed extracts of *Irvingia gabonensis* could cause degenerative transfomations of both liver and testes in the male mammal at accumulated high concentrations.

M5007A Embryo and neonate phenotyping identifies new genes essential for mammalian development. *A. Flenniken*[1], J. Ellegood[2], L. Nutter[1], L. Bower[3], D. Rowland[3], L. Lanoue[3], D. Clary[3], F. Benso[4], S. Newbigging[1], M. Henkelman[2], C. McKerlie[1], K. Lloyd[3], The DTCC-KOMP2 Consortium. 1) The Centre for Phenogenomics, Toronto, Canada; 2) Mouse Imaging Centre, Toronto, Canada; 3) University of California, Davis, USA; 4) Charles River Laboratories, Wilmington, USA.

Identifying the structural basis of developmental anomalies using imaging, gross morphology, and histology has led to new insights into gene function. In the last 5 years, the DTCC Consortium, one of three members of the NIH KOMP2 project and a part of the IMPC, has generated knockout mouse lines for 850 unique genes selected for having little to no pre-existing functional annotation. Mutant lines that survive post-weaning are tested in a multi-system phenotyping pipeline from 9 to 16 weeks of age, while lines that fail to give birth to homozygous offspring or survive post-weaning at 3 weeks of age undergo an alternative pipeline. To identify developmental abnormalities leading to death before (embryo lethal) and after (subviable) birth, we screened mutants for viability at different developmental stages to determine the window of lethality and imaged the animals using sensitive methods for each stage. Our screen uses optical projection tomography (OPT) for embryos identified as homozygous lethal at embryonic day (E)12.5 but viable at E9.5, micro-computed tomography (micro-CT) for lines viable at E15.5 but lethal before birth, and high resolution magnetic resonance imaging (MRI) of whole brains of postnatal day (P)7 mice for lines that are

viable at birth but lethal before weaning. DTCC uses an automated image analysis system that is applied to 8 biological replicates comprised of either sex per mutant line. A mutant population average scan is overlaid for comparison to an age-matched wild type population average 3D atlas to identify and quantitate differences with <5% false discovery rate. Automation eliminates bias, increases throughput, and enhances sensitivity to detect differences. Our analysis also includes evaluation and annotation of gross morphology in freshly dissected embryos using a structured set of e-Mouse Atlas Project (EMAP) and Mammalian Phenotype (MP) ontology terms. Staining for lacZ expression analysis is completed at E12.5 for all embryo lethal and neonate subviable lines that have been analyzed at E15.5. Histological assessment of paraffin-embedded sections is done on embryos and placentas for lines analyzed at E9.5 or E15.5 and on brains and whole bodies of neonates analyzed at P7. Examples of pleiotropic, quantified, and characterized gross and subtle phenotypes from each of the imaging modalities and histology will be presented. To date, our pre-weaning viability screen of 688 mutant lines has found 197 lines (29%) either lethal (114 lines; 17%) or subviable (83 lines; 12%). These morphological findings from image analysis with histology of mutant embryos and neonatal mice have provided new and informative insights into gene function essential for mammalian development. Supported by NIH grants U42OD011175 and U54HG006364.

M5008B Gene expression and regulation in food restricted mice. *D. J. Guarnieri*, T. Nguyen, V. Pat, R. Ruh, S. Terhaar, P. Sohal. Saint Bonaventure Univ., Saint Bonaventure, NY.

While it has been widely recognized that food restriction enhances learning and motivation, the neural mechanisms underlying this adaptation are not well defined. It is likely that changes in gene expression underlie the behavioral response to food restriction. Previously, microarray analysis was conducted on animals that had been food restricted (75% of normal caloric intake) over the course of five days (FR-5). Changes in gene expression were confirmed by quantitative PCR (qPCR) within the hypothalamus, as well as three brain regions within the meso-cortico-limbic circuitry including the medial prefrontal cortex (mPFC). The purpose of our experiments is to assess the role of the glucocorticoid receptor (GR) in mediating observed changes in gene expression, with a focus on *Cdkn1a, Arrdc2,* and *Mertk*. We hypothesized that similar molecular adaptations to FR-5 may also occur in peripheral tissue, and show that all three genes are up-regulated in the mouse kidney. We also hypothesized that some adaptations may occur in an acute restraint stress model and tested this by assessing gene expression in mice that were immobilized for 30 minutes. We found that *Cdkn1a* is up-regulated in the mPFC while *Arrdc2* and *Mertk* are unchanged 2.5 hours after the stressor. Additionally, we show that *Mertk* is up-regulated in the male but not the female kidney, while *Arrdc2* shows adaptation in both sexes (FR-5). In order to address whether these genes represent direct targets of the GR, we use bioinformatic approaches to identify relevant GBRs (glucocorticoid binding regions) and plan to use reporter assays in mammalian cells to assess whether they are functional GREs (glucocorticoid responsive elements). These ongoing studies will better characterize the transcriptional response to mild food restriction and will determine the generality of the response across stress models, tissue types and in males versus females. Ultimately, we anticipate that these studies will allow us to address the role of these molecular responses in mediating long-term behavioral changes after mild and chronic stress.

M5009C The role of *Arid1a* as a suppressor of spontaneous mammary tumors in mice. *N. Kartha*, L. Shen, C. Maskin, J. Schimenti. Cornell University, Ithaca, NY.

Human cancer genome studies have identified the SWI/SNF chromatin remodeling complex member *ARID1A* as one of the most frequently altered genes in several tumor types. Its role as an ovarian tumor suppressor has been functionally demonstrated in compound knockout mice. In my primary thesis work, I have found genetic and functional evidence that *Arid1a* is a bona fide breast cancer tumor suppressor, using the *Mcm4*^{chaos3} mouse model of sporadic mammary carcinogenesis. Nearly all mammary tumors that form in these mice contain a deletion removing one *Arid1a* allele, while the remaining intact allele is silenced or downregulated in many cases. The epigenetically silenced allele could be reactivated by treatment with the cytosine methyltransferase inhibitor 5-azacytidine. Restoration of *Arid1a* expression in a *Chaos3* mammary tumor line greatly impaired its ability to form tumors following injection into cleared mammary glands, indicating that ARID1A insufficiency is crucial for maintenance of these tumors. Transcriptome analysis of tumor cells before and after re-introduction of *Arid1a* expression revealed alterations in growth signaling and cell-cycle checkpoint pathways, suggestively in a TRP53-dependent manner. These preliminary results provide *in vivo* evidence for a tumor suppressive and/or maintenance role in breast cancer. My current thesis work involves the generation of a mammary-specific conditional knock-out mouse model of *Arid1a*, which will help determine whether loss of ARID1A is an initiating driver of mammary tumors. I am also attempting to induce expression of the remaining *Arid1a* allele present in multiple *Chaos3* mammary tumor cell lines in a locus-specific manner, using CRISPR-activation (CRISPRa) technology. If successful, this would indicate a potential opportunity for therapeutic intervention in ARID1A-deficient human breast cancer subtypes.

M5010A Mitochondrial Fetal Drive in Response to Nutritional Stress During Gestation. *Robert Kesterson*[1], Tonia Schwartz[2], Laura Lambert[1], Larry Johnson[1], Daniel Kennedy[1], David Allison[1], Scott Ballinger[1]. 1) University of Alabama at Birmingham, Birmingham, AL; 2) Auburn University, Auburn, AL.

Mitochondrial and nuclear genome interactions play a role in many diseases, and are of increasing concern with the advent of mitochondrial transfer techniques to create “three-parent babies”. During gestation in mammals, the placenta regulates growing energetic demands of developing offspring which may have long-term consequences on fertility, fecundity, and fetal programming. In this respect, we were curious about the impact of maternal-offspring mtDNA mismatch upon fetal development and response to nutritional stress. Mitochondrial-Nuclear eXhange (MNX) mouse strains (containing the nucleus from C57BL/6J and the mitochondrial genome from C3H/HeN mice) were used to assess sources of genetic variation that regulate placental (dys)function, fetal programming, and fetal development in response to nutritional stress. Ten two-cell embryos of either mismatched (MNX) or matching (C3H) mitochondrial and nuclear backgrounds were transferred to the ostia of

oviducts in C3H pseudopregnant mice and developed to term. Females from each combination were randomly assigned to either ad lib (AL) diet or 30% caloric restriction (CR) during gestation [n=6 surrogate-embryo genotype combination (AL MNX, CR MNX, AL C3H, CR C3H)]. At day 18 of gestation (near full-term) fetuses and placentas were removed by cesarean section and total number of pups, pup body weight and placental weight recorded.

Results: While neither placental weight (0.1007±0.0059g AL MNX, 0.0931g CR MNX, 0.1034±0.005g AL C3H, 0.09722±0.0171g CR C3H), nor average weight (1.049±0.1410g AL MNX, 0.8739g CR MNX, 1.047±0.1342g AL C3H, 0.7020±0.2664g CR C3H) of pups developed to full term were significantly different per group, only one full term pup was recovered from the CR MNX cohort of 60 embryos transferred (1.67%) compared to 9 in the AL MNX (15%) group. The ad libitum groups produced similar numbers (31.67% MNX and 33.3% C3H) of pups that developed normally to embryonic day 18.

Conclusions: In comparing dietary restriction relative to ad lib, fetuses with mismatched mtDNA relative to the nuclear genome were at higher risk of miscarriage. Further studies are ongoing to determine the effects mtDNA mismatch on maternal physiology; however, these data indicate differences in survivability in response to nutritional stress between embryos of matching or mismatched nuclear and mitochondrial genomes, demonstrating that variation in the fetal mitochondrial genome alters placental and fetal development in response to gestational dietary restriction.

M5011B A spontaneous mutation of neurexin III in the 129S1/SvImJ strain of mice enhances empathic fear behavior. *S. Keum*, A. Kim, H.-S. Shin. Institute for Basic Science (IBS), Daejeon, KR.

Empathy is an important emotional process that involves the ability to recognize and share emotions with others. We previously developed an observational fear learning (OFL) behavioral assay to measure empathic fear in mice. In the OFL task, a mouse is conditioned for fear to the context where it observes a conspecific demonstrator receiving aversive stimuli. We have recently reported that empathic fear response is highly variable among 11 inbred mouse strains, and innate differences in conditioned fear, anxiety, locomotor activity, sociability and preference for social novelty are not significantly correlated with OFL among those strains. However, the genetic factors underlying variability in empathic fear remain to be determined. Intriguingly, we have found that mice of the 129S1/SvImJ (129S1) strain, exhibit a marked increase in OFL, as compared with another 129S substrain, 129S4/SvJaeJ (129S4). Through genetic and molecular analyses, a nonsynonymous mutation of arginine to tryptophan (R498W) in neurexin III (*Nrxn3*) was identified as the causative variant. This mutation occurs at a residue that is well conserved among mammalian species and is predicted to be deleterious to the protein by *in silico* databases. We have further determined that a deletion of *Nrxn3* in the anterior cingulate cortex leads to a decrease in OFL. Knock-in mice with the R498W mutation by the CRISPR/Cas9 system are currently being tested. Taken together, we propose that *Nrxn3* is an important regulator in neural circuits of OFL. These works also demonstrate the validity of the approach to utilize substrains to identify genes and alleles regulating social behaviors.

M5012C Animal Models in Diabetes Research. *K. G. Kumar*, Ana Perez. Taconic Biosciences Inc, Hudson, NY.

Diabetes is a disease characterized by hyperglycemia due to lack of insulin. Animal models are useful to study the pathophysiology and complications of diabetes. The studies shown below provide some characterization parameters on monogenic, multigenic and diabesity models that are critical for choosing the best models.

Goto-Kakizaki rat is an inbred model bred selectively for insulin resistance. As this model is not bred in a classical way of inbreeding, some genetic heterogeneity is expected. We observed variability in hyperglycemia and tested if this is due to genetic heterogeneity by selective improvement of phenotype. We found a significant improvement in the hyperglycemia within a generation (pre-selection vs post-selection glucose levels - 160.0+1.1 vs 174.8+1.6 mg/dl; $p<0.001$; n=3990). The data suggests that the genetic heterogeneity for hyperglycemia is prevalent in this model and could be exploited for identification of candidate genes for hyperglycemia.

NOD model is also an inbred model to study type I diabetes, it develops diabetes due to insulitis starting at about 8 weeks of age. There are many gene-environment interactions influencing the penetrance of diabetic phenotype in this model. We assessed whether environmental variation due to change in health status can alter the penetrance of Diabetes in NOD/MrkTac model. Our data shows that the health status variation may not be an influencing factor for the disease as the colonies show no variability in diabetic prevalence in 2 different health statuses.

Diet induced obesity (DIO) in C57BL/6NTac strain is being used for testing many drugs against diabesity and associated complications. This model have functional nicotinamide nucleotide transhydrogenase (*Nnt*) gene that is absent in the "J" strain. NNT is a major source of mitochondrial NADPH and its functional loss results in mitochondrial redox abnormalities. Our phenotypic study shows that DIO Tac model is heavier, have higher cholesterol and are more insulin resistant than age matched DIO Jax model.

Leptin receptor deficiency in C57BLKS genetic background is an inbred monogenic model, which shows sustained rise in blood sugar as the animal ages (200 mg/dl at 4 weeks to 500 mg/ dl at 9 weeks of age) due to depletion of beta cells.

We will present data that will compare and contrast the use of these models and their parameters that need to be considered when breeding these for studies. Ideally, diversity seen in human patients can be studied using more than one model.

M5013A Integrated analysis of the Jackson Laboratory Knockout Mouse Project 2 (KOMP2) data. *Vivek Kumar*, Donghyung Lee, Vivek Phillip, James Clark, Karen Svenson, Robert E. Braun, Stacey Rizzo, Elissa J. Chesler, Vivek Kumar. The Jackson Laboratory, Bar Harbor, ME.

The Knockout Mouse Project at The Jackson Laboratory has characterized over 300 mouse knockout lines in 28 assays including 10 behavioral and 18 metabolic/physiology assays. This public dataset represents one of the largest using a classical rapid test battery approach. Here we present a comprehensive analysis of this data. We have statistically modeled the environmental and genetic contributions to phenotype variation using multiple statistical approaches. By modeling environmental variables captured in individual test metadata fields, we are able to

increase the sensitivity and precision with which mutants can be detected. By modeling across behavioral, metabolic and physiological phenotypes we provide rich phenotypic resource for the mouse genetics community.

M5014B Identifying Causal Variants for an Allergen-Induced Inflammation QTL. *L. Laudermilk*, S. Kelada. UNC Chapel Hill, Chapel Hill, NC.

Introduction: In asthma, neutrophil levels in sputum are correlated with disease severity and lung function, hence a better understanding of the genes and pathways that affect neutrophilic inflammation in these patients may offer new insights into disease pathogenesis. To identify genes that control neutrophilic inflammation, our lab applied a house dust mite model of asthma to incipient lines of the Collaborative Cross (CC). We identified a quantitative trait locus (QTL) for neutrophils and an associated chemokine, CXCL1, on Chr 7 and subsequently identified *Zfp30* as a candidate gene. In aggregate, our results indicated that a *Zfp30* cis-eQTL underlies variation in CXCL1 and neutrophil recruitment. However, the specific causal variant(s) remain to be identified. We sought to identify the causal variants that regulate *Zfp30* expression level as a way to reveal important regulatory mechanisms of inflammation and disease-related phenotypes. **Methods:** Gateway cloning, luciferase assays, qPCR, and site-directed mutagenesis were used to clone candidate regulatory regions of *Zfp30* from representative mouse strains and test the ability of these regions to recapitulate *in vivo* expression patterns. **Results:** We found that *Zfp30* is differentially expressed in both CC lines and founder strains of the CC. *Zfp30* expression levels in mice from the preCC correlate with the haplotype of the 5' region of the gene, resulting in three expression groups (high, medium, and low). Using a combination of publically available SNP genotype data and DNAseI footprinting data, we identified a ~500 bp candidate regulatory region of the *Zfp30* promoter which contains a single putative causal variant (rs51434084). Using reporter assays with haplotypes from representative CC strains, we show that this region of the *Zfp30* promoter is sufficient to recapitulate *in vivo* patterns of expression at both the mRNA and protein level. Furthermore, mutagenesis of rs51434084 conferred a significant change in expression levels, successfully capturing the expression difference between high and medium *Zfp30* expression groups. **Conclusion:** These results indicate that rs51434084 plays a significant role in the *Zfp30* cis-eQTL and therefore likely affects CXCL1 levels and neutrophil chemotaxis. Future experiments will determine the mechanism of the variant's impact on gene expression and characterize the mechanism by which ZFP30 regulates CXCL1 and other targets.

M5015C Identification of Genetic Modifier Loci that Affect Early Sudden Death in a Mouse Model of Accelerated Heart Aging. *S. Lewis*, H. Higuchi, T. Takimoto, W.-H. Lee, S. Ikeda, A. Ikeda. University of Wisconsin-Madison, Madison, WI.

Purpose: The purpose of this research is to identify genetic modifiers that interact with the transmembrane protein 135 (*Tmem135*) gene to cause early sudden death in a transgenic (TG) mouse model overexpressing *Tmem135* that exhibits heart abnormalities similar to those in the aged heart. Finding genes that interact with *Tmem135* will help elucidate the role of TMEM135 in the early onset and accelerated progression of aging in the heart and death by heart failure.

Introduction: *Tmem135* encodes a transmembrane protein that regulates mitochondrial dynamics. Overexpression of *Tmem135* causes fragmentation of the mitochondria both *in vitro* and *in vivo* in the myocardium. *In vivo*, *Tmem135* overexpression leads to phenotypes in the heart including hypertrophy, collagen accumulation, heart dysfunction, and early adult death, which are similar to abnormalities observed in aged hearts. Furthermore, the gene expression profile of TG hearts is similar to that of the aged mouse hearts. While backcrossing TG mice generated in the FVB background onto the C57BL/6 background, we found that a number of mice die suddenly around postnatal day 21. Increasing the C57BL/6 background increases death in TG mice, suggesting that either the C57BL/6 alleles of the modifiers interact with *Tmem135* to cause early sudden death or FVB alleles are protective against sudden death by heart failure.

Methods: To find genetic modifiers contributing to early sudden death, we conducted quantitative trait locus (QTL) analysis in a semi-quantitative fashion using mice generated by the FVB -C57BL/6 intercross and backcross to C57BL/6. A total of 35 mice, 16 of which suffered sudden early death, were genotyped across the genome using 779 markers to differentiate C57BL/6 and FVB alleles. Mice were categorized as either 0, for survival, or 1, for sudden death. Using R/QTL, we conducted a whole-genome scan with 1000 permutations to determine thresholds for selective candidate QTLs.

Results/Conclusion : QTL analysis identified 2 loci on Chromosomes 2 and 17 that affect early sudden death (p =0.014 and p=0.02, respectively). On Chromosome 2, the peak lod score was 4.6 at 51.215 cM. This QTL has a 95% confidence interval between rs4223268 (68.2 cM) and rs1347690 (80.332 cM). On Chromosome 17, the peak lod score was 4.25 at 28.138 cM. This QTL has a 95% confidence interval between rs3696834 (14.38 cM) and rs3657117 (35.6 cM). Based on our results, genes within our identified loci likely interact with *Tmem135* to affect sudden death by heart failure in young mice.

M5016A Resistance mitigating effect of *Artemisia annua* on *Plasmodium berghei* ANKA and *Plasmodium yoelii*. *Kangethe Lucy*[1,2,3], Sabah Omar[2], Nganga Joseph[3], Kinyua Johnson[3], Hassanali Ahmed[4]. 1) Technical University of Kenya, Nairobi, Kenya; 2) KEMRI, Nairobi ,Kenya; 3) JKUAT, Nairobi, Kenya; 4) Kenyatta University, Nairobi, Kenya.

Resistance of *Plasmodium falciparum* to antimalarial drugs is a major problem in malaria eradication. Artemisinin derivatives particularly in combination with other drugs are thus increasingly used to treat malaria.The study was designed to demonstrate resistance mitigating effect of *Artemisia annua* phytochemicals on *Plasmodium berghei* and *P. yoelii*. Swiss albino mice were inoculated with the murine plasmodia and thereafter treated for 4 days with the *A. annua* and with the pure artemisinin. After 4 days parasitemia was determined and effective doses 50 and 90 were calculated. The doses were utilised to determine concentrations to be used in resistance development.The ED_{50} AND ED_{90} with *P. berghei* were 1.43 and 7.18 mg/kg.day respectively. After 10 exposures and 20 exposures the ED_{50} were determined again and relative sensitivity index (RSI) was calculated as new ED_{50} /ED_{50} initial.

The RSI increased in artemisinin exposed parasites but the same was not true with *Artemisia annua* exposed parasites. Moreover on removal of drug pressure the acquired resistance was not stable and the parasites were more sensitive once more.

M5017B Long-term exercise positively benefits body composition and metabolism during aging in a sex-dependent manner. *R. C. McMullan*[1], S. A. Kelly[2], K. Hua[1], J. Faber[1], F. Pardo-Manuel de Villena[1], D. Pomp[1]. 1) University of North Carolina-Chapel Hill, Chapel Hill, NC; 2) Ohio Wesleyan University, Delaware, OH.

The aging process is associated with declining exercise abilities and unhealthy changes in the ratio of lean body mass to fat. Exercise, even at reduced levels, can ameliorate the physiological changes associated with aging. Exercise is well-known to protect against many chronic diseases and to extend life expectancy. Despite these benefits, willingness to engage in exercise – and physiological responses to exercise – vary widely in human populations. Unfortunately, long-term exercise is difficult and costly to measure in human cohorts. Furthermore, the physiological effects of aging in humans are confounded with important changes in lifestyle and environment that are often difficult to quantify. We used the common inbred mouse strain C57BL/6J to examine long-term patterns of exercise during aging, as well as the resulting physiological consequences of long-term exercise, in a well-controlled environment. Male (n=30) and female (n=30) mice that were already 1 year old (reflecting approximately 40 year old humans) were randomized to treatments of exercise (access to voluntary running wheels) or no exercise until they were 2 years old (reflecting approximately 70 year old humans). Body composition and metabolic traits were measured prior to, throughout, and at the end of the treatment period. Wheel running levels (distance, speed, duration) were greater in females compared to males and declined with age. Sex-dependent differences in body-composition trajectories were observed during the aging process. Long-term exercise significantly reduced body mass and percent body fat, while maintaining percent lean mass; however, the magnitude of these effects was also sex-dependent. This study provides robust evidence that long-term exercise can be used as a preventative measure against age-related weight gain and changes in body composition that have negative implications on health. Furthermore, we demonstrate that inbred mouse strains can be robustly used to characterize the effects of long-term exercise and factors (e.g. sex, age) modulating these effects. This will facilitate more detailed studies on the relationships between exercise and health in aging populations, including the potential impact of genetic predisposition.

M5018C Mutations in PI(3,5)P_2 biosynthesis and neurological disease in human and mouse. *Miriam Meisler*, Guy Lenk. Univ Michigan, Ann Arbor, MI.

Positional cloning of a spontaneous insertional mutation of the gene *Fig4* in 2007 revealed the mammalian role of this endolysosomal gene first studied in yeast. The FIG4 protein functions in a protein complex with VAC14 and PIKFYVE to generate the signaling lipid PI(3,5)P_2. Mammalian neurons are particularly susceptible to reduced levels of PI(3,5)P_2, which result in cell vacuolization and neurodegeneration. Knockout of FIG4 specifically in neurons results in neurodegeneration, and expression specifically in neurons rescues the null mouse. Through a combination of screening and exome sequencing, several human neurological disorders with mutations in this pathway have been identified, including the peripheral neuropathy Charcot-Marie-Tooth Disease and a form of polymicrogyria with seizures. Studies of mice carrying a common human mutation revealed a defect in myelination that is being studied as a model of neuron/glial interaction. The cellular vacuolization phenotype is being used in genetic and chemical screens for modifiers of severity. We have also explored the effects of strain background on *Fig4* phenotypes. The *ingls* mutation of mouse *Vac14* resembles the *Fig4* mutant mouse, and analysis human variants of *VAC14* is in progress. The interplay between human and mouse genetics has been essential to our growing understanding of the function of PI(3,5)P_2 signaling in mammalian cells.

M5019A Systematization of the regulation of mammalian chromosome biology with evolutionary genetics & OMICs: A synopsis - 2016. *F. S. Nallaseth*[1,2,3,4,5,6,7,8,9], R. Felder - Gibbions[10], Z. S. Guo[5,11], J. Ceci[4,12], I. S. Han[13], R. DeLisio[6], M. J. Dewey[4], D. Woodbury[10], L. A. Schein[10], M. L. Tracey[8], J. B. Whitney III[3]. 1) LISNJ, Belle Mead, NJ 08502; 2) CBSA, Boston, MA; 3) MCG, Augusta, GA 30912; 4) USC, Columbia, SC 29208; 5) Huffington CA, MCB, Baylor CM, Houston, TX 77030; 6) RIMB, Nutley, NJ 07110; 7) FHCRC, Seattle, WA 98109; 8) FIU, Miami, FL 33199; 9) FAU, Boca Raton, FL 33431; 10) RWJUH, Piscataway, NJ 08854; 11) U Pittsburgh Cancer Inst, Pittsburgh, PA 15213; 12) HJKRI, U Buffalo, NY 11427; 13) U Ulsan, Seoul, Korea.

Application of principles regulating evolutionary genetics, testis determination (TD) & chromosome biology confirm induction of Y rearrangements & epigenetic modifications in interspecific (IS) combinations of mouse genomes & Y chromosomes. Chimeric adult males with >90% XX somatic & testicular cells confirm *Sry* dispensability. This & 3 methods confirmed genetically modulated rearrangements in the direct & inverted repeat (DR/IR) dense ~200 kb TD *Sxr*-region spanning the 34 kb IR *Sry* locus/gene of fertile males, at high frequency in all tissues, germlines & species. This is consistent with the spectrum of high frequency serendipitous subversions of chromosome biology (SHFSSCB) reported in IS mice from natural hybrid zones (NHZ) & lab matings. Induction by unbiased, evolutionary divergence, rather than by drug or heteroduplex selection, retains the pathological relevance of errors in endogenous sequences, native loci & developmental contexts - with systematization & control of inducing networks by mouse genetics. Also isolated is a putative retrotransposon encoded fusion ORF: SRY-HMG (splice site?)-LINE-1 transposase. *Sry* & yeast (*S.c.)* IR are similar as known sites of double strand breaks (DSB) processed into double Holliday Junctions (dHJ) & their rearrangement products. In *S.c.* (& mouse?) the choice between dissolution (& repair) or resolution (& deletions) of dHJ is a consequence of the interactions of the Sgs1 helicase/Top3 topoisomerase/Rmi1 heteromer with Rad51. EMSA & 'Pull Down' assays confirm that Rmi1 & Top3/Rmi1 preferentially (>10x) bind HJ over 10 synthetic recombinational or replicational structures. The dimer but neither monomer, stimulates Sgs-1N/HJ complex formation. Complexes with HJ have ~6x> affinity than with pseudoreplication forks (pRF) & so this choice between the 2 activities of Sgs1 at stalled forks may be imposed by DNA structure & the dimer. Structural similarity with unstable replication slow zones (RSZ)/fragile sites (FS) & *cis* suppressors of viral *Oris* may also predict *Sxr* instability. These results are a basis for an unbiased & integrative approach to systematizing, surveilling & controlling mammalian genome biology, preempting (disease) mutations & shifting therapeutic paradigms!

M5020B A Novel Mouse Model of Leptomeningeal Melanocytic Disease Based on the Overexpression of GRM1 (mGluR1). *Joseph W. Palmer*, Juliano Freitas, Lida Kos. Florida International University, Miami, FL.

Leptomeningeal disease (LMD) is a rare form of cancer that forms in the two inner most layers that surround the central nervous system (CNS) called the leptomeninges. The leptomeninges is made up of the dura mater and the arachnoid layer, and is responsible for the circulation of cerebral spinal fluid (CSF) throughout the CNS. The occurrence of primary LMD is extremely rare, and there are limited case studies involving the pigment producing cells called melanocytes that naturally reside in the leptomeninges. When these melanocytes become oncogenic they can produce pigmented lesions in the CNS called melanocytomas. Recent evidence indicates that leptomeningeal melanocytic tumors in adult patient's harbor mutations in GNAQ and GNA11, two G proteins that are activated downstream of certain G protein coupled receptors(GCPRs) such as metabotropic glutamate receptor 1, GRM1 (mGluR1). Transgenic mice that overexpress *Grm1* exclusively in melanocytes under the regulation of the dopachrome tautomerase promoter, B6-Tg(Dct-Grm1)ESzc, spontaneously form cutaneous melanocytic neoplasia in the ears and tails. The goal of this study was to investigate if the overexpression of *Grm1* in leptomeningeal melanocytes also lead to the formation of LMD. Tg(Dct-Grm1)ESzc mice showed a significant increase in the accumulation of ectopic pigment in the posterior region of the brain specifically along the transverse sinus between the cerebellum and cortex. The transgenic mice also presented large melanocytic lesions on the cranial floor. 73.9% of mice examined (n=23) exhibited bilateral or unilateral ectopic pigment distribution in the posterior region of the brain. While in control mice no pigment was found (n=5). These results show that the upregulation of *Grm1* increases the distribution of pigment found associated within the CNS of mice. With limited treatment available to patients, the significance of this study lies in the development and characterization of a reliable mouse model for this rare tumor type so as to provide insight into the mechanism at work and possible treatment approaches.

M5021C One RING to Rule Them All: RNF212 Regulates The Size of The Ovarian Follicle Pool. *H. Qiao*, H. Neil. UC Davis, Davis, CA.

A key determinant of female reproductive lifespan is the size of the resting oocyte pool following extensive oocyte elimination during fetal and perinatal periods. Excessive oocyte culling occurs in response to excessive transposon activity, defects in meiotic prophase, and various forms of DNA damage. For example, in mice lacking SPO11 or MSH4, two key recombination factors, normal numbers of oocytes are present at birth, but most oocytes die within a few days. *Rnf212* encodes a RING-family E3 ligase that promotes protein modification by the ubiquitin-like molecule, SUMO. We previously showed that RNF212 acts at recombination sites to promote chromosomal crossing over. Unexpectedly, we now show that *Rnf212* mutation restores the resting oocyte pools of both *Spo11* and *Msh4* mutants. These data implicate RNF212-mediated SUMOylation as a novel aspect of the meiotic checkpoint-signaling pathway that leads to oocyte apoptosis.

M5022A Effect of ketogenic diet on endurance running performance in males and females of two genetically distinct mouse strains. *Andreea Radulescu*[1], William Barrington[2], David Threadgill[2]. 1) University of Surrey, Guildford, Guildford, GB; 2) Texas A&M University, College Station, Texas, USA.

Proper nutrition is a key component of athletic performance. Traditionally, endurance athletes have used high-carbohydrate diets to maximize glycogen stores and fuel their performance. Low-carbohydrate, high-fat ketogenic diets, however, have recently gained popularity among endurance athletes to boost performance and fat loss. Athletes assert that adaptation to a low-carbohydrate diet can improve the body's ability to utilize fat stores by increasing its ketone utilization. The few human studies that analyzed the impact of low-carbohydrate diets on endurance performance show mixed results. However, these studies have very low sample sizes and only examined males. We found that a ketogenic diet can greatly increase endurance running performance in a genetic background- and sex-dependent manner. The study compared forced running performance of five C57BL/6J and FVB/NJ mice of each sex fed ad libitum Western or ketogenic diets for three months. Ketogenic diet-fed C57BL/6J female mice increased their running distance by 89% versus Western diet-fed mice. Male C57BL6/J mice, however, did not have a significant diet effect. FVB/NJ mice of both sexes improved running distance. Ketogenic diet-fed female FVB/NJ mice increased running distance by 70% and males by 49%. The results were independent of fat mass of the mice. Current studies are investigating whether sex-specific hormones are involved in the disparate effects of ketogenic diet on running performance in male and female C57BL/6J mice by ovariectomizing and castrating mice and comparing their forced running phenotype to sham surgery controls. Assessing the role of sex hormones in adaptation to a low-carbohydrate, high-fat diet will help identify the cause of the sex differences on endurance running performance leading to a better understanding of the role of ketogenic diets on exercise performance and the improving ability to identify individuals who might benefit from a ketogenic diet.

M5023B IMPC metabolic phenotyping: Systemic search for new gene functions associated with disturbances in energy balance regulation and glucose homeostasis. *Jan Rozman*[1,10], Robert Brommage[1], Birgit Rathkolb[1,2,10], Manuela Oestereicher[1], Stefanie Leuchtenberger[1], Martin Kistler[1], Valerie Gailus-Durner[1], Helmut Fuchs[1], Eckhard Wolf[2,10], Martin Klingenspor[3,4], Monica Campillos[5,10], Aakash Chavan Ravindranath[5,10], Thomas Werner[6,7], Christine Schuett[1], The IMPC Consortium[9], Martin Hrabe de Angelis[1,8,10]. 1) German Mouse Clinic, Inst. of Experimental Genetics, Helmholtz Zentrum Muenchen, Germany; 2) Inst. of Molecular Animal Breeding and Biotechnology, Gene Center, Ludwig-Maximilians-Universitaet Muenchen, Germany; 3) Technical University Munich, Else-Kroener-Fresenius Center for Nutritional Medicine, TUM School of Life Sciences Weihenstephan, Freising, Germany; 4) Technical University Munich, ZIEL - Institute for Food and Health, Freising, Germany; 5) Systems Biology of Small Molecules, Institute of Bioinformatics and Systems Biology, Helmholtz Zentrum Muenchen, 85764 Neuherberg, Germany; 6) Departments of Internal Medicine and Nephrology, University of Michigan, Ann Arbor, Michigan, USA; 7) Genomatix GmbH Muenchen, Germany; 8) Chair of Experimental Genetics, Center for Nutrition and Food Sciences Weihenstephan, Technische Universitaet Muenchen, Germany; 9) The International Mouse Phenotyping Consortium, MRC Harwell, Oxfordshire, UK; 10) German Center for Diabetes Research, Helmholtz Zentrum Muenchen, 85764 Neuherberg, Germany.

The International Mouse Phenotyping Consortium (IMPC) aims to generate, phenotype, and offer a knock-out mouse model for every protein-coding gene. Disturbances in energy balance regulation or glucose homeostasis result in diseases such as obesity and type 2 diabetes mellitus. We are especially interested in genes linked to these metabolic disorders. Therefore, IMPC phenotyping data were used to identify novel genotype-phenotype associations. From the IMPC adult phenotyping pipeline we selected 7 clinically relevant parameters: (1) blood glucose levels after overnight fasting, (2) area under the curve during the glucose tolerance test, (3) non-fasting triglycerides, (4) body mass, (5) metabolic rate and (6) oxygen consumption both normalized to body mass, and (7) respiratory exchange ratio. Depending on the completeness of uploaded data, phenotyping data were obtained from 329 mutant lines (for metabolic rate) to 1649 mutant lines (for body mass). Phenodeviants were selected based on the ratio of absolute mean mutant divided by absolute mean wildtype (wt) parameter values, resulting in a new index value that ranged between 0.2 (i.e. 20% of wt) and 2.8 (i.e. 280% of wt) depending on the parameter. In brief, we could both confirm published knowledge regarding functional associations to metabolism (*Mrap2* and *Cpe*) as well as identify novel genes that could be linked to human disorders. The combination of more than one parameter ratio (e.g. strong deviations in glucose clearance, fasted blood glucose, and triglyceride levels in 1.4 % of the genes) also helped to detect new disease models. The dataset may be useful for analysis of metabolic pathways and identification of novel regulatory networks.

M5024C Extracellular matrix perturbations in the urinary tract of mouse model of vesicoureteral reflux. *F. Tokhmafshan*[1], I. Gupta[2]. 1) McGill Univ., Montreal, Canada; 2) McGill Univ., Montreal, Canada.

Background: Anomalous development of the ureterovesical junction (UVJ), which joins the ureter to the bladder, is associated with vesicoureteral reflux (VUR): the abnormal retrograde flow of urine from bladder towards the kidneys. VUR is prevented by the muscular layer of the ureters and the bladder that function like a valve to occlude the UVJ. Human studies have demonstrated that refluxing UVJs have elevated levels of fibrillary collagens and degeneration in the smooth muscle layer. This suggests that the integrity of the ECM is crucial for preventing VUR.

Hypothesis: Perturbations in the expression and assembly of fibrillary collagens and elastic fibres, as well as the smooth muscle composition of the developing urinary tract result in a UVJ that refluxes.

Results: The inbred C3H/HeJ (C3H) mouse line has been previously shown by our laboratory to be a fully penetrant model of recessively inherited VUR with a UVJ defect. We have mapped VUR in the C3H mouse to the *Vurm1* locus (LOD=7.4) spanning 22Mb on the proximal end of Chromosome 12. Within this locus we have identified putative disease-causing variants in a number of ECM-related genes such as *Itgb8, Itgbp1, Lmb1, Fbln5*. The C3H as well as the non-VUR C57Bl/6J (B6) mouse line have been used to study the above mentioned ECM components throughout urinary tract development (embryonic day (E)15, newborn, adult) using special stains: Sirius Red (fibrillary collagens), Masson's trichrome (collagen), Verhoeff's Van Gieson (elastic fibres), as well as immunohistochemistry and western blot analysis. Type I and type III collagens are detected in the musculature layer of the ureter and the bladder at E15, and they are also observed in the lamina propria starting at the newborn stage. Collagen fibres grow in length and thickness with age with a preponderance of type I collagen noted in adult mice. Elastic fibres are sparse and interwoven between collagen fibres in the lamina propria and the musculature of the ureter and the bladder in newborn and adult mice. Starting at the newborn stage, the relative amount of fibrillary collagens in the ureter and the bladder of C3H mice is significantly higher than in B6 mice. The musculature of the bladder in C3H mice exhibits degenerative changes at the newborn stage that continue to adulthood. While there are no qualitative differences in elastic fibres in the ureter and bladder of C3H vs. B6 mice, quantitative analysis is ongoing. The increase in the fibrillary collagen content of the bladder and ureter in C3H mice could result in a stiffer bladder and UVJ that prevents the occlusion of the UVJ and results in VUR.

Conclusion: Our results suggest there is a link between ECM perturbations and VUR.

M5025A Translating between human and mouse genetics and phenotypes using the Human-Mouse: Disease Connection. *M. Tomczuk*, S. M. Bello, C. L. Smith, J. A. Kadin, J. E. Richardson, J. T. Eppig, the MGI Staff. The Jackson Laboratory, Bar Harbor, ME.

The mouse is an excellent translational model for human disease research, providing rich phenotype-to-genotype data for studying disease mechanism, as well as evoking candidate genes for human diseases and suggesting new mutant model development in mice. Mouse Genome Informatics (MGI, www.informatics.jax.org), has developed the Human-Mouse:Disease Connection (HMDC, www.diseasemodel.org) portal for improved access to and visualization of these data. Search results in the HMDC are displayed in interactive grids and tables that are dynamically linked to MGI data such as detailed gene and phenotype information, pertinent disease model references, and available mouse model resources through repositories via the International Mouse Strain Resource (IMSR). Here we use human Myelodysplastic Syndrome (MDS) as an example of how MGI search tools aid in identifying available mouse models of human disease, quickly provide access to information on genes known to cause the disease, and identify human candidate disease genes and possible treatment targets.

MDS is a group of hematopoietic disorders in which the bone marrow does not produce sufficient blood cells. To identify experimental mouse models of MDS, investigators can search for disease terms in the HMDC. The results of a search on 'Myelodysplastic Syndrome' show that mutations in the *ASXL1* human gene are implicated in MDS and that mutations in the *Asxl1* mouse homolog show analogous symptoms. This model may be explored for possible therapy targets. The table indicates seven other mouse genes (*Atg7*, *Bap1*, *Crebbp*, *Mybl2*, *Polq*, *Samd9l, Srsf2*) with mutations that are reported as MDS models that are not yet associated with the human ortholog as causative genes of the disease in human and may be new potential candidate disease genes. Three human genes (*GATA2*, *SF3B1*, *TET2*) are implicated in this condition in which orthologous mouse mutants have not yet been reported to model this syndrome. Mutations targeting these mouse genes may be interesting to evaluate as potential murine disease models. In addition, the Phenotypes and Alleles Query form can be used to search by phenotypic terms, such as 'abnormal myelopoiesis' and 'anemia' to obtain a comprehensive list of mutant mouse alleles presenting phenotypes similar to human disease symptoms.

Coming in August 2016, the HMDC will see some exciting changes, including a simplified query form and the incorporation of the Human Phenotype Ontology so that mouse phenotypes can be more directly compared with human disease phenotypes, allowing for easier translation between mouse and human data. Supported by NHGRI grant HG000330.

M5026B Identifying enhancers that regulate genes critical in mouse spermatogenesis. *T. Tran*, John Schimenti. Cornell University, Ithaca, NY.

Enhancers are non-coding DNA fragments that increase the concentration of active transcriptional machinery at promoter sites, therefore to positively drive gene expression. Furthermore, enhancers are known to reside in regions of open chromatin, range from 50 bases to 20 kilobases long, and contain sequences necessary for transcription factor and/or coactivator binding (Li et al., 2016). Beyond these characteristics and a handful of previously identified enhancers, there is much more to learn. A good way to start is by identifying enhancers sequences at a genome-wide level.

We aim to identify enhancers that regulate meiotic genes, specifically genes involved in spermatogenesis. Spermatogenesis is the male version of meiosis, where primordial germ cells undergo two rounds of cellular division to produce four haploid spermatozoa. It is critical that all genes necessary for spermatogenesis are transcribed at the correct time and place, otherwise viable sperm cannot be produced and the organism is infertile. To identify enhancer sequences involved in spermatogenesis, we will use two genome-wide sequencing techniques, ATAC-seq and PRO-seq, on mouse spermatocyte DNA. Both techniques allow us to map the chromatin state, nucleosome patterning, and RNA polymerase positioning across the entire spermatocyte genome. Along with the fact that enhancers are situated within 50KB of a gene's transcription start site (TSS), we can compare our list of spermatogenesis genes and their known TSS loci to the genomic profile and predict enhancer sequences.

Loss-of-function mutants are usually associated with having point mutations or indels in the gene's coding sequence. Therefore, translation goes awry and growing peptide chains have incorrectly incorporated amino acids or truncation due to early stop codons. However, an alternative hypothesis is that disrupted gene expression is due to mutations in the gene's non-coding sequence, like an enhancer. A future aim is to incorporate previously discovered non-synonymous, single nucleotide polymorphisms (SNPs) into identified enhancer sequences and look at the effects on gene transcription.

M5027C Investigating the phenotype of *Lyplal1* knockout mice. *R. A. Watson*, A. S. Gates, F. E. Calvert, W. E. Bottomley, Sanger Mouse Pipelines, C. J. Lelliott, I. Barroso. Wellcome Trust Sanger Institute, Cambridge, GB.

Several GWAS studies have found an association between variants close to the lysophospholipase-like 1 (*Lyplal1*) locus and metabolic traits, including central obesity, fatty liver and waist-hip ratio (where the effect is more significant in females than males). LYPLAL1 is also upregulated in the adipose tissue of obese patients, and a mutation has been identified in a lipodystrophic patient with no other known mutation. However, the physiological role of LYPLAL1 is not fully understood. We investigated the role of LYPLAL1 using a knockout mouse model.

Lyplal1 knockout mice (C57BL/6N-*Liplal1*$^{tm1b(KOMP)Wtsi}$, from the KOMP repository) were initially characterised on a normal chow diet by the Sanger Mouse Pipeline, with no phenotype observed. The mice were then challenged by being placed on a high fat diet (HFD) at 6 weeks of age. The phenotype of these mice was investigated up until 28 weeks of age using various tests, including DEXA body composition analysis, glucose and insulin tolerance tests and indirect calorimetry. *Lyplal1*$^{-/-}$ mice were indistinguishable from wild type mice in all *in vivo* tests performed. Several tissues were collected for further *ex vivo* analysis. *Lyplal1* knockout was confirmed by Western blot. However, no effect of *Lyplal1* knockout was observed on organ weight or on the expression of a range of metabolic genes. Further investigations including tissue morphology analysis and RNAseq are ongoing, to gain a better understanding of the biological role of LYPLAL1.

M5028A Analysis of odor identification in B6;129-*Psen1*^{tm1Mpm} Tg(APPSwe, tauP301L)1Lfa/Mmjax mice. *Lisa S. Webb*, Stephen Fink, Quinton Pace, Rachel Schendzielos, Nazifa Khan, Benjamin Genovese, Katie Whitcomb, Emma Croushore, Harold J. Grau, Darlene A. Mitrano. Christopher Newport University, Newport News, VA.

Alzheimer's Disease (AD) is a progressive neurodegenerative disease affecting a significant and growing proportion of the elderly population. There are several mouse models exhibiting a variety of AD phenotypes on a multiple genetic backgrounds available to study AD. The model we use is the B6;129-*Psen1*^{tm1Mpm} Tg(APPSwe,tauP301L)1Lfa/Mmjax (3xTg-AD) mouse, a triple transgenic model that develops both the amyloid-b plaques and neurofibrillary (tau) tangles. Our study aims to provide more information regarding the various cognitive and biochemical characteristics of the 3xTg-AD model compared to the background and parental strains. Here we report our preliminary data buried food tests examining olfactory effects, specifically the ability to *identify* (rather than discriminate between) odors.

M5029B SIK1 is a key regulator of adipose mass, glucose and lipid metabolism in mice. *D. West*[1], S. Roy[1], AJ Nava[1], M. Adkisson[1], K. Lloyd[2]. 1) Childrens Hospital of Oakland Research Institute, Oakland, CA; 2) University of California, Davis, CA.

SIK1 is a serine/threonine kinase belonging to a three-member AMP-activated protein kinase family. Both SIK2 & SIK3 reportedly have roles in lipid and glucose metabolism in adipose tissue and liver respectively, while a functional role for SIK1 in adipose tissue or liver function has not been described. In a preliminary study, we found decreased adipose depot mass in both female and male *Sik1*$^{tm1(KOMP)Vlcg}$*-/-* mice at ~50-days-of-age mutants with normal body weight. In a follow-up study conducted as part of the KOMP2 adult phenotyping pipeline (http://www.mousephenotype.org/impress), we found significant differences in body composition, glucose & lipid metabolism (all $p < 0.0001$; Mixed Model; n=8 F *Sik1-/-* , n=246 F *Sik1+/+*, n=8 M *Sik1-/-*, n=239 M *Sik1+/+*). Compared to control mice, *Sik1*$^{tm1.1(KOMP)Vlcg}$*-/-* mice exhibited dramatically reduced body fat and body fat/body mass ratios (fat mass/total mass: F-/- = 0.13 ± 0.01; F+/+ = 0.186 ± 0.002; M-/- = 0.114 ± 0.01; F+/+ = 0.220 ± 0.003; Mean ± SEM), and a significantly increased lean mass/body mass ratio. In addition, there were significant decreases in

circulating total cholesterol, HDL-cholesterol, and insulin relative to controls, and a markedly improved area under the glucose tolerance test compared to controls. At 50 days of age, *Sik-/-* male mice had significant alterations of gene expression in liver, muscle, and adipose tissue consistent with a derangement of lipid and glucose metabolism. These data support a role for SIK1 in the regulation of adipose mass, glucose and lipid metabolism. Supported by NIH grants U42OD011175, U54HG006364, DK085124.

M5030C High-throughput multi-system phenotyping identifies pleiotropy and novel gene function. *D. West*[1], I. Morse[2], C. McKerlie[3], K. Lloyd[4], The DTCC-KOMP2 Consortium[1,2,3,4]. 1) Children's Hospital of Oakland Research Institute, Oakland, CA; 2) Charles River Laboratories, Wilmington, MA; 3) The Center for Phenogenomics, Toronto, Canada; 4) University of California, Davis CA.

Our ongoing project's goal is to discover and relate poorly-annotated genes to informative functional information and identify novel phenotypes associated with human disease as part of a high-throughput mouse production and phenotyping pipeline. Adult phenotyping data are now available for ~680 uniquely targeted mutant mouse strains produced and phenotyped by the DTCC Consortium, one of three members of the NIH KOMP2 project and a part of the International Mouse Phenotyping Consortium (IMPC). Mutants were produced from genes prioritized on the basis of interest expressed by the scientific community and selected for having little to no pre-existing functional annotation. Mice for this pipeline were generated by microinjection of targeted C57BL/6N stem cells, chimeric founders were backcrossed to C57BL/6NCrl mice, and target-confirmed heterozygous mutant mice were intercrossed to produce homozygotes for phenotyping. A total of 197 lines were either embryo lethal or partially subviable prior to weaning as homozygotes, and for a subset of these lines adult phenotyping was completed in heterozygous mice. The phenotyping pipeline uses 16 mice (8 females; F, 8 males; M) per strain and co-raised wild type controls. Mice enter the standardized IMPC comprehensive adult phenotyping pipeline (http://www.mousephenotype.org/impress) at ~9 weeks of age, with weekly tests ending in necropsy and blood collection at week 16. We found one or more phenotypic difference compared with controls in ~60% of the mutant lines ($p < 0.0001$; Mixed Model Analysis). Individual phenotypes (not including viability) were assigned to 16 broad categories. The most frequent phenodeviants were found in tests assessing metabolism (clinical chemistry, glucose tolerance test, and indirect calorimetery), behavior, the nervous system (auditory brain stem response and prepulse inhibition), and the musculoskeleton system (bone mineral content and bone morphology). Examples of pleiotropic, statistically validated, and characterized phenotypes from each of these categories will be presented. These findings provide significant novel functional annotation for many genes of interest to the scientific community. Data are readily available at: http://www.mousephenotype.org/; and mutants can be recovered from cryopreserved germplasm at https://www.komp.org/. Supported by NIH grants U42OD011175, U54HG006364. We thank the outstanding efforts of the DTCC Production and Phenotyping Teams.

M5031A Newly formed heterotopic bone in Fibrodysplasia Ossificans Progressive still requires Activin A for maintenance and expansion. *LiQin Xie*, Lily Huang, Nanditha Das, Xialing Wen, Lili Wang, Genevieve Makhoul, Andrew Murphy, Vincent Idone, Aris Economides, Sarah Hatsell. Regeneron Pharmaceuticals, Tarrytown, NY.

Fibrodysplasia ossificans progressiva (FOP) is a rare genetic disorder characterized by episodic but cumulative heterotopic ossification (HO). The HO in FOP develops by an endochondral process that involves a cartilage intermediate and which overall appears to mirror normal endochondral bone formation. As this heterotopic bone develops, it connects to the normal skeleton (by a process that is currently not understood), and these connections eventually start to bridge joints, resulting in progressive immobility, and eventually death. FOP is caused by mutations in the type I BMP (bone morphogenetic protein) receptor ACVR1, the most mutation altering arginine 206 to histidine ($ACVR1^{R206H}$). We have generated a genetically and physiologically accurate mouse model of FOP – 129;B6N-$Acvr1^{tm2Vlcg}$ ($Acvr1^{[R206H]FlEx}$)/+ Gt(ROSA26)$Sor^{tm3.1(cre/ERT2)Vlcg}$/+. In this model, the HO process is initiated by treating the mice with tamoxifen, that effectively converts the conditional allele – $Acvr1^{[R206H]FlEx}$ – to its mutant counterpart – $Acvr1^{R206H}$ – thereby generating mouse cohorts with the same genotype as FOP patients. Using this model, we demonstrated that there is an absolute requirement for activin A to kickstart the process of HO. This requirement for activin A was demonstrated *in vivo* using neutralizing antibodies to activin A. However, in these experiments the anti-activin A antibody was administered at the same time as initiation of HO, and hence this setting only addressed the requirement of activin A at the initial stages of HO, prior to the formation of cartilage. We explored whether activin A continues to play a role after the endochondral process has started and even when partly mineralized heterotopic lesions could be observed. Our results indicate that inhibition of activin A with a fully human monoclonal antibody completely blocks formation of HO in this model of FOP when the antibody is administered 9 days after initiation of the model. To further test delayed treatment's effect on already formed – yet still nascent – HO, anti-activin A Ab was injected at 3 weeks post initiation of the model. With 3-weeks treatment, existing HO volume (lesion size) decreased by 37±41 mm^3 in activin A Ab treatment group ($p<0.05$), while it increased by 19±45 mm^3 in isotope control group. In summary, these results demonstrate a continued role for activin A even after mineralized heterotopic bone lesions have formed and indicates that anti-activin A may be able to reverse the progression of nascent (and not fully mineralized) heterotopic bone.

M5032B A trypsin-like protease from *Alternaria alternata* allergens promotes airway inflammation through activation of protease-activated receptor-2/β-arrestin signaling. *M. C. Yee*[1], H. L. Nichols[1], K. Pal[1], D. Polley[2], K. J. Lee[1], M. Ming[1], M. D. Seigler[1], M. D. Hollenberg[2], M. O. Daines[3], S. Boitano[3], K. A. DeFea[1]. 1) University of California, Riverside, CA; 2) University of Calgary, Calgary, AB, Canada; 3) University of Arizona, Tucson, AZ.

Fungal *Alternaria alternata* exposure is correlated with increased morbidity and a higher risk of fatal asthma attacks in asthmatic patients. *Alternaria* allergens contain serine proteases capable of activating coagulation factor II (thrombin) receptor-like 1, F2RL1, [proteinase-activated receptor-2 (PAR_2)] and promote airway inflammation that is dependent upon protease activity. We have previously shown that PAR_2-dependent airway inflammation is mediated through the β-arrestin 2 activated pathway. Thus, we hypothesized that proteases from *Alternaria*

filtrates will promote activation of the β-arrestin 2 (ARRB2) dependent cellular signaling pathways that mediate airway inflammation in murine models of *Alternaria*-induced asthma. We identify a single alkaline serine protease, with trypsin-like characteristics, AASP (Alternaria Alkaline Serine Protease) that can activate PAR_2, as demonstrated by recruitment of β-arrestin 2 to PAR_2 and mobilization of intracellular Ca^{2+} in cultured cells. Using histological and flow cytometric analyses, we demonstrate that *Alternaria*-induced airway inflammation requires both PAR_2 and ARRB2, as demonstrated by the reduced recruitment of leukocytes (particularly eosinophils and CD4+ T-cells) into the lung, goblet cell hyperplasia, and thickening of the lung epithelium in B6-*F2rl1*^{tm1Jkaw}/*F2rl1*^{tm1Jkaw} or B6-*Arrb2*^{tm1Rjl}/*Arrb2*^{tm1Rjl}, compared to wild-type mice. These inflammation parameters are also reduced by treatment of mice with Soybean Trypsin Inhibitor (SBTI) during the administration of *Alternaria* allergens, indicating that AASP is likely necessary for the inflammation induced by *Alternaria*. These are the first experiments demonstrating that the PAR_2-β-arrestin 2-dependent signaling axis is important for asthma induced by household allergens. Our studies also suggest that targeting this pathway via biased antagonism with a PAR_2-targeted ligand could be a new avenue of therapeutic intervention for asthma.

M5033C An OVA-sensitized and MCh-challenged mouse phenotyping screen for new genes involved in lung function and respiratory disease. *Y. Zhu*[1], Mohammad Eskandarian[1], Ann Flenniken[1], Amy Woroch[1], Lily Morikawa[1], KC Kent Lloyd[2], Frank Benso[3], Colin McKerlie[1], The DTCC-KOMP2-Phase1 Consortium. 1) The Centre for Phenogenomics, Toronto, ON, CA; 2) Mouse Biology Program, University of California, Davis, USA; 3) Charles River Laboratories, Wilmington, USA.

This project's goal was to discover and relate poorly-annotated genes to respiratory function and inflammatory lung disease as part of a high-throughput mouse production and phenotyping pipeline. Sixty strains of knockout mice were produced, expanded, and screened using 16 mice (8 females; F, 8 males; M) per strain. Twelve mice (6F, 6M) were homozygous knockouts and 4 mice were co-raised wild type controls (2F, 2M). All mice were sensitized with an inert allergen (ovalbumin; OVA) over 21 days. On day 22 mice were challenged with a non-allergen airway agonist (Methacholine; MCh) followed by measurement of enhanced pause (Penh), respiratory rate, tidal volume, peak expiratory flow (PEF), and expiratory time (Te) using unrestrained whole-body plethysmography (WBP) to assess respiratory function, lung development, and airway hyperreactivity. Measurements were taken at baseline and at concentrations of 0, 12.5, 25, and 50 mg/ml MCh. In addition serum immunoglobulin (OVA-specific IgG_1 and IgE) was measured by ELISA and standardized semi-quantitative histopathology scoring was used to assess allergic airway disease and acquired immune response/TI hypersensitivity. Scoring evaluates airway wall thickening, inflammatory cell infiltration, fibrosis, and Clara cell hyperplasia characterized by hyper secretion, mucus metaplasia, and airway mucus plugging.

The 60 strains of knockout mice had cumulative histopathology scores between 1.25 and 2.94 compared to the wild-type average of 1.93 (n=231). The 5 genes which caused the highest scores (2.31 – 2.94) were: *Svs2*, *Slc47a2*, *Adipoq*, *Fbxl22*, and *Arap1*. These 5 strains also had either significantly increased Penh ($p \leq 0.05$), or decreased PEF ($p \leq 0.05$), or increased Te ($p \leq 0.05$), or a combination of increased Penh and decreased PEF compared to wild type mice. The 5 knockout strains with the lowest histopathology scores had no abnormal WBP measurements.

We report a standardized and validated method to screen presumptive null mutant mouse strains with poorly annotated genes for abnormal phenotypes associated with respiratory function and inflammatory lung disease. Strains with high histopathology scores correlated with abnormal lung function results. One strain with decreased tidal volume and Penh (airway hyperreactivity) after sensitization may be particularly interesting as a potential drug target. All of the mouse strains used in this screen are freely available to the research community and may provide new models for hypothesis-driven mechanistic studies or purpose-driven drug target research.

M5034A Investigating Operative DNA Damage Response Pathways in Mouse Primordial Germ Cells. *J. C. Bloom*, J. C. Schimenti. Cornell University, Ithaca, NY.

The ability of organisms to pass their genetic information onwards to subsequent generations is crucial for survival and propagation of a species. In mice, primordial germ cells (PGCs) are set aside very early in development to become the germline lineage. PGCs are first distinguishable as a group of 45 cells in the epiblast of 6-6.5 day old embryos (E6-6.5). These cells then simultaneously migrate and proliferate to the genital ridges (the location of the future gonads) at E10.5 and by E13.5 the population of PGCs reaches its ultimate peak of approximately 25,000 cells.

Because DNA replication associated with rapid PGC proliferation is subject to spontaneous errors, and because PGCs carry the genetic information that will be passed down to the next generation, mechanisms exist to avoid the propagation of these mutations. In accordance with the desire to maintain genomic integrity in the germline, studies have revealed that PGCs are, to a greater extent than somatic cells, highly sensitive to genetic defects and environmental perturbations affecting DNA. While studies of cultured somatic cells and single-celled eukaryotes such as yeast have elucidated DNA damage response pathways, cell cycle checkpoints, and DNA repair mechanisms, our understanding of these processes in the mammalian germline is much less clear. To investigate how genomic integrity is maintained in the mammalian germline, we are characterizing DNA damage response mechanisms in primordial germ cells. We found that mutations affecting two different DNA damage response pathways: Fanconi Anemia that respond to errors in DNA replication and MCM9 being involved in double strand break repair, trigger cell cycle slowdown rather than apoptosis. Double mutant analyses suggested that canonical checkpoint pathways are not involved in responding to these defects in PGCs. To further explore these findings, we are conducting studies to examine mutational burden in mice defective for certain checkpoint pathways, as well as using CRISPR/Cas9 genome editing to develop *in vivo* DNA damage pathway sensors.

M5035B *Top3b*-null Mice Show Defective Neurogenesis, Synaptic Plasticity and Increased Anxiety. *Y. Joo*, W. Peng, Y. Wang, S. Ghosh, K. Fisbein, R. Spencer, H. van Praag, M. Mattson, W. Wang. NIH, Baltimore, MD.

Topoisomerase 3b (TOP3B), the first RNA topoisomerase, interacts with FMR1 (FMRP), the disease gene product in fragile X mental retardation syndrome. Increasing evidence suggests that TOP3B regulates RNA metabolism and promotes synapse formation. A recent study also shows that individuals carrying deletion of *TOP3B* gene are at increased risk of developing schizophrenia and intellectual disability. However, the functional role and pathologic mechanism of TOP3B in mental disorders are unclear. Here we show that *Top3b*-deficient mice have increased anxiety and intensified fear conditioned memory compared with wild type mice in several behavioral tests. In addition,*Top3b*-deficient mice display enlarged ventricles, a phenotype commonly observed in schizophrenia patients. These enlarged ventricles could be due to reduced proliferation and differentiation of adult neural stem cells in subventricular zone (SVZ) and hippocampus of *Top3b*-deficient mice. Furthermore, we show that two forms of protein synthesis-dependent synaptic plasticity, long-term depression (LTD) and long-term potentiation (LTP) that involve activation of metabotropic glutamate receptors (mGluRs), are impaired in the hippocampus of *Top3b*-deficient mice. Mechanistically, TOP3B binds to a group of mRNAs, which are crucial for adult neurogenesis and newly developed tissue structure; and may regulate an emotional condition including anxiety level and fear memory. Our data demonstrate that TOP3B is required for adult neural genesis and synaptic plasticity, and provides a mechanism for how its mutation can lead to neurodevelopmental disorders.

M5036C Investigating how cytoskeletal protein mutations cause Amyotrophic Lateral Sclerosis disease using neuronal cells differentiated from mouse embryonic stem cells. *Kim Nguyen*, Lisa Schneper, Kathryn Sheldon, Zhonghua Gao, James Broach. Penn State Hershey Coll of Medicine, Hershey, PA.

Amyotrophic Lateral Sclerosis (ALS) affects 15,000 to 21,000 Americans at any one time (ALS association). Unfortunately, this destructive motor-neurodegenerative disease still remains untreatable largely due to a lack of knowledge in the disease mechanisms and a lack of model organism for drug screen. Currently, known causative genetic mutations of ALS only account for ~6% of ALS cases despite the total ALS heritability being 50%. Not only is there a tremendous knowledge gap in the genetic basis of ALS, but also the associated clinical phenotypes are complicated and disconnected to the known genetics. Therefore, the goal of our study is to *identify and characterize the genetic factors underlying the disease and specifically correlating these to various groups of ALS clinical features*. To understand genetic mechanism underlying ALS disease, we have recruited and exome-sequenced more than one hundred ALS patients. In addition to rare damaging variants in ALS causative genes such as *SOD1* and *TARDBP (TDP43)* we have found *de novo* compound heterozygous mutations in cytoskeletal-related proteins such as DNAH2, DYNC2LI1, STARD9 and NRP2. The *ex vivo* functional characterization of mutations were established in mouse embryonic stem cells (mESC) by CRISPR knockout technology with the presumption that compound heterozygous mutations abolish protein function. Two CRISPR targets per gene were generated and transfected into neuronal-fluorescent mESC. Single positive knockout cell were FACS-sorted and propagated for validations. Validated knockout clones then are used for differentiation into motor neurons, astrocytes, and oligodendrocytes. Phenotypes of neuronal cell viability and neurite outgrowth length and numbers are then accessed by live-cell staining, fixed-cell staining and qRT-PCR. The results of the *ex vivo* characterization will establish the roles of cytoskeletal-related proteins in ALS and will also allow us to generate mouse models that could be great contributions to the ALS field.

M5037A Androgen receptor plays distinct roles in prostate basal and luminal cells and is required for rare stem cell activities in both compartments. *Z. Wang*[1], Q. Xie[1], T. Cai[2], H. Corrigan[1], S. Joshua[1]. 1) University of California Santa Cruz, Santa Cruz, CA; 2) National Institute of Biological Sciences, Beijing, China.

Androgen is an important steroid hormone regulating prostate physiology, and its signal through the androgen receptor (AR) plays critical roles in prostate development and cancer progression. It has been shown that prostate stromal AR and epithelial AR have different functions in organogenesis. Yet the role of epithelial AR in prostate homeostasis and cancer initiation remains controversial. Recent studies have provided a clearer picture of the cell lineage relationships in the prostate epithelium, but how AR regulates them is unclear.

Here, using genetic lineage tracing, we carefully investigated the role of AR in different epithelial cell types of the adult prostate. We show that AR has a heterogeneous expression pattern in adult basal cells, and is dispensable for basal cell maintenance. However, AR is cell-autonomously required for the luminal differentiation capability of rare basal stem cells *in vivo*. In contrast, AR loss in luminal cells induces a brief period of cell proliferation and disrupts their normal columnar cell morphology and polarity, but it does not affect luminal cell survival or androgen-mediated regression-regeneration. Interestingly, we find that during regeneration AR is selectively required for the multipotency of castration-resistant *Nkx3-1*-expressing luminal stem cells (CARNs), as it prevents their differentiated daughter cells from apoptosis. Finally, we show that PTEN loss can override AR-loss defects in both basal and luminal compartments to initiate prostate tumors. Our data reveal the multifaceted roles of AR in different prostate epithelial cell types for orchestrating tissue homeostasis *in vivo*, and highlight the distinct mechanisms utilized by AR in rare basal and luminal stem cells. Our results also argue for a less prominent role of epithelial AR in early prostate cancer initiation.

M5038B Mammalian Retinal Regeneration in Response to an α7 nAChR Agonist. *M. K. Webster*, H. B. Bach, C. L. Linn. Western Michigan University, Kalamazoo, MI.

Irreversible vision loss due to disease, age or damage reduces quality of life worldwide and is a substantial burden on national healthcare. Previous studies in this lab have shown that α7 nicotinic acetylcholine receptor agonists are capable of providing neuroprotection in a glaucoma model. We seek to understand if and how the selective α7 nicotinic acetylcholine receptor agonist, PNU-282987, leads to proliferation of adult mammalian retinal neurons in Long Evans rats. To determine if PNU-282987 triggers proliferation of retinal neurons, animals were treated with 1 mM PNU-282987 and 1 mg/mL BrdU twice a day for varying amounts of time. Antiboides against BrdU revealed

that new retinal neurons were generated in a dose and time dependent manner and double labeling using antibodies against specific retinal neurons demonstrated evidence of new photoreceptors, retinal ganglion cells as well as BrdU positive cells in the inner nuclear layer.

A well-established source of new retinal neurons in other vertebrate model organisms is the Müller glia. To determine if Müller glia are the source of new BrdU positive cells in PNU-282987 treated rat eyes, Müller glia and progenitor cells were examined for BrdU colabeling. This demonstrated that Müller glia are in fact BrdU positive and express the proliferation marker PCNA. Further, nestin, a neural progenitor cell marker, and PCNA positive cells were observed in the inner nuclear layer. This data supports the hypothesis that Müller glia give rise to new retinal progenitor cells and that these are the cells that then differentiate and gave rise to different types of mature neurons between 7 and 28 days after treatment with PNU-282987.

To begin to understand the gene pathways responsible for proliferation mediated by the selective α7 nicotinic acetylcholine receptor agonist, mRNA-seq was performed on animals treated with PNU-282987. Our pathway analysis demonstrated that after only 3 days of treatment there was significant changes in a number of key signaling pathways known to be involved in development and retinal regeneration in other vertebrate systems. As adult mammalian neurons do not typically regenerate or proliferate, we conclude that PNU-282987 is somehow reversing this process. Our results will have important implications for uncovering mechanisms to induce dedifferentiation and subsequent regeneration of the mammalian retina.

M5039C A Transgenic Mouse Model for Understanding *cis* and *trans* Mechanisms of lncRNA *Jpx in vivo*. *S. Carmona*, B. Lin, T. Chou, S. Sun. University of California, Irvine, Irvine, CA.

Mammals experience a gene dosage imbalance between males and females due to their differing number of X chromosomes. The contrasting levels of X-linked gene products are resolved by X-Chromosome Inactivation (XCI), in which the long-noncoding RNA (lncRNA) *Xist* is activated in females and coordinates long-term gene silencing of one X Chromosome. *Jpx*, another lncRNA expressed from a locus just proximal to *Xist*, is able to activate *Xist* expression by binding to and removing CTCF protein from the *Xist* promoter. While a *Jpx* deletion is lethal in differentiated female mouse embryonic stem (mES) cells, *Jpx* overexpression causes ectopic *Xist* expression in both male and female mES cells. This project aims to understand how well our knowledge of *in vitro* lncRNA mechanisms remain true *in vivo* (in a live animal), specifically for *cis* and *trans* gene regulatory mechanisms. Thus, we used a BAC transgene to produce mouse lines overexpressing *Jpx* [Tg(Jpx)#Shsn], or *Jpx* and *Xist* together [Tg(Jpx, Xist)#Shsn]. We found that transgenic animals are viable, visibly normal, and fertile. Both male and female parents are able to transmit the transgene to their offspring; however, in certain lines we observed a significant lack of transgenic mice derived from the male parent. We also found that *Jpx* and *Xist* expression tend to increase together when located proximally to each other (in Tg (Jpx, Xist) mice), indicating that *Jpx* has a *cis* preference *in vivo*. Our data suggest that *Jpx* holds a consistent mechanism *in vitro* and *in vivo*, and that*Jpx* may have an unstudied role in spermatogenesis and imprinting.

M5040A The cytosine methylase DIM-2 and the H3K9 methylase DIM-5 mediate clustered mutation of repetitive DNA sequences in *Neurospora crassa*. *E. Gladyshev*, N. Kleckner. Harvard University, Cambridge, MA.

In somatic cells of mammals, plants and filamentous fungi, repetitive DNA is normally silenced in the form of heterochromatin with the contaminant occurrence of methylated cytosines (5mC) and methylated histone H3 lysine 9 residues (H3K9me2/3). The basis for the selective silencing of repetitive sequences has been proposed to involve aberrant products of DNA replication and repair, sequence-specific binding proteins, and RNA-based mechanisms. The pathway of heterochromatin assembly has been elucidated in particular detail in the filamentous fungus *Neurospora crassa*. In this organism, DNA methylation is established by DIM-2, a classical cytosine methylase, which is recruited to chromatin by the physical association with HP1 that recognizes H3K9me3 created by DIM-5, a Su(var)3-9 lysine methylase. Here we show that DIM-2 can promote clustered cytosine-to-thymine mutations in the germline (premeiotic) cells of Neurospora. This process is specifically dependent on the presence of repetitive DNA and requires DIM-5. Our previous studies have shown that repetitive sequences are designated for mutation in the absence of Rad51, and that this process involves the pattern of homology recognition expected for direct interactions between intact, co-aligned DNA duplexes. Taken together, our findings suggest that direct interactions between intact DNA duplexes may serve as the fundamental trigger of heterochromatin assembly on repetitive sequences. A mechanism for occurrence of clustered mutations is also of interest for the etiology of cancer, where extensive chromosomal duplications and clustered mutations are prominent features.

M5041B Histone H3R17me2a Mark Recruits TET3 to Initiate Active DNA Demethylation in mouse Zygotes. *Y. Hatanaka*[1*], N. Shimizu[2], K. Morita[2], M. Satoh[2], A. Honda[1,3], M. Hirose[1], S. Kamimura[1,4], N. Ogonuki[1], T. Nakamura[5], K. Inoue[1,4], Y. Hosoi[2], T. Nakano[6], K. Matsumoto[2], A. Ogura[1,4,7]. 1) RIKEN BioResource Center, Ibaraki, JP; 2) Kinki Univ., Wakayama, JP; 3) Miyazaki Univ., Miyazaki, JP; 4) Tsukuba Univ., Ibaraki, JP; 5) Nagahama Institute, Shiga, JP; 6) Osaka Univ., Osaka, JP; 7) Univ.of Tokyo, Tokyo, JP.

[**Introduction**]The parental genomes in zygotes undergo 5-methylcytosine (5mC) oxidation by a dioxygenase TET3, which converts 5mC to 5-hydroxycytosine (5hmC). However, its interacting proteins have not been identified yet. We have reported that maternal gonad specific expression gene (*1700011E24RIK* or GSE) is essential for 5mC oxidation in mouse zygotes. To understand how GSE protein is involved in 5mC oxidation, we sought to identify the maternal factors interacting with GSE in mouse zygotes. [**Methods**]To investigate the interaction of GSE-TET3 and identify its interacting protein, we performed yeast two-hybrid system using cDNA library of MII oocytes and ovaries and co-immunoprecipitation using PN3 zygotes. We performed immunostaining of 5mC and 5hmC and methylated DNA immunoprecipitation (MeDIP) and hydroxymethylated DNA immunoprecipitation (hMeDIP) analysis in *Line1* retrotransposon sequence using knockdown (KD) by injecting the siRNA and knockout (KO) zygotes at PN3 and 5 stages. We treated TBBD, a specific inhibitor of methylation at H3R17, in growing oocytes and collected zygotes by performing *in vitro* maturation and intra cytoplasmic sperm injection (ICSI).[**Results and Discusion**]We showed that GSE interacted with TET3 and maternal methyltransferase like 23 (METTL23), a novel arginine methyltransferase that catalyzed asymmetric

dimethylated histone H3 arginine 17 (H3R17me2a). Knockout of GSE or KD of METTL23 resulted in significant reduction of 5mC oxidation, as demonstrated by an increased 5mC level and a decreased 5hmC level in the male pronucleus. This was most likely due to deficient pronuclear localization of TET3. The impaired 5mC oxidation was confirmed by MeDIP and hMeDIP in *Line1* in zygotes derived from maternal GSE- or METTL23-KD. Treatment with TBBD reduced the H3R17me2a level in the both pronuclei, and caused higher 5mC and lower 5hmC levels in the male pronucleus. Thus, TET3-dependent 5mC oxidation in zygotes is regulated by specific histone modification H3R17me2a.

M5042C Downregulation of MBD2, a Mi-2/NuRD Chromatin Remodeling Complex Component, Potentiates Erythroid Terminal Differentiation and Hemoglobin Synthesis by Allowing the DNA Binding of TFCP2 (CP2c) TF Complexes. *Chul Geun Kim*[1], Min Young Kim[1], Ji Sook Kim[1], Hea Young Eum[1], Dae Hyun Ha[1], Seung Han Son[1], Mi-Ae Park[1], Yea Woon Kim[2], Eun Jung Baek[3], AeRi Kim[2], Ji Hyung Chae[1]. 1) Hanyang University, Seoul, KR; 2) Pusan National University, Pusan, KR; 3) Hanyang University, Guri-si, KR.

Regulation of erythropoiesis and globin gene expression had been intensively investigated, as an effort to improve the management of common but devastating genetic hemoglobinopathies, leading to breakthroughs for the understanding of regulation of eukaryotic gene expression. A heterohexameric ternary transcription factor (TF) complex of TFCP2 (CP2c), CYP27B1 (CP2b), and PIAS1 (CBP) binds to the α-globin promoter to induce transcriptional activation of α-globin in erythroid cells (Kang et al., Nucleic Acids res, 2010), while CP2c homotetramer is known to charge in most cases. We found that GATAD2A (p66α), a component of the Mi-2/NuRD chromatin remodeling complex (CRC), interacts with CP2c/CP2b per se and represses CBP-mediated α-globin expression by modulating both their DNA binding and cellular protein levels. Interestingly, the p66α protein level was not changed during erythroid differentiation *in vitro* and *in vivo* and, instead, MBD2/MBD3, other components of the Mi-2/NuRD CRC and known to directly interact with p66α, was dramatically reduced in their expression: the transcriptional activity of CBP is inversely correlated with expression levels of MBD2 and MBD3. We have studied how the interplay between CP2c TF complexes and Mi-2/NuRD members potentiates terminal erythropoiesis and globin gene expression using multi-disciplinary tools of methods, and found that MBD2/3 directly regulates p66α function to CP2c TF complexes and thus downregulation of MBD2 potentiates erythroid terminal differentiation and hemoglobin synthesis by allowing the DNA binding of CP2c TF complexes. Our findings open up a new mode of CRC action on transcriptional regulation in general and a molecular execution mechanism of erythropoiesis at the terminal stage by interplay between CRC and TFs, leading to transcriptional induction of globin gene expression.

M5043A A Targeting Small Molecule Inhibitor of MBD2-GATAD2A Interaction Induces Myeloid Leukemia Cell-specific Cell Death. *Chul Geun Kim*[1], Min Young Kim[1], Insung Na[2], Young Su Lim[1], Ji Sook Kim[1], Yu Chen[2], Arjan van der Vaart[2], Eun Jung Baek[4], Young Yeol Lee[3], Buom-Yong Ryu[5], Vladimir N. Uversky[2]. 1) Hanyang University, Seoul, KR; 2) University of South Florida. Tampa, USA; 3) Hanyang University College of Medicine, Seoul, KR; 4) Hanyang University College of Medicine, Guri-si, KR; 5) Chung-Ang University, Ansung, KR.

Mi-2/NuRD (Nucleosome Remodeling and Deacetylase) chromatin remodeling complex (CRC), an assemblage of proteins that combine key epigenetic regulators necessary for histone deacetylation and demethylation, is known to be an epigenetic reader of DNA methylation that regulates genes involved in normal development and neoplastic diseases. To our surprise, we have found that MBD2 and MBD3 are downregulated, with no disruption of the integrity of the Mi-2/NuRD complex, during terminal differentiation of MEL cells *in vitro* as well as normal erythropoiesis in the bone marrow. In further, we confirmed that MBD2 downregulation potentiates terminal erythroid differentiation and transcriptional activation of both α- and β-globin genes via recruitment of TFCP2 (CP2c) TF complexes to their promoters. In accordance with the previous report that MBD2 recruits the CHD4 nucleosome remodeling protein to the complex via a coiled-coil interaction with GATAD2A (p66α), spontaneous differentiation of MEL cells occurred by arbitral disruption of MBD2-p66α interaction or MBD2 knock down. Along with previous report that MBD2 knock out mice are viable and fertile, our data indicate that MBD2-p66α interaction is involves in gene silencing in general, but is dispensable in normal differentiation of some types of cells, i.e., erythroid lineage cells and also strongly suggest that disruption of MBD2-p66α interaction induces normal differentiation or cell death of some types of leukemia, like MEL cells which are arrested at the proerythroid stage. Based on this, we identified small molecules disrupting MBD2-p66α interaction using a computer aided molecular docking and tested their usefulness as an anticancer drug in various available cancer cell lines. We found that a drug 086567 shows a specific anticancer effect to myeloid leukemia cells with IC50 = ~20 μM, and also confirmed its anticancer effect in the mouse xenograft model of MEL cells. Mechanistically, this drug causes cell cycle arrest at various stages, leading to chromosomal aneuploidy and apoptotic gene expression.

M5044B Genome wide analysis of transcriptional profiles of *Usp22* mutant placentas reveal impaired cancer signaling cascades. *E. Koutelou*[1], A. Schibler[1], L. Wang[1], H.-P. Chao[1], X. Kuang[1], A. Salinger[1], Y. Lu[1], Y.-C. Chen[3], M. Wilson[2], B. Atanassov[1], D. Tang[1], S. Dent[1]. 1) UT-MD Anderson Cancer Center, Science Park, Smithville, TX; 2) UT-MD Anderson Cancer Center, Houston, TX; 3) Baylor College of Medicine, Houston, TX.

USP22, a component of the SAGA complex, is overexpressed in highly aggressive cancers, but the normal functions of this deubiquitinase are not well defined. We determined that loss of USP22 function in mice results in embryonic lethality between E12.5 and E14.0 due to defects in extraembryonic placental tissues that result in a failure to establish proper vascular interactions with the maternal circulatory system. These defects correlate with abnormal gene expression patterns that reflect defective receptor kinase signaling, including TGF-beta and RTK pathways. As these same pathways are often hyperactivated in cancer, our data provide the first insights to UsP22 functions that may be tied to oncogenesis.

M5045C Imprinted DNA methylation status can be reconstituted by combining activity of distinct *H19* ICR elements in mice. *H. Matsuzaki*, K. Tanimoto. University of Tsukuba, Tsukuba, Ibaraki, Japan.

Allele-specific DNA methylation at differentially methylated regions (DMRs) is critical for controlling imprinted genes expression and early embryogenesis in mammals. We previously demonstrated that the *H19* imprinting control region (ICR), a DMR in the *Igf2/H19* locus, was capable of acquiring paternal-allele-specific DNA methylation (imprinted methylation) when ectopically introduced into mouse genome (transgenic mouse; TgM). By using this genetic approach, we have dissected the *H19* ICR activity and identified a couple of *cis* elements essential for protecting the fragment from undesired methylation on the maternal allele. To test if these elements, when combined and introduced into heterologous CG-rich sequences, are sufficient to generate imprinted methylation status, we conducted reconstitution experiments. We employed a bacteriophage lambda DNA fragment as a scratch sequence, generated its TgM, and found that the fragment acquired DNA methylation regardless of its parental origin. Then, we introduced CTCF binding sites and Sox-Oct motifs of the mouse *H19* ICR into the lambda DNA (termed "LCb") and found that transgenic LCb fragment in mouse exhibited unmethylated state irrespective of their parental origin.

In this study, to search for *cis* elements essential for depositing paternal-allele specific methylation, we generated multiple TgM lines carrying a series of 5'-truncated *H19* ICR fragments and identified the 118-bp region as a candidate element carrying such an activity. When these sequences were internally deleted from the intact *H19* ICR transgene (2.9-kb) in mouse, the mutant fragment failed to acquire DNA methylation after paternal transmission. Finally, we appended the 118-bp sequences to the LCb fragment (termed "LCb118") and tested its ability to instruct imprinted methylation in TgM. The fragment became capable of acquiring DNA methylation only when paternally inherited. These results demonstrated that the 118-bp region was necessary and sufficient for acquisition of paternal allele-specific DNA methylation in TgM. Furthermore, combination of specific DNA sequences, rather than general property of the local DNA sequence, such as GC-content, determines identity of a DMR.

M5046A On the role of the epigenetic factor PRDM9 in meiosis of the wild mouse. *Z. Trachtulec*[1], P. Flachs[1], F. Pratto[2], C. L. Baker[3], R. Sedlacek[1], K. Paigen[3], R. D. Camerini-Otero[2], P. M. Petkov[3], O. Mihola[1]. 1) Division BIOCEV, Institute of Molecular Genetics ASCR, Prague, Czech Republic; 2) National Institute of Diabetes, Digestive, and Kidney Diseases, NIH, Bethesda, MD, USA; 3) Center for Genome Dynamics, The Jackson Laboratory, Bar Harbor, ME, USA.

The histone-3-lysine-4-trimethyl(H3K4me3)transferase PRDM9 (PR domain containing 9) determines the sites of the double-stranded breaks (DSBs) initiating meiotic recombination in the mouse, human, and cattle by binding at specific DNA sequences known as hotspots. The rapid evolution of the DNA-binding domain of the PRDM9-encoding gene is a response to the consequences of the meiotic paradox (the most often used hotspots disappear most quickly from the population) that leads to new hotspots. Deletion of the *Prdm9* gene from the laboratory mouse induces a shift of the DSBs to other H3K4me3 sites including promoters and a complete arrest of meiotic prophase I. Some organisms, such as dogs, birds, and baker´s yeast that lack PRDM9, have recombination hotspots that are conserved in closely related species and often located near promoters. We therefore investigated if PRDM9 is essential for meiosis in the wild mouse, using two types of *Prdm9* mutations and two wild-derived mouse strains. We phenotyped these mice by indirect immunofluorescent labeling of spread nuclei to assess synapsis and DSB repair, finding that mutant phenotypes depend on genetic background. To reveal hotspot positions, the products of anti-H3K4m3 and anti-DMC1 (a DSB-repair protein) testicular chromatin immunoprecipitations were sequenced and analyzed. We will present the phenotyping results of these *Prdm9*-deficient mice including the epigenomic analyses.

M5047B Full length transcript sequencing of wild derived mouse strains identifies strain specific novel gene structures. *Monica I. Abrudan*[1], Anne Czechanski[2], Laura Reinholdt[2], Marcela Sjoberg[1], Thomas M. Keane[1]. 1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, GB; 2) The Jackson Laboratory, Bar Harbor, ME.

The mouse gene annotation is currently based on the C57BL/6J strain, whereas there is much less evidence for gene structures in genetically distant strains such as CAST/EiJ, PWK/PhJ, and SPRET/EiJ. These distant strains are important as they include founders for recombinant panels such as the Collaborative Cross (CC) and the Diversity Outbred Cross (DO). Short read RNA-Seq has previously been generated and used to explore the splicing landscape of these strains. Full length transcript reconstruction from short reads is difficult and there has not yet been a systematic effort to generate full length cDNA sequencing for the wild-derived strains. In this experiment, we generated matched long read Pacbio cDNA and Illumina RNA-Seq for two tissues (liver and spleen) and four strains (C57BL/6J, PWK/PhJ, CAST/EiJ, and SPRET/EiJ). The vast majority of the Pacbio reads contain full length transcripts. We find that spleen has a significantly richer transcriptional landscape. The PacBio cDNA reads capture on average 23% more unique protein coding genes in spleen than in liver, across all strains, despite the fact that there exist similar total numbers of reads in the two tissues. Using a conservative approach, in liver Pacbio cDNA we found 2760, 2812, 3352 and 3460 novel splice junctions in C57BL/6J, CAST/EiJ, PWK/PhJ, and SPRET/EiJ respectively. Intersecting the splice junctions extracted from the PacBio cDNA reads, we find 91 splice junctions specific to wild derived strains only, absent from GENCODE and from the C57BL/6J cDNA reads. From the analysis of the Illumina RNA-Seq reads, we find on average 1189 new splice junctions in each sample, across all strains, in liver and 1328 in spleen. Using the PacBio cDNA reads, we identify a potential new gene belonging to the PHD Finger family, specific to SPRET/EiJ, located on Chromosome 14. This novel transcript was also confirmed by the AUGUSTUS gene prediction pipeline. In a similar fashion, we identified a potential new isoform of a protein phosphatase, *Ppp2r3d*, also specific to SPRET/EiJ, that has also been predicted by AUGUSTUS.

M5048C Integration of heterogeneous cross-species functional genomics data in GeneWeaver.org *J. A. Bubier*[1], G. Sutphin[1], M. A. Langston[2], E. J. Baker[3], E. J. Chesler[1]. 1) The Jackson Laboratory, Bar Harbor, ME; 2) University of Tennessee, Knoxville, TN; 3) Baylor University, Waco, TX.

The use of model organisms to understand mechanisms of phenotypic diversity, development, aging, health and disease has been highly productive but faces challenges due to the unique nature of each model organism and its characteristics. The widespread application of whole genome functional studies and the diversity of sequenced genomes has created the critical mass of data necessary for efficient large-scale and cross-species data integration. The conservation of underlying pathways across species enables us to identify generalized mechanisms of disease. GeneWeaver.org is a database and suite of tools that allows users to integrate, query and analyze heterogeneous data from 10 supported species, with a variety of research applications. User submitted gene sets from individual or bulk uploads are seamlessly integrated and analyzed in light of a database containing sets of genes corresponding to Gene Ontology, Mammalian Phenotype Ontology, Comparative Toxicogenomics Database Chemicals, OMIM, MeSH annotations as well as pathway based gene sets from resources such as Pathway Commons, Kyoto Encyclopedia of Genes and Genomes (KEGG), and Molecular Signatures Database (MSigDB). The available tools use statistical methods and graph-based algorithms to perform set-set matching operations on gene sets and network edges. The results are presented in a dynamic graphical output. As an example, we applied GeneWeaver to a set of 73 gene sets derived from diverse experimental types related to aging across six species (yeast, worm, fly, rat, mouse and human). The most highly connected gene among the cross species gene sets was identified as the tetraspanin transmembrane protein family member *tsp-7* (*Cd63* in mice). Experimental validation of *tsp-7* using bacterial-fed RNAi in *C. elegans* demonstrated a 10.2% extension of mean lifespan compared to empty vector (p=0.009, n=627). This example illustrates how aggregating experimental evidence of a variety of data types (differential RNA expression, QTL, proteomic, etc.) enables the discovery of novel genes common to conserved processes.

M5049A High throughput screening of International Knock-out Mouse Consortium leads to novel gene-phenotype annotations. *J. Clark*, C. Smith, K. Svenson, B. Braun, J. Eppig, E. Chesler. The Jackson Laboratory, Bar Harbor, ME.

The Jackson Laboratory

The Knock-Out Mouse Project and The International Mouse Phenotyping Consortium was formed to perform characterization of a comprehensive collection of mammalian genes through the systematic perturbation and phenotypic analysis of single gene disruptions performed by the International Knock-out Mouse Consortium. To date, The Jackson Laboratory has 444 fully characterized mutant strains examined with a wide range of phenotypic assays. Genes were prioritized by the research community, often based on information of phenotypic importance in one or more domain areas. However, the breadth of the phenotyping platform provides many additional new annotations even for these known genes. Each new phenotypic annotation generated by IMPC analysis is reported to Mouse Genome Informatics, and these annotations can be compared to existing information on known phenotypic alleles. A preliminary analysis of these annotations reveals that mutant strains generated and phenotyped by The Jackson Laboratory, 1478 phenotype annotations (or approximately 55% of the 2,674 total JAX strain phenotype annotations) for 243 unique genes were novel. Of the remaining 199 genes, 4,804 annotations were derived from MGI literature and submitted data curation, and 1,196 mostly novel phenotype annotations resulted from The Jackson Laboratory phenotyping pipeline. Additional analysis including targeted curation of genes and phenotypes characterized by the IMPC, and evaluation of the structural relations among annotations across phenotypic alleles will enable more precise quantitation of the knowledge gained by this consortium.

Support: NIH Grant# U54 HG006332.

M5050B New exome sequencing of wild derived inbred strains of mice significantly improves power to link phenotype and genotype. *Matt Dean*[1], Peter Chang[1], Emily Kopania[1], Matt Salomon[1], Lorraine Provencio[1], Rachel Mangels[1], Sara Keeble[1], Brent Young[2], Annie Orth[2], Francois Bonhomme[3], Jeffrey Good[1]. 1) University of Southern California, Los Angeles, CA; 2) Université Montpellier; 3) University of Montana.

The mouse has proven to be a powerful system to dissect the genetic and environmental influences on phenotypic variation, even informing the study of diseases in humans. In spite of a wealth of discoveries, most modern mouse strains are related to each other in complex ways, and have captured only a small fraction of genetic variation known to segregate in their wild progenitors. Wild-derived mice have the potential to increase power to connect phenotype to genotype by introducing novel single nucleotide polymorphisms (SNPs) to science. Here, we enrich exomes from 26 wild derived strains (the so-called Montpellier strains) and perform high throughput sequencing to an average coverage of 20 X. SNP's were called using an extremely conservative customized pipeline. We identified 1.14 million SNPs in our dataset, approximately 20% of which are not currently known in existing databases of mouse genetic variation. Simulations show that these new genetic variants increase mapping resolution. In addition, there are over 300 genes with an early stop codon segregating in the first 50% of the protein, providing potential alternatives to existing knockout resources. The novel genetic variation discovered here promises to increase the power of mouse genetics.

M5051C Deep genome sequencing and variation analysis of 13 inbred mouse strains defines candidate phenotypic alleles, private variation, and homozygous truncating mutations. *A. G. Doran*[1], K. Wong[1], J. Flint[2], D. J. Adams[1], K. W. Hunter[3], T. M. Keane[1]. 1) Wellcome Trust Sanger Institute, Cambridge, Cambridgeshire, GB; 2) The Wellcome Trust Centre for Human Genetics, Roosevelt Drive, Oxford OX3 7BN, UK; 3) Laboratory of Cancer Biology and Genetics, NCI, NIH.

Background

The Mouse Genomes Project is an ongoing collaborative effort to sequence the genomes of the common laboratory mouse strains. In 2011, the initial analysis of sequence variation across 17 strains found 56.7M unique SNPs and 8.8M indels. We carried out deep sequencing of 13 additional inbred strains (BUB/BnJ, C57BL/10J, C57BR/cdJ, C58/J, DBA/1J, I/LnJ, KK/HiJ, MOLF/EiJ, NZB/B1NJ, NZW/LacJ, RF/J, SEA/GnJ and ST/bJ) cataloging molecular variation within and across the strains. These strains include important models for immune response, leukemia, age-related hearing loss and rheumatoid arthritis. We now have several examples of fully sequenced closely related strains that are divergent for several disease phenotypes.

Results

Approximately, 27.4M unique SNPs and 5M indels were identified across these strains compared to the C57BL/6J reference genome (GRCm38). The amount of variation found in the inbred laboratory mouse genome has increased to 71M SNPs and 12M indels. We investigate the genetic basis of highly penetrant cancer susceptibility in RF/J finding private novel missense mutations in DNA damage repair and highly cancer associated genes. We use two highly related strains (DBA/1J and DBA/2J) to investigate the genetic basis of collagen induced arthritis susceptibility and identify several candidate genes and biological pathways with potential roles in collagen induced arthritis pathogenesis.

Conclusion

This study significantly expands the catalog of fully sequenced laboratory mouse strains and now contains several examples of highly genetically similar strains with divergent phenotypes. We show how studying private missense mutations can lead to insights into the genetic mechanism for a highly penetrant phenotype.

M5052A Functional annotation of proteoforms in the Mouse Genome Database using the Protein Ontology. *H. J. Drabkin*[1], K. R. Christie[1], C. N. Arighi[2], C. H. Wu[2], J. A. Blake[1]. 1) The Jackson Laboratory, Bar Harbor, ME; 2) University of Delaware, Newark, DE.

The concept of one gene/one polypeptide suggested in the 40's and 50's was dispelled in the late 70's with the discovery of splicing. A single eukaryotic gene can encode multiple protein isoforms due to the usage of alternate promoters or polyadenylation sites, alternative splicing of the primary transcript to generate different mRNAs, and/or selection of alternative start sites during translation of an mRNA. A protein can be further subjected to a single or multiple of post-translational processing including proteolytic cleavage as well as protein amino acid modifications. The functioning or cellular location of these different protein entities (proteoforms) can often be quite different.

The Protein Ontology (PRO, http://proconsortium.org) is a resource that supplies unique identifiers to specific proteoforms resulting from expression of a gene. These forms are organized in an ontological framework that explicitly describes how these entities relate. The ontology currently has over 68,000 isoforms and 2,200 modified proteoforms, which are either imported from high-quality sources or added via literature-based annotation by PRO curators.

The Mouse Genome Informatics (MGI, http://www.informatics.jax.org) is the international database resource for the laboratory mouse. It provides integrated genetic, genomic, and biological data to facilitate the study of human health and disease. MGI uses the Gene Ontology (GO, http://www.geneontology.org) for functional annotation of mouse genes. The GO defines concepts used to describe gene product functioning, location, and participation in biological processes, as well as relationships between these concepts. At MGI, when GO literature-based manual annotation applies to a specific proteoform this is indicated using PRO. These annotations are grouped according to the encoding gene, and can be displayed at MGI, as well as at the Amigo database of the Gene Ontology Consortium (http://amigo.geneontology.org/amigo). The annotations are also provided to the PRO website, where they can be viewed in the context of other proteoforms.

Supported by NIH Grants HG000330, HG002273, and GM080646.

M5054C Rapid evolution of co-amplified X and Y chromosome genes and genomic structures in mice. *A. Kruger*, J. Mueller. University of Michigan, Ann Arbor, MI.

The mammalian X and Y chromosome have diverged considerably since their evolutionary origins as autosomes. The mouse X and Y Chromosome, however, have undergone convergent evolution by independently acquiring and co-amplifying three gene families not present on the human sex chromosomes. Here we examine the evolutionary dynamics of these three X-Y co-amplified gene families and their genomic structures in rodents. We find that they were acquired via transposition and retrotransposition events followed by subsequent amplification. Our between species comparison of the three X-Y co-amplified gene families reveals they are among the most rapidly evolving genes on the rodent sex chromosomes. Moreover, comparison of their gene family members sequence divergence within mice highlights distinct protein regions under strong positive selection. Together with the rapid evolution of their protein-coding sequences, the genomic structures within which these gene families are harbored vary significantly in copy number. By tracking the evolutionary trajectory of the three X-Y co-amplified gene families we are gaining insights into the coevolution of their sequence diversification and massive amplification.

M5055A The future of reference assembly updates. *V. A. Schneider*, on behalf of the Genome Reference Consortium and NCBI Annotation Team. NIH/NCBI, Bethesda, MD.

An organism's reference genome assembly provides a standard coordinate system for reporting, a substrate for annotation and serves as the basis for analyses ranging from the study of individual genes to population genomics. As a result, the quality and content of a reference assembly is critical to research success. The Genome Reference Consortium (GRC) is responsible for updates to the mouse and zebrafish reference genome assemblies, including closing gaps, correcting path and sequencing errors and adding sequence to represent diversity. The chromosomes of the clone-based reference genome assemblies for these species each represent a single strain, C57BL/6J and Tü, respectively. However, due to inter-strain variation, some genomic regions are insufficiently represented by a single strain. Historically, the GRC has provided sequence representations for additional mouse strains at divergent regions with alternate loci scaffolds that are also comprised of finished, clone-based sequence. However, costs associated with mapping and sequencing genomic clones have limited this effort. As sequencing costs continue to fall and read lengths grow longer, though, ongoing and planned efforts by various investigators to sequence and assemble high quality genomes from different mouse and zebrafish strains provide the GRC with new opportunities to represent diversity and correct errors. We will present examples of recent curations to the mouse and zebrafish reference assemblies, as well as plans for curation in the context of multiple high quality assemblies. NCBI provides bioinformatics and database support for the GRC and annotates these reference assemblies, including the alternate loci, as part of its genome annotation pipeline. Annotation features include genes, RefSeq transcripts, genomic clone placements, repeats and genomic sequences not included in the assembly. Additionally, the GRC provides annotations that provide information about assembly quality and curation efforts. These annotations can be viewed in the NCBI Map Viewer, which permits the simultaneous display of genomic maps with different coordinate systems, as well as the Genome Data Viewer, a browser that supports the upload of user data, enabling it to be viewed alongside NCBI annotations. We will demonstrate how to use these browser resources to evaluate GRC-curated reference assemblies. The GRC welcomes public feedback on the mouse and zebrafish assemblies and displays information about regions under review on its website (http://genomereference.org).

M5056B Identifying genetic factors associated with extinction of strains in the Collaborative Cross. *J. R. Shorter*, F. Pardo-Manuel de Villena. University of North Carolina, Chapel Hill, NC.

The Collaborative Cross (CC) is a research population of inbred mouse strains derived from an eight way cross using five classical inbred strains and three wild-derived strains representing three subspecies. The CC is genetically diverse because it combines together the genomes of the eight strains; A/J, C57BL/6J, 129S1/SvImJ, NOD/ShiLtJ, NZO/HlLtJ, CAST/EiJ, PWK/PhJ, and WSB/EiJ. This genetic diversity is essential for trait mapping studies, as classical inbred mouse strains can only capture a fraction of genetic variation found in the CC. However, this high level of genetic diversity may also act as a double-edged sword. The Dobzhansky-Muller model of hybrid incompatibility predicts that crosses between closely related species may produce inviable or infertile offspring. This is the result of allelic incompatibles across different loci that have evolved during the process of speciation. We observe an unusually high level of extinction in the CC strains, over 90%, which is much higher than comparable inbred reference panels. To investigate this high extinction rate, we are taking several different approaches. First, we will use living and extinct CC strains to find significant genotype ratio distortion sites that indicate allelic incompatibilities. We will also investigate genotype ratio distortion in the Diversity Outbred (DO) population that was created from 160 CC strains, but does not have the same infertility and inviability issues. We also will collect approximately 1000 pairs of productive and non productive mice that represent the last two generation of each extinct CC strain. This data set will be used in a mapping study to identify genetic factors that led to strain infertility. Finally, we will validate candidate allelic incompatibilities by using selective crosses of living DO and CC strains.

M5057C The genomes of *Mus caroli* and *Mus pahari* uncover the evolutionary dynamics of the mouse lineage. *D. Thybert*[1,2], The Caroli - Pahari genome consortium. 1) The Genome Analysis Center, Norwich, GB; 2) European Bioinformatic Institut, Hinxon-Camrbidge, GB.

The lack of genomes from intermediate species between the *Mus musculus* and the rat has hindered the study of genomic mechanisms involved in the divergence of the mouse from the other mammals. Here, we present the complete genome sequences of *Mus caroli* and *Mus pahari* which diverged 3 MYA and 6 MYA from *Mus musculus*. The genomes of these two species enable an analysis of evolutionary dynamics within the Muridae lineage that uncovers the mechanisms which fashioned the specificity of the mouse genome. For instance, our analysis shows both that a wave of inter-chromosomal rearrangement occurring between 3 and 6 MYA shaped the karyotype of the laboratory mouse ancestor and that genome integration of retrogenes has been increased in the *Mus* lineage. By taking advantage of the comparable divergence time of *Mus caroli* and *Mus pahari* from the laboratory mouse with chimp and gorilla from human, we can unravel the evolutionary mechanisms specific to *Muridae* from evolutionary mechanisms common to both mammalian clades to better understand the evolutionary mechanisms that shaped the mouse genome.

M5058A Genetic pest management technologies to control invasive rodents. *D. M. Kanavy*, D. W. Threadgill. Texas A&M University, College Station, TX.

Many strategies exist to manage invasive pests, ranging from poison to trapping, with varying degrees of success. Genetic technologies are increasingly being applied to insect pests, but not vertebrates. We propose to implement a genetic strategy to eradicate invasive mouse populations as another tool for pest control.

Mus musculus, the common house mouse, is one of the most widespread invasive species. Mice threaten human health, agriculture, and biodiversity on many islands, most specifically seabirds. The Farallon Islands are one example of a threat against biodiversity, with the ashy storm petrel being endangered by the predation of burrowing owls, which are attracted to the island due to the large population of invasive mice. Rodenticides are the most common method of eradicating mice, but their use leads to poisoning of non-target species and has limited

efficacy against mice. An approach that could eliminate non-target species disruption would be to combine genetically engineered mice, which for example produce a daughterless phenotype, with a gene drive system that could make the genetic technique self-sustaining. There are naturally occurring and artificial gene drive systems. For this project, we have investigated exploiting a naturally occurring gene drive, the t-complex. Using the t^{w2} haplotype of the t-complex, which is a full t-haplotype lacking the embryonic recessive lethality found in many other t-complex alleles, we observed the t^{w2} haplotype being transmitted to offspring with a transmission distortion ratio of 92.4%. We are currently exploring combining this natural gene drive system with genetic alterations that would produce daughterless offspring as an approach to effectively crash an invasive population without adversely affecting other species.

M5059B Unexpected translation reinitiation by on-target CRISPR-Cas9 genome editing. *S. Makino*, R. Fukumura, Y. Gondo. RIKEN BioResource Center, Tsukuba, Ibaraki, JP.

Translation initiation is emerging as one of the key mechanisms in regulation of gene expression. Translation is usually initiated from the first 5' ATG codon with the certain flanking sequence, e.g. Kozak sequence. In the presence/occurrence of nonsense mutation near 5' region in ORF, translation is sometimes reinitiated from a downstream inframe ATG codon, producing mutant protein lacking an N-terminal region. Such N-truncated protein has been reported as a responsible genetic factor for several human diseases. Some shortened proteins act as a hypomorphic protein and others act as a dominant negative protein. However, it has been known at all neither what extent translation reinitiation universally occurs nor how we may generally assess even if it may exist.

Here we show the concrete case of translation initiation *in vivo* and how to validate the event *in vitro* by using a dual-tagged expression vector. In the process of CRISPR-Cas9 genome editing, we have succeeded in introducing several out-of-frame indel mutations biallelically to knockout the endogenous *Gli3* gene. Unexpectedly, almost full length of the GLI3 protein was expressed in the homozygous mutants *in vivo*. The dual-tagged vector revealed that the expressed mutant GLI3 proteins lacked N-terminal residues but had intact C-terminal.

Thus, translation reinitiation indeed occurred *in vivo*. The *in vivo* assessment system with the dual-tagged vector is practically applicable for any genes, e.g., for the diagnosis of human diseases as well as for designing genome-editing vectors.

Moreover, translation reinitiation has been also found without mutations; e.g., upstream open reading frames (uORFs) regulate gene expression in response to environmental conditions. Thus, the time has come to investigate if in general translation reinitiation has a critical regulatory role of gene expression as a new paradigm in the central dogma.

M5060C Optimisation and high-throughput production of CRISPR/Cas9-mediated knockout mouse strains. *E. J. Ryder*, B. Doe, B. Rosen, J. Bottomley, G. Duddy, K. Boroviak, M. Thomas, E. Brown, D. Gleeson, D. von Schiller, D. Sethi, M. Woods, R. Ramirez-Solis, Sanger Mouse Genetics Project. Wellcome Trust Sanger Institute, Cambridge, GB.

The creation of targeted mutations by the use of CRISPR/Cas9 gene editing has revolutionised the process and possibilities of altering the function of genes in a wide variety of animals and plants. We describe the challenges of transitioning this technology into a high-throughput mouse production environment with the generation and characterisation of over one hundred new mutant mouse strains.

The majority of our CRISPR-mediated knockout strains are the result of whole exon deletions in which two guide RNAs are designed per flanking region to maximise the chance of a successful double-strand break. The gRNAs and Cas9 mRNA are introduced into 1-cell mouse zygotes by cytoplasmic injection and the G0 mice screened by a rapid PCR/qPCR method to determine the level of mosaicism and the percentage of putative deletion events. The mutation is then sequence-verified in the next generation to ensure that complete deletion of the exon has occurred.

We have found that the use of the CRISPR/Cas9 system has significant advantages in both the speed and level of generation of new strains, and has allowed us to significantly reduce the numbers of animals needed to achieve germline transmission.

M5061A Elevated canonical Wnt signalling disrupts development of the embryonic midline and may underlie cases of *ZIC3*-associated Heterotaxy. *R. Arkell*, A. Alzahrani, K. Diamand, J. Ahmed, K. Barratt. Australian National University, Canberra, ACT, AU.

Heterotaxy is a congenital abnormality where the internal thoraco-abdominal organs demonstrate abnormal arrangement across the left-right (L-R) axis of the body. It can affect the development of the heart, liver, lungs, intestines, and spleen. The L-R embryonic axis is established early in embryogenesis when unidirectional signals emanate from a specialised structure at the embryonic midline, called the node, to initiate distinct molecular pathways on the left and right sides of the developing embryo. The gene most commonly mutated in human cases of Heterotaxy is the X-linked *ZIC3*, but the mechanism by which the ZIC3 transcription factor prevents Heterotaxy remains unknown. A genetic screen for mutations that affect murine embryogenesis identified a novel null allele of *Zic3*, called katun (*Ka*). The mutant embryos exhibit Heterotaxy and also incompletely penetrant, partial (posterior) axis duplications and anterior truncation. These latter two phenotypes are redolent of elevated canonical Wnt signalling and analysis of *Ka* embryos reveals ectopic expression of direct targets of Wnt/β-catenin mediated transcription in mutant embryos. ZIC3 is a member of the Zic family of transcriptional regulators and previous work has shown that ZIC proteins can inhibit Wnt/β-catenin mediated transcription when overexpressed in cell lines. This raises the possibility that dysregulated Wnt signalling may contribute to Heterotaxy. We have investigated this notion by analysis of the murine batface (*Bfc*) gain-of-function allele of β-catenin that results in elevated Wnt/β-catenin signalling. We find this strain exhibits incompletely penetrant defects of L-R axis formation and synergises with the *Zic3 Ka* allele to produce an increased incidence of L-R axis defects. In both the *Ka* and *Bfc* strains, the node of homozygous embryos is misshapen and contains patches of non-ciliated cells that express endoderm genes. Moreover we find that human *ZIC3*-Heterotaxy associated mutations encode proteins that are defective in their ability to inhibit Wnt/β-catenin mediated transcription. Overall this provides strong evidence that Wnt dysregulation may underlie cases of ZIC3-associated Heterotaxy.

M5062B HOX proteins are essential for motor neuron subtype differentiation and connectivity by regulating the expression of *Ret/Gfra* genes. *C. Catela*[1], M. M. Shin[1], D. H. Lee[1], J. P. Liu[2], J. S. Dasen[1]. 1) NYU School of Medicine, New York, NY; 2) University of Virginia School of Medicine, Charlottesville, VA.

Precise regulation of gene expression is fundamental for the generation of neuronal diversity and circuit assembly during development. However, the transcriptional mechanisms that establish patterns and levels of gene expression in a given neuronal population remain largely elusive. Here we show that HOX/HOX cofactor interactions in motor neuron (MN) subtypes are essential for their specification and connectivity through regulation of the expression of *Ret/Gfra* surface receptors, essential for MN organization, axon branching and guidance. HOX and MEIS transcription factors control the levels of *Ret* and define the expression pattern of *Gfra1* and *Gfra3* in MN subtypes. Deletion of *Ret* and *Gfra3* in mice results in MN organization and innervation defects similar to those observed in HOX mutants. Finally, ectopic expression of *Ret* and *Gfra1* is sufficient to cause MNs to respond to limb derived signals, circumventing the necessity for *Hox* genes. These results show that one of the strategies of *Hox* genes is to regulate the levels and expression pattern of cell surface receptors, gating the ability of MNs to respond to limb signals. Future experiments will aim to uncover the full spectrum of effector genes downstream of HOX networks, providing novel insights into the transcriptional strategies employed by Hox proteins during MN subtype development.

M5063C Genetic studies of large mammalian sex chromosome palindromes harboring testicular germline genes. *Q. Ellison*, J. Mueller. University of Michigan, Ann Arbor, MI.

In placental mammals, the sex chromosomes are enriched for large (>10kb), nearly identical (>99% nucleotide identity), palindromes, which harbor genes expressed during testicular germ cell development. Despite their abundance, the molecular function of these palindromes has not been explored, in part due to their repetitive nature. Y chromosome palindromes are thought to have evolved to facilitate gene conversion between palindrome arms, allowing for the removal of deleterious mutations on the otherwise non-recombining Y chromosome. On the freely recombining X chromosome, an additional function for palindromes is suggested. I propose that the structure of large palindromes may facilitate transcriptional activation of their associated genes during testicular germ cell development. This proposition is based on the finding that genes associated with sex chromosome palindromes are expressed predominantly or exclusively in post-meiotic testicular germ cells, when single-copy X-linked genes are transcriptionally silenced. To determine whether palindrome structure is necessary for the expression of palindrome-associated genes in post-meiotic testicular germ cells, I am genetically dissecting two distinct mouse X chromosome palindromes using the CRISPR genome engineering technique to flip or delete single palindrome arms. In mouse lines I have generated that carry either inverted or deleted palindrome arms, I am currently in the process of measuring expression levels of palindrome-associated genes. I will also determine if there are defects in post-meiotic testicular germ cell development.

M5064A Embryonic Spacing in the C3H Mouse: A Model for Abnormal Pregnancies in Mammals? *S. A. Fletcher*[1], J. Dackor[3], D. W. Threadgill[1,2], D. S. Threadgill[1]. 1) Interdisciplinary Program of Genetics, Department of Veterinary Pathobiology, Texas A&M University, College Station, TX; 2) Department of Molecular and Cellular Medicine, Texas A&M University, College Station, TX; 3) 3 Department of Genetics, University of North Carolina, Chapel Hill, NC.

Previous research has indicated tightly regulated, even spacing of embryos during implantation is the conserved phenotype seen not only in the mouse and rat but also in other species such as the rabbit, pig, cow, sheep, and human. This critical event is described as embryos spaced evenly along each of the uterine horns of these species, and is an important factor in the health of both the pregnancy and the embryos. For some species this spacing can result in abortion, and in the case of cattle, a condition can occur in response to shared placentas in which sharing of placental vasculature by male-female twins can result in the masculinization of the female fetus. The importance of the proper spacing of embryos has also been suggested from human studies concerning ectopic pregnancies, placental previa, and cases where human fetuses sharing the same placenta are at increased risk of perinatal mortality and morbidity due to twin-twin transfusion syndrome, selective intrauterine growth restriction, and a higher incidence of congenital heart malformations.

The purpose of this study is to determine the genetic factors responsible for the uneven spacing in the C3H mice and its implications. This study utilizes both wild type C3HeB/FeJ (C3H) and C57BL/6J (B6) mice for the purpose of comparison, control, and matings. Wild type C3H mice display reproducibly uneven spacing of their embryos immediately before implantation while wild type B6 mice display the typical phenotype. The use of C3H/B6 recombinant inbred lines will allow us to look at which crosses are affected by uneven spacing and to identify candidate genes responsible for this phenotype through regional origination analysis of each line affected. Regulated contraction of the uterus is suggested to be critical to proper embryo spacing in placental mammals and knockout mice models for *Lpar3* and *Pla2g4a* demonstrated uneven embryo spacing.

Embryo transfers using the parental strains will allow for the determination of message origin, embryo-uterine cross talk, and give insight into the control of embryo spacing in the mouse. RNAseq on uterine tissue and embryos collected from parental strains before implantation will allow us to look at differing expression levels between strains and at the expression levels of potential candidate genes.

Finally, in our wild-type C3H mouse model, we will address the possibility of freemartins occurring in embryos with fused placentas as a result of the uneven spacing. Tattooing techniques will be utilized for identification, postnatal, of pups that share or have fused placentas *in utero*.

M5065B Role of a 3'UTR-dependent DAZL suppression in mouse postnatal ovary. *K. Fukuda*[1], T. Naka[3], A. Suzuki[3], Y. Saga[1,2], Y. Kato[1,2]. 1) SOKENDAI, Mishima, JP; 2) NIG,Mishima, JP; 3) Yokohama national Univ., Yokohama, JP.

Oogenesis is a crucial process for producing healthy female gamete, oocyte, in ovary. One of essential genes for oogenesis is *Dazl* (deleted in azoospermia-like) that is an RNA-binding protein implicated in translational promotion in mice. Because of its indispensable role in progression of meiosis Ⅰ in embryonic gonads and in progression of meiosis Ⅱ after ovulation, *Dazl* is thought to be required throughout oogenesis.

However, its role in oocyte growth in postnatal ovary remains unknown. To address this question, we analyzed *Dazl* expression by qPCR and western blotting. Surprisingly, we found that DAZL protein was decreased in postnatal ovaries, whereas the higher level of *Dazl* mRNA was maintained from embryo to juvenile ovaries. These results indicate that DAZL is post-transcriptionally suppressed after birth. We asked whether or not *Dazl* is suppressed via its 3'UTR in ovary. To investigate this hypothesis, we asked whether *Dazl* translation is suppressed via its 3'UTR or not by analyzing a bacterial artificial chromosome (BAC) carrying transgenic mouse line in which the *Dazl* 3'-UTR was flanked with Frt sequences followed by rabbit β-globin 3'-UTR. We crossed the BAC transgenic mice to Gt(ROSA)26Sortm2(FLP*)Sor (Rosa-Flp) mice to remove the *Dazl* 3'-UTR and investigated the DAZL expression. The results showed that DAZL expression was increased when the 3'–UTR was removed, suggesting that *Dazl* translation is suppressed in a 3'–UTR–dependent manner. In order to investigate the effect of excess DAZL on female reproduction, we examined the litter size of transgenic females. Interestingly, female mice expressing excess DAZL produced reduced number of offspring. These data indicate that 3'UTR–dependent suppression of DAZL in postnatal oocytes is important for female reproduction. These data also indicate the presence of a mechanism to suppress DAZL expression in the 3'UTR dependent manner.

M5066C SOX9 in developing heart valves and adult valve disease. *P. A. Hoodless*[1,3], V. C. Garside[1], M. Bilenky[2], R. Cullum[1]. 1) Terry Fox Laboratory, BC Cancer Agency, Vancouver, BC, CA; 2) Genome Sciences Centre, BC Cancer Agency, Vancouver, BC, CA; 3) Dept. of Medical Genetics, University of British Columbia, Vancouver, BC.

Abnormal heart valve formation leads to a third of all cardiovascular birth defects. Valve defects can have detrimental effects on heart function and can lead to an increase in disease susceptibility. SOX9 is an essential transcription factor required in the development of the embryonic heart valves in mouse. Without its expression in this tissue, embryos have functional heart defects, fail to thrive, and die around E13.5. Previously, we identified the global transcriptional targets of SOX9 in embryonic day (E) 12.5 developing atrioventricular canal (AVC). Unlike many other transcription factors, SOX9 binding is heavily biased to the transcription start site and adjacent promoter regions. we have found that SOX9 has a universal role in regulation of cell cycle and proliferation genes across multiple cell types. Furthermore, analysis of heart ChIP-Seq libraries and transcriptome profiles on *Sox9*-deficient E12.5 heart valves revealed that SOX9 directly controls a critical network of transcription factors known to be involved in heart valve development. We have now generated SOX9 ChIP-seq data from E10.5 embryonic hearts, a time at which SOX9 expression is initiating in the AVC. In addition, we have used histone modification ChIP-Seq data to evaluate the chromatin landscape around the SOX9 binding sites. These histone modifications exhibit asymmetric patterns around the SOX9 site. Integration of data from the earlier time point (E10.5) builds a more complete picture of the regulation by SOX9. Additionally, from motif analysis of this data as well as proteomic analysis, critical factors bound with or to SOX9 in the developing valve have been identified. Our examination of the underlying mechanisms of SOX9 binding, gene expression changes when SOX9 is absent provides insights into the functional role that SOX9 plays in heart development.

M5067A Linear-(de)ubiquitination – a (uro)chordate specific mechanism - regulates Wnt signaling in the mouse. *S. Ivantsiv*[1,2], S. Almeida[1,2], R. Niibori[2], W. Dunham[1,2], A. C. Gingras[1,2], S. Cordes[1,2]. 1) University of Toronto, Department of Molecular Genetics., Toronto, ON, Canada; 2) Lunenfeld Tanenbaum Research Institute, Mount Sinai Hospital., Toronto, ON, Canada.

Ubiquitination is a post-translational modification that is crucial for many physiological processes and when disrupted, can lead to human diseases, including autism and neurodegenerative disorders. During ubiquitination, a covalent bond is generated usually between the carboxy-terminal amino acid of ubiquitin and a lysine in the target protein. Ubiquitin itself contains seven lysines that can undergo ubiquitination to form polyubiquitin "chains". An atypical linear ubiquitin chain (called Met1-Ub), which involves fusing the carboxy-terminus of one ubiquitin to the starting methionine of another, emerged in (uro)chordates. Only the linear ubiquitin assembly complex (LUBAC) is known to have linear ubiquitinating activity to date. We identified the first known dedicated linear deubiquitinase *Otulin (Gumby/Fam105b)*. Prior to our work, linear ubiquitination was only known to have postnatal roles in inflammation and adaptive immunity. By analyses of an allelic series of *Otulin* mouse mutants, we showed that linear (de)ubiquitination regulates facial nerve and craniofacial development and angiogenesis.

The *OTULIN* gene resides on human chromosome 5p15.2 (mouse Chromosome 15), deletions of which are associated with craniofacial deficits, intellectual disability and behavioral anomalies seen in Cri du Chat Syndrome (CdCS) patients. By pursuing an interaction between the Wnt signaling component disheveled 2 and OTULIN, we discovered a role for linear ubiquitination in modulating canonical Wnt signaling. In brief, linear ubiquitination inhibits, while deubiquitination (re)activates canonical Wnt signaling. Disruption of Wnt signaling can cause craniofacial anomalies, neural tube defects and neuronal dysfunction, and, thus, may lie at the heart of some CdCS symptoms.

To analyze the roles of linear (de)ubiquitination homeostasis in Wnt signaling and of relevance to CdCS, we have generated a conditional *Otulin* null mutant, which exhibits more severe neurobiological deficits than the extant *Otulin* point mutants. Moreover we have used AP-MS and the linear ubiquitin binding domain (UBAN) of the NEMO protein fused to glutathione-binding protein (UBAN-GST) to recover OTULIN client proteins. Using this approach we show that linear (de)ubiquitination of key Wnt signaling components controls their subcellular fate and thus regulates Wnt signaling.

This work highlights a new chordate-specific level of regulation of WNT signaling. Furthermore OTULIN belongs to a family of pharmaceutically targetable deubiquitinases and thus may present a novel target for modulating WNT dependent processes relevant to human disorders.

M5068B Sperm proteome maturation in the mouse epididymis. *T. Karr*[1], S. Skerget[2], M. Rosenow[3]. 1) Kyoto Institute of Technology, Kyoto, JP; 2) Arizona State University, Tempe, AZ; 3) Caris Life Sciences, Phoenix, AZ.

In mammals, transit through the epididymis, which involves the acquisition, loss and modification of proteins, is required to confer motility and fertilization competency to sperm. The overall dynamics of maturation are poorly understood, and a systems level understanding of the complex maturation process will provide valuable new information about changes occurring during epididymal transport. Using shotgun discovery proteomics, we report the proteomes of sperm collected from the caput, corpus and cauda segments of the mouse epididymis, identifying 1536, 1720 and 1234 proteins respectively. This study identified 765 proteins that are present in sperm obtained from all three segments. We also identified 1766 proteins that are potentially added (732) or removed (1034) from sperm during epididymal transit. Phenotypic analyses of the caput, corpus and cauda sperm proteomes identified 60 proteins that have known sperm phenotypes when mutated, or absent from sperm. Our analysis indicates that as much as one-third of proteins with known sperm phenotypes are added to sperm during epididymal transit. GO analyses revealed that cauda sperm are enriched for specific functions including sperm-egg recognition and motility, consistent with the observation that sperm acquire motility and fertilization competency during transit through the epididymis. In addition, GO analyses revealed that the immunity protein profile of sperm changes during sperm maturation. Finally, we identified components of the 26S proteasome, the immunoproteasome, and a proteasome activator in mature sperm.

M5069C The role of *Robo* genes during development of the intervertebral discs. *Lisa Lawson*, Lance Denes, Brian D. Harfe. University of Florida, Gainesville, FL.

Lower back pain is an often chronic and debilitating condition that poses an economic burden of 100 billion annually in the United States alone. Based on recent projections made by the Global Burden of Disease Study, lower back pain is now predicted to be the leading cause of disability worldwide. Degenerative disc disease is a known contributor to lower back pain. Despite its high lifetime prevalence and economic burden, few effective therapies exist to reverse discogenic back pain. One critical obstacle to disc regenerative therapy, which aims to restore disc function by replacing damaged cells with healthy cells, is that the ontogeny of intervertebral disc cells and the mechanisms by which the discs are formed are not understood. Using the mouse model system we identified potential roles for ROBO-SLIT signaling during development of the intervertebral discs. ROBO-SLIT signaling is known to mediate organogenesis of the brain, kidneys, and foregut through a chemotactic mechanism. The role of ROBO-SLIT signaling during vertebral column and intervertebral disc morphogenesis is unknown. Using molecular approaches, we have determined that *Robo* and *Slit* mRNAs are expressed in complementary patterns during mouse disc development. We found that in the absence of ROBO1 and ROBO2 receptors the vertebral column forms with aberrantly shaped intervertebral discs that contain enlarged annulus fibrosus cells. Lineage tracing analysis using the *Gt(ROSA)26Sor*$^{tm4(ACTB\text{-}tdTomato,\text{-}EGFP)Luo}$ (Rosa-mTmG) dual fluorescence reporter mouse showed that the disc phenotype was not caused by aberrant cell migration and/or cell mixing of nucleus pulposus an annulus fibrosis cells in the disc. Based on the dysregulated presence of *Ihh* and *Col10a1* mRNA in the vertebral growth plates of double *Robo* mutant mice, we propose that the observed disc morphology may result from disruption of ROBO-mediated growth plate dynamics in vertebrae adjacent to the forming discs.

M5070A Study of dendritic cell development *in vitro* and *in vivo* using immortalized hematopoietic stem and progenitor cells. *Chien-Kuo Lee*, Yi-Fang Fan, Ching-Yu Lu. National Taiwan University College of Medicine, Taipei, TW.

Dendritic cells (DCs) are specialized immune cells critical for regulating the innate and adaptive immune responses. While DCs, including conventional DC (cDC) and plasmacytoid DC (pDC) are short-lived and are constantly replenished from their progenitors of myeloid and lymphoid lineages, the study of developmental control of DCs is hampered by limited numbers of the progenitor cells. Here we immortalized hematopoietic stem and progenitor cells (iHSPC) by introducing an inducible *Hoxb8* gene into 5-fluorouracil (5FU)-treated mouse bone marrow. The iHSPCs were able to develop into pDC and cDC in response to Flt3 ligand (FLT3L) treatment. Moreover, the iHSPCs were capable of producing T, B, macrophages and granulocytes in addition to DCs when adaptively transferred into γ-irradiated recipient mice, suggesting that the iHSPCs retained their pluripotency for differentiation. We have previously shown that common lymphoid progenitors (CLPs) exhibited higher pDC potential than did cDCs. TLR-induced inflammation or influenza virus infection remodeled the developmental program by promoting cDC formation but inhibiting pDC generation *in vitro* and *in vivo* through upregulation of, *Id2*, a cDC-specific factor and downregulation of *Tcf4* and *Spib*, two pDC-specific factors. Interestingly, the iHSPCs also phenocopied the developmental features of primary CLPs in response to the same stimulation. Lentivirus-mediated RNA silencing in iHSPC had identified STAT3 and AKT as key signaling molecules controlling pDC development from the progenitors. Knockdown of either molecule resulted in increased cDC but reduced pDC potential from iHSPCs. A similar phenotype was observed in conditional knockout of STAT3 in primary progenitor cells. These results have demonstrated that iHSPC is a powerful tool to systemically investigate signaling events dictating DC homeostasis at steady-state and inflammation. Since malfunction or uncontrolled activation of pDCs is associated with autoimmune diseases, such as systemic lupus erythematosis and psoriasis, this study may provide potential therapeutic strategies to circumvent the diseases.

M5071B A novel hypomorphic smoothened allele results in impaired sonic hedgehog signaling and skeletal defects. *A. B. Long*, J. Ben-Ami, T. Caspary. Emory University, Atlanta, GA.

Smoothened (SMO) plays a key role in vertebrate hedgehog (Hh) signaling, which regulates patterning and proliferation in many tissues through three ligands: sonic (SHH), Indian and desert hedgehog. We have identified an autosomal recessive mutation in mouse *Smo* that causes impaired Hh signaling leading to defects in neural tube patterning and skeletal development. Our mutant, *Smo*^{m1Tc} (AW4), was isolated during a forward genetic *N*-ethyl-*N*-nitrosourea (ENU) screen. Using chromosome mapping and sequencing, we determined the mutation to be a conserved asparagine to lysine change at amino acid 223 of the SMO protein. Through analysis of the mutant embryos, we saw a moderate

dorsalization of the neural tube, consistent with decreased SHH signaling. We isolated fibroblasts from the AW4 embryos and observed decreased levels of target gene transcription after treatment with SHH-conditioned media. Curiously, we saw no SMO enrichment in cilia upon SHH stimulation of AW4 fibroblasts, as occurs in wildtype cells. SMO is a seven-transmembrane G protein-coupled receptor with an extracellular binding pocket. The AW4 mutation, located in the extracellular domain of SMO, is likely to alter the binding pocket of SMO. While *Smo*-null mutants die at E9.0, the AW4 mutant embryos survive until birth – permitting examination of SMO-dependent skeletal development, with a particular focus on craniofacial and limb structure, both of which are abnormal beginning at embryonic day 10.5. The mutant midface and maxilla are both hypomorphic with a moderate collapse toward the midline, and the phalanges are short compared to wildtype embryos. Taken together, our results indicate AW4 is a hypomorphic *Smo* allele and suggest that ciliary SMO enrichment is not absolutely required for pathway activation.

M5072C Mice mutant for *Cecr2*, which codes for a chromatin remodelling protein, show severe male subfertility that significantly improves with age. *Heather E. McDermid*, Chelsey B. Weatherill, Kenji Rowel Lim, Vivian V. Nguyen, Ross C. Humphreys, Kacie A. Norton. University of Alberta, Edmonton, AB, Canada.

Mammalian reproduction requires an exquisitely complex interplay of genes which must be regulated spatially and temporally to ensure both development of the gonad and successful fertilization of gametes. Part of this process depends on chromatin remodellers, which are able to affect nuclear processes such as gene transcription, DNA replication, recombination or repair through modulation of chromatin structure. Mutations in chromatin remodelling gene *Cecr2,* which is expressed in spermatogonial cells, result in an unusual form of male subfertility that is most severe at maturity and improves with age. This improvement is demonstrated by three different measures. First, mutant males (BALB/c-*Cecr2*$^{Gt(pGT1)Hemc}$/*Cecr2*$^{Gt(pGT1)Hemc}$) are least fertile immediately after sexual maturity (42-60 days). Within 2 months, litter sizes improve from 11.7% to 58.3% of the litter sizes of their wildtype brothers. Second, histological analysis reveals severe defects in the seminiferous tubules of newly mature males, including tubules that have very few cell layers and are not completing spermatogenesis. These defects become less prevalent and less severe with age, until testes at 3+ months appear close to normal in structure. Histological analysis of immature testes shows that mutant testes at 14 days are indistinguishable from wild type, and defects are first visible at between 19 and 21 days. Third, analysis of wildtype eggs, fertilized *in vivo* and collected 5 hours later, indicate that subfertility in mutants is due to fewer oocytes being fertilized. Mutants males aged 42-60 days show a fertilization rate of ~5% compared to their wild type brothers. At 60-100 days of age the mutant males show ~35% of the normal fertilization rate, and after 100 days the fertilization rate is not significantly different between mutants and wild types. Intriguingly, this partial rescue of the age dependent phenotype may be due to increasing levels of *Cecr2* transcript within the mutant testis, either from the previously characterized *Cecr2* transcript with a hypomorphic mutation, or from a novel transcript expressed from a newly discovered alternate exon 1. Determining how *Cecr2* causes subfertility in mice and the mechanism by which the phenotype improves with age will advance our understanding of the various roles that chromatin remodeling plays during spermatogenesis and fertilization.

M5073A Regulation of murine coat color by transgenic expression of endothelin 3. *Javier Pino*, Lidia Kos, Alexander Durango. Florida International University, Miami, FL.

The production of pigment involves several signaling molecules essential for the proper development and function of melanocytes. Lethal yellow mice (A^y) have a non-functional MC1R pathway leading to the production of pheomelanin in the hair. Doxycycline (dox) inducible transgenic mice that express *Edn3* under the keratin 5 promoter Tg(KRT5-Edn3)#Kosl showed hyperpigmentation of the skin and coat. Tg(KRT5-Edn3)#Kosl darkened the coat color of A^y mice. We hypothesize that EDN3 compensates for the absence of MC1R signaling by upregulating melanogenic genes. To test if continuous transgenic *Edn3* expression is required to maintain a dark pigmentation phenotype in A^y mice, dox was administered to newborn pups, deactivating transgenic *Edn3* expression. After 6 weeks of dox treatment, the coat color of A^y Tg(KRT5-Edn3)#Kosl mice was similar to those of A^y littermates. The comparative analysis of dorsal hairs from A^y and A^y Tg(KRT5-Edn3)#Kosl mice using high performance liquid chromatography showed that transgenic *Edn3* expression significantly increased both eumelanin and pheomelanin in A^y mice. The number of melanocytes in hair follicles of Tg(KRT5-Edn3)#Kosl mice as evidenced by immunofluorescence with an antibody against tyrosinase related protein 1 was similar to that of non-transgenic littermates. Gene expression analysis of the hair bulbs of A^y Tg(KRT5-Edn3)#Kosl mice showed that EDN3 up regulates the expression of melanogenic genes such as tyrosinase. Our results indicate that the paracrine expression of *Edn3* from keratinocytes is capable of generating and maintaining a dark coat color in the absence of a functional MC1R pathway by the regulation of melanogenic genes.

M5074B Simulation of transient oscillatory *Neurog3* expression during pancreatic duct development. *G. K. H. Przemeck*[1,2], Hendrik B. Tiedemann[1], Elida Schneltzer[1], Johannes Beckers[1,2,3], Martin Hrabe de Angelis[1,2,3]. 1) Helmholtz Zentrum Muenchen, Neuherberg, Germany; 2) German Center for Diabetes Research (DZD), Neuherberg, Germany; 3) Technische Universitaet Muenchen, Freising, Germany.

During pancreas development, *Neurog3* positive endocrine progenitors are specified by Delta/Notch (D/N) mediated lateral inhibition in the growing ducts. During neurogenesis, genes that determine the transition from the proneural state to neuronal or glial lineages are oscillating before their expression is sustained. Although the basic gene regulatory network is very similar, cycling gene expression in pancreatic development was not investigated yet, and simulations of lateral inhibition in pancreas development excluded by design the possibility of oscillations. Here, we developed a dynamic 3D model of a growing duct that results in an oscillatory phase before the determination of endocrine progenitors by lateral inhibition. The basic network (D/N + Hes1 + Neurog3) shows scattered, stable *Neurog3* expression after displaying transient expression. Furthermore, examining network designs that were discussed in neurogenesis we included Hes1 negative

feedback and show the consequences for *Neurog3* expression in pancreatic duct development. A weakened HES1 action on the *Hes1* promoter allows the coexistence of stable patterning and oscillations. In this way, we argue for a unified mode of D/N mediated lateral inhibition in neurogenic and pancreatic progenitor specification.

M5075C Oscillatory Expression of cyclin A2 Requires the E2F Consensus Binding Site. *Jessica B. Rakijas*, Lindsey N. Kent, M. Cecilia Cuitino, Gustavo Leone. The Ohio State University, Columbus, OH.

The Rb-E2F pathway is a critical signaling axis that controls cell cycle transitions. The E2F family of transcription factors comes in two varieties: activators (E2F1-3) and repressors (E2F4-8). The RB tumor suppressor can repress E2F target gene expression through physical interaction with both E2F1-3 activators by inhibiting their transactivation function and E2F4-6 repressors by forming protein complexes that inhibit gene expression. The non-canonical E2F7 and 8 repress gene expression independent of RB. It is generally accepted that modulation of gene expression is a direct result of promoter binding by a transcription factor. As evidence, site-specific transcription factors, such as E2F, appear to require a consensus DNA binding sequence to assert their function. However, it is unclear how a transcription factor family with such varied mechanisms of action can regulate the same genes purportedly through the same DNA binding site. Thus, the purpose of this study is to test the limits of the assumption that all E2Fs require the presence of an intact DNA binding site to regulate target gene expression in a periodic fashion during the cell cycle and development.

We have taken an alternative approach to investigate the requirement of E2F-binding for transcriptional regulation of genes through the cell cycle in both mouse embryo fibroblasts (MEFs) and intact mouse tissues. To this end, we have generated a novel knock-in mouse of a critical cell cycle gene, cyclin A2 (*Ccna2)* by introducing a promoter mutation disrupting the established E2F binding site (STOCK-*Ccna2*^{tm2Gle}). In cycling cells, *Ccna2* expression is dynamic, increasing in late G1, peaks in early G2 and is shut off before the end of mitosis. In the developing liver, *Ccna2* expression is also dynamic, showing high expression during embryogenesis and early postnatal development, but is nearly undetectable by sexual maturity. Using real time PCR and western blot, we demonstrate that in knock-in MEFs and mouse liver, the expression of *Ccna2* RNA and protein is static over the cell cycle and developmental time, respectively. Additionally, we have shown using immunohistochemistry that mutant animals have higher liver macrophage infiltration than their wildtype counterparts, suggesting disruption to E2F binding affects tissue homeostasis in addition to ectopic expression of E2F target genes. We conclude that the E2F binding site in the *Ccna2* promoter is required for cell cycle- and developmentally-dependent oscillatory expression of *Ccna2*, yielding higher levels of inflammation in developing livers.

M5076A The cilia protein ARL13B regulates axon guidance in the mouse hindbrain. *S. K. Suciu*[1,3], L. E. Mariani[2,3], J. Ferent[4], J. Guo[5], E. S. Anton[5], F. Charron[4], T. Caspary[3]. 1) Genetics and Molecular Biology Graduate Program; 2) Neuroscience Graduate Program; 3) Emory University, Atlanta, GA 30322; 4) IRCM, Montreal, Quebec, Canada; 5) University of North Carolina, Chapel Hill, NC 27599.

Sonic hedgehog (SHH) signaling is a critical developmental pathway best known to regulate cell fate specification and cell proliferation. This occurs in the cilium through SHH activation of downstream effector smoothened (SMO) and GLI transcription factors. Additionally, SHH regulates axon guidance in the developing spinal cord and optic chiasm through a distinct, transcription-independent pathway. *Arl13b* encodes a small GTPase enriched in cilia that regulates transcription-dependent SHH signaling at the level of and downstream of SMO. Recessive mutations in *ARL13B* cause the ciliopathy Joubert Syndrome (JS), a disorder defined by intellectual disability, cerebellar hypoplasia, and physical deformities. JS is diagnosed by MRI-evidence of a hindbrain malformation known as the Molar Tooth Sign, which is caused in part by the white matter tracts called superior cerebellar peduncles (SCPs) failing to cross the midline of the brain. JS patients also exhibit midline crossing defects in the optic chiasm and failure of the corticospinal tract to cross the midline. Collectively, these phenotypes indicate JS patients display axon guidance defects; however, no known mechanism connects cilia genes such as *ARL13B* to the regulation of axon guidance. Because transcription-independent SHH signaling can regulate axon guidance, and *ARL13B* mutations lead to axon guidance defects in JS, we hypothesize that ARL13B also regulates transcription-independent SHH signaling to direct axon guidance in the developing brain. To test this hypothesis, we examined SCPs direction and uniformity in mouse brains lacking either SMO or ARL13B in projection neurons by performing diffusion tensor imaging (DTI) MRI. We showed that SCPs lacking SMO display significant midline crossing defects in the hindbrain, indicating axon guidance in these projection neurons is SMO dependent and suggesting SHH as a possible guidance cue. Furthermore, there is a midline crossing defect in SCPs lacking ARL13B, supporting our hypothesis that ARL13B regulates this transcription-independent SHH signaling pathway. Our ongoing work continues to investigate the role of ARL13B and SMO in SCP midline crossing through DTI and fluorescent tract tracing. Through these methods, we aim to define the role of ARL13B in transcription-independent SHH signaling and form a novel connection between ciliary genes and axon guidance.

M5077B Population Variability and The Teratogenic Effects of Exposure to 2, 3, 7, 8-Tetrachlorodibenzo-p-dioxin During Pregnancy. *M. R. Warren*[1,2], D. Threadgill[1,2]. 1) Texas A&M Health Science Center, College Station, TX; 2) Texas A&M College of Veterinary Medicine and Biomedical Sciences, College Station, TX.

Dioxin, formally known as 2, 3, 7, 8-tetrachlorodibenzo-p-dioxin (TCDD), is a well-known toxin that exhibits carcinogenic and deleterious effects on various tissues and organs. People are exposed to small amounts of this persistent environmental pollutant through everyday products (i.e. styrofoam cups) and common foods. Dioxin exposure during pregnancy is a particular concern as it heightens the risk of fetal malformations. While toxin susceptibility often varies among individuals due to genetic differences, current studies of the teratogenic effects of dioxin do not account for inter-individual variability when evaluating exposure risks. Our study aims to evaluate the effects of dioxin exposure on pregnant females and their embryos in genetically diverse mice to determine how genetic background impacts susceptibility.

According to the National Research Council (NRC), dose-response will linearize with non-cancerous endpoints even when accounting for genetic variability among the population. To test this prediction, we developed an *in vivo* study with a panel of mice that collectively mimic the

amount of genetic variability present in human populations. In this study, 36 strains of pregnant female mice are being exposed to increasing doses of TCDD (0.001, 0.01, 0.1, 1, 10, 50, 100 ng/kg/day) for a period of 10 days following mating. At day (D)10.5 post mating the mice are euthanized and organs (kidney, liver, spleen, brain, uterus, lungs) and embryos collected.

Initial data identified several strains, such as 129S1/SvlmJ and CC019, as "resistant" to all levels of exposure. These strains showed no significant differences in implantation trends or the stage of embryonic development in comparison to untreated controls. High dose exposure led to a significant decrease in implantation rate in non-resistant strains, such as C57BL/6J and CBA/J. High dose exposure of TCDD (50 ng/kg and 100 ng/kg, per day) in these mice caused a trend toward a decrease in the number of viable embryos and delayed development within certain strains.

The data has shown interstrain differences greatly impacts the level of response and the overall outcome of pregnancy during exposure to TCDD. Ultimately the study will determine whether dose responses are linear when analyzed on individual genetic backgrounds, as they are when performed on a combined, genetically mixed population.

M5078C The meiotic functions of aurora kinases during spermatogenesis in mice. *Stephen Wellard*[1], Alexandra L. Nguyen[2], Karen Schindler[2], Philip Jordan[1]. 1) Department of Biochemistry and Molecular Biology, Johns Hopkins Bloomberg School of Public Health, Baltimore, Maryland, USA; 2) Department of Life Sciences, Rutgers University, New Brunswick, New Jersey, USA.

Co-ordination of the dynamic chromosomal events during meiosis is critical to ensure accurate chromosome segregation for the next generation. Missegregation of chromosomes during meiosis can cause chromosomal aneuploidies, which result in miscarriage and genetic disorders such as Down syndrome. Previous studies conducted in budding yeast have implied that aurora kinases (AURKs) impact a number of critical events during the meiotic prophase I to metaphase I transition (G2/MI), including the disassembly of the synaptonemal complex (SC) and the faithful production of a bipolar spindle. While the events of meiosis are evolutionarily conserved, the mechanisms for controlling these events can differ markedly between distant species, complicating attempts to bridge findings in lower eukaryotes to humans. For instance, budding yeast expresses a single AURK protein, whereas mammals express three AURKs (AURK A, B, and C) with AURKB and AURKC showing structural and functional similarities. To delineate the meiotic roles of these three mammalian AURKs in mice, we have used a combination of chemical and genetic approaches to abrogate AURK activity at various stages of meiotic prophase I. By inducing wild type spermatocytes to undergo the G2/MI transition with okadaic acid (OA) in the presence of specific AURK inhibitors, we have determined a functional role for AURKB and AURKC in initiating desynapsis disassembly of the lateral element component of the SC, SYCP3. Cells treated with AURKB/C inhibitors failed to disassemble SYCP3 stretches and were unable to complete the G2/MI transition. This phenotype was not observed in cells treated with a specific AURKA inhibitor. To gain further insight in the functions of AURKB and AURKC during spermatogenesis, novel STOCK-*Aurkb*$^{tm2.1Mama}$ Tg(Spo11-cre)1Rsw or Tg(Hspa2-cre)1Eddy conditional knockout mice and B6;129S5-*Aurkc*^{tm1Lex} knockout mice were characterized. Despite defects being observed in histological sections of testes as well as aberrancies in spindle morphology of metaphase cells, both AURKB and AURKC mutant mice were fertile. This work supports the meiotic specific function of AURKB and AURKC in the disassembly of the SC during the G2/MI transition, and implies that these two kinases may play functionally compensatory roles in mammalian meiosis. Our current work is focusing on assessing STOCK- *Aurkc*^{tm1Lex} , *Aurkb*$^{tm2.2Mama}$ double knockout mice to further evaluate the meiotic specific functions of the aurora kinases, and improve our understanding of meiotically derived human disorders such as defects that can result in infertility, miscarriage, and developmental abnormalities.

M5079A Epithelial development of pharyngeal arches and intestine requires a member of S100 protein. *S. Xie*[1,2], J. Li[1,2], T. Zhong[1,2]. 1) State Key Laboratory of Genetic Engineering,Fudan University, Shanghai, China; 2) Collaborative Innovation Center of Genetics and Development, Fudan University, Shanghai, China.

Although S100 calcium binding (S100) proteins are unique calcium-binding proteins with time-dependent patterns of expression, their roles in vertebrate development and organogenesis remain unknown. Here we identify that a member of *s100a* subfamily, is necessary for epithelial development of the pharyngeal arches and the gut tube. We generated transgenic zebrafish in which the expression of enhanced green fluorescent protein (EGFP) is under the control of a 4 kb upstream regulatory element of *s100* gene. The EGFP positive cells widely distribute along the surface of the transgenic embryos during early development and then are restricted to the epithelial layer covering pharyngeal arches, olfactory placodes and the gut tube. The EGFP positive cells in the intestinal epithulium display polarized enteroendocrine cell morphology and produce pancreatic peptide. We show that knockdown using morpholinos (MOs) of the *S100a* gene causes curved embryo bodies, reduction of *fgf3* expression and loss of posterior pharyngeal arches. Intestinal endocrine cells expressing *nxk2.2a*, a homeodomain transcriptional factor marking enteroendocrine cells, are absent in the *s100a* gene deficient embryos. Moreover, knockdown of *nkx2.2a* abolishes a subset of the *s100a* subfamily-expressing entroendocrine cells, whereas reducing the *s100a* subfamily in *nkx2.2a*-deficient embryos completely eliminates these enteroendocrine cells, revealing a regulatory complexity during enteroendocrine cell formation. We also established the germline mutant of the *s100a* gene using transcription activator-like effector nuclease (TALEN). All these findings thus establish the first known roles for S100 proteins during vertebrate development, and provide biological insights into the roles of epithelial patterning in development of the pharyngeal arches and the intestine.

M5080B Establishing bipotentiality for gonadal differentiation. *Y. Yang*, S. Sorensen, M. J. Wilson. University of Otago, Dunedin, NZ.

The distinction between sexes is one of the most obvious example of morphological dimorphism in the animal kingdom, that highlights one of the most crucial fate decisions made *in utero*; to become a male or female. In order for sexual development to occur, the formation of gonad anlagen is first required. Mammalian gonads are unique among the animal kingdom as they arise from a bipotential progenitor gonadal tissue called the urogenital ridge (UGR). However, very little is known about how the molecular networks that shape its formation and the molecular

preparations made to allow for two developmental trajectories. The LIM-homeobox gene, *Lhx9* is among only a handful of genes known to be required for UGR formation, but it's regulatory network, and that of the UGR is poorly understood. In order to investigate the molecular underpinnings involved in UGR formation, we took a large-scale approach using chromatin immunoprecipitation followed by next generation sequencing (ChIP-seq) to identify genes involved in this process.

ChIP-seq on mouse UGRs was preformed for LHX9 to target regions in the chromatin where LHX9 regulates. In addition ChIP-seq was also performed on two histone modification marks, H3K4me3 and H3K27me3, which highlight regions of active and repressive transcriptional states respectively. Regions in the genome where LHX9 or the histone marks were found were validated using ChIP-qPCR and *in situ* hybridization.

Targets of LHX9 validated by ChIP-qPCR were found to be required for processes such as sex determination, sexual differentiation, cell proliferation, angiogenesis and cell migration. In addition, several other targets whose expression patterns in the UGR were not previously characterized was determined by *in situ* hybridization. Furthermore, looking at both histone mark ChIP-seq datasets, many genes were found to possess a 'bivalent' histone modification dynamic, whereby both H3K4me3 and H3K27me3 were found in the promoter or enhancer regions. This histone dynamic has been characterized as a feature that highlights certain lineage regulatory genes, holding them in a 'poised' transcriptional state. In particular, many genes involved in the *Wnt* signaling pathway were identified to possess bivalent histone marks. Several genes of the *Wnt* family were validated via ChIP-qPCR. Bringing both ChIP-seq datasets together, we provide a wider scope of the transcriptional and epigenetic regulatory network that is necessary for UGR formation, but also the preparation for sexual development.

M5081C Embryonic lethality in mice expressing conditionally-stabilized *Ctnnb1* under control of Tg(Vil-cre)997Gum. *E. Yusi*[1,2], R. Lynch[2], D. Threadgill[2]. 1) University of Surrey, Guildford, United Kingdom; 2) Texas A&M University, College Station, TX.

CTNNB1 (beta-catenin), which is degraded through a ubiquitin-dependent mechanism, is stabilized upon activation of the WNT pathway and functions as a transcriptional co-activator of WNT-responsive genes. Some cancers like colorectal cancers develop dominant acting mutations in *Ctnnb1* that lead to constitutive WNT signaling and cellular transformation. In this study, originally designed to develop a model of CTNNB1-induced colon cancer, we observed that mice carrying both a conditional stabilizing mutation of the *Ctnnb1* gene (*Ctnnb1*^{tm1Mmt}, hereafter called *Ctnnb1*$^{F(Ex3)}$) and a Cre recombinase whose expression is under the control of the murine villin 1 promoter (Tg(Vil-cre)997Gum/J, hereafter called Vil-cre) believed to be specific to the colon and kidney die during embryonic development. To isolate the time point of embryonic death, pregnant dams were euthanized and their embryos dissected at various time points, starting with E10.5. All embryos were inspected for gross abnormalities, and PCR was used to determine the genotype of the embryos. We found that while no double-heterozygous mice were observed neonatally, the litters dissected at E10.5 were developmentally normal and exhibited Mendelian inheritance ratios, suggesting the observed embryonic lethality was not due to preimplantation defects as has been reported for *Ctnnb1* null embryos. However, an increase in reabsorption sites was noted at E13.5 and some remaining embryos exhibited delayed development. These abnormal embryos were found to carry both the *Ctnnb1*$^{F(Ex3)}$ and Vil-cre alleles. These results are suggestive of placental defects. Identifying the molecular mechanisms underlying the cause of embryonic lethality will allow us to better characterize the role of canonical WNT signaling in placental development. Furthermore, the *Vil1* gene has been implicated in gut development and is known to be expressed as early as E9, but has yet to be involved in placental development. Ongoing efforts are focusing on the determining the exact cause of embryonic lethality in *Ctnnb1*$^{F(Ex3)}$), Vil-cre double mutants.

M5082A Post-transcriptional regulation of mouse neurogenesis by pumilio proteins. *M. Zhang*, D. Chen, J. Xia, W. Han, G. Hermes, N. Sestan, H. Lin. Yale University, New Haven, CT.

Mammalian neurogenesis is a key aspect of embryogenesis and persists throughout lifetime. Extensive studies have discovered various regulators of neurogenesis. But little is known about the post-transcriptional regulation that delivers much more rapid and subcellularly localized control of gene expression.

The purpose of this project is to study the post-transcriptional regulation of mouse neurogenesis by two RNA binding proteins, pumilio (PUM) 1 and 2—the two murine members of the evolutionarily conserved PUF protein family. This family is known to mediate post-transcriptional regulation. PUF proteins are required for germline stem cell maintenance in *Drosophila* and *C. elegans* and for spermatogenesis in mice, but their function in neurogenesis has not been well established.

To investigate the function of PUM1 and PUM2 in neurogenesis, we generated double conditional knockout mice by crossing *Pum1* and *Pum2* double loxP mice (with loxP sites flanking certain exons) with a mouse line carrying a Cre-expressing transgene driven by the nestin promoter. PUM1/2 are depleted by the Nes-cre in the entire central nervous system by E15.5. In these mice, we observed severe atrophy of the dentate gyrus (DG) in neonatal and adult brains along with drastically increased apoptosis in neonatal brains. This is very exciting as adult neurogenesis occurs in DG to generate new neurons for the hippocampus--the learning and memory center. Consistent with this phenotype, our behavioral tests revealed that *Pum* mutants are largely impaired in learning and memory. Using markers for different cell types along neurogenesis we found that removal of PUM1 and PUM2 led to increased EOMES (Tbr2)-positive neuronal progenitors but decreased DCX-positive immature neurons. Moreover, the cultured neural stem cells from the double knockout DG are deficient in forming neurospheres and display defects in proliferation and survival. All these lines of evidence suggest that PUM1 and PUM2 together regulate neurogenesis by preventing immature differentiation and apoptosis, which sustains the homeostasis of newborn neurons.

To identify PUM target mRNAs and downstream pathways, we performed iCLIP (cross-linking immunoprecipitation) using PUM1/2 antibody and neonatal brain lysates. The RNA targets and binding sites are identified; they are involved in pathways that are crucial to neurogenesis such as cell proliferation, differentiation, apoptosis, and cytoskeleton.

Overall the results have shown that PUM1 and PUM2 together play a vital role in regulating mouse neurogenesis at post-transcriptional level by regulating their RNA targets in various pathways.

M5083B Wnt/beta-catenin signaling modulates cytoskeleton dynamics to direct mammalian neural tube closure. *C. Zhou*, T. Zhao, Q. Gan, R. Lassiter, Y. Wang, A. Stokes. University of California Davis, School of Medicine, Sacramento, CA.

We have recently demonstrated that neuroepithelial beta-catenin is required for caudal neural tube closure by regulating critical downstream transcription factors *Pax3* and *Cdx2* in the dorsal neural folds. Our unpublished data demonstrate that conditional ablation of a key WNT coreceptor LRP6 in neuroepithelial cells of the dorsal neural folds also causes spina bifida with diminished expression of *Pax3* and *Cdx2*, which are similar as seen in the neuroepithelial beta-catenin mutants. We demonstrate that genetic activation of beta-catenin in the dorsal neural folds can rescue neural tube closure defects in the conditional *Lrp6* mutant mice. These results demonstrate a previously undetermined role of canonical Wnt/beta-catenin signaling pathway in caudal neural tube closure. To further address the roles of Wnt/beta-catenin signaling in neural tube closure and underlying mechanisms, we have generated novel mutants by conditional gene-targeting in the non-neural surface ectodermal cells. Our preliminary results demonstrate that surface ectodermal Wnt/beta-catenin signaling is required for the closure processes of the entire neural tube, which may mainly act through regulation of F-actin-based cytoskeleton dynamics. Because beta-catenin is also a cell adhesion molecule, we have preliminarily addressed the undetermined role of cell adhesion in neural tube closure. Our results reveal novel mechanisms underlying mammalian neural tube closure, which may provide a basis for better understanding and addressing the cause and prevention of neural tube closure defects in humans.

M5084C An inbred *Tp53* rat model exhibits a tumor spectrum similar to human Li-Fraumeni syndrome. *J. Amos-Landgraf*[1], S. Hansen[1], M. Hart[1], S. Busi[1], K. Jones[2], E. Bryda[1]. 1) University of Missouri, Columbia, MO; 2) Huntsman Cancer Institute, Salt Lake City, UT.

Somatic mutations in the *TP53* tumor suppressor gene are one of the most commonly observed genetic alterations in cancer, and germline mutations in *TP53* result in Li-Fraumeni syndrome and predispose individuals to a variety of early-onset cancers. Current *Tp53* mouse and rat models have significant phenotypic and genetic limitations and often do not recapitulate the certain aspects of human disease. The majority of *Tp53* rat mutants are maintained as outbred stocks, potentially contributing to the variability of the phenotypes. We used a marker-assisted speed congenic approach to transfer a well-characterized *Tp53* mutant allele from an outbred Sprague Dawley (SD) rat stock to the genetically inbred Fischer 344 (F344) rat to create the F344-*Tp53*$^{tm1(EGFP\text{-}Pac)Qly}$/Rrrc rat strain. On the F344 genetic background the tumor spectrum shifted, with the primary tumor types being osteosarcomas (32%) and meningeal sarcomas (32%), compared to the hepatic hemangiosarcoma (80% incidence in homozygotes) and lymphoma (55% incidence in heterozygotes) identified in the original outbred stock model. The F344 model is more consistent with the early onset of bone and central nervous system sarcomas found in humans with germline *TP53* mutations. Osteosarcomas represented 36% and 31% of tumors that developed, in homozygous and heterozygous animals, respectively, and were highly representative of the human disease radiographically and histologically, with tumors harbored primarily on long bones with frequent pulmonary metastases.

We crossed the F344-*Tp53*$^{tm1(EGFP\text{-}Pac)Qly}$/Rrrc knockout rat to the F344/NTac-*Apc*^{Pirc} model of familial colon cancer to determine the effect on intestinal and extracolonic cancer development. There was no significant change in tumor multiplicities between any of the genotypic classes; however, there was a reduced number of *Tp53* homozygous mutants than expected and no female homozygous mutants were recovered.

The F344-*Tp53*$^{tm1(EGFP\text{-}Pac)Qly}$/Rrrc knockout rat is a powerful model to investigate compelling questions surrounding the development of osteosarcomas and meningeal sarcomas in the context of an inbred genetic background allowing for easy maintenance of the model and introgression of additional mutations that already exist in other strains on the F344 background. Importantly, the rapid onset of osteosarcomas and the unique lammellar bone structure in the rat compared to mice fills a current void in animal models that recapitulate human pediatric osteosarcomas and may facilitate studies to identify therapeutic targets.

M5085A *Arl13b* is a Novel Target for the Treatment of Medulloblastoma. *S. N. Bay*[1,3,8], B. D. Brown[2,4,8], J. Wen[2,8], R. C. Castellino[2,5,6,7,8], T. Caspary[1,8]. 1) Department of Human Genetics; 2) Department of Pediatrics; 3) Genetics and Molecular Biology Program; 4) Cancer Biology Program; 5) Aflac Cancer and Blood Disorders Center; 6) Children's Healthcare of Atlanta; 7) Winship Cancer Institute; 8) Emory University, Atlanta, GA 30322.

Medulloblastoma is a tumor of the cerebellum and is the most common malignant brain tumor of childhood. Current therapies, while effective, introduce severe negative consequences to patients, and new molecular approaches are needed. Overactivated sonic hedgehog (SHH) signaling causes about 30% of medulloblastomas. In vertebrates, SHH signaling requires the primary cilium, and pathway members – including SHH's receptor patched1 (*Ptch1*), obligate pathway transducer smoothened (*Smo*), and Gli family transcription factors – dynamically traffic in and out of cilia. Mutations in SHH pathway genes (including *Ptch1* and *Smo*) cause medulloblastoma, but Gli repressor has been shown to be protective against medulloblastoma formation. We study a ciliary GTPase called *Arl13b* that uniquely regulates SHH, both at the level of SMO and downstream of SMO, where it regulates Gli activator but not Gli repressor. Loss of *Arl13b* results in ligand-independent constitutive low-level pathway activation but prevents maximal signaling and spares Gli repressor, making ARL13B an attractive target for developing therapies. We hypothesized that the loss of *Arl13b* could reduce the high levels of pathway activation responsible for SHH-derived medulloblastoma formation while leaving Gli repressor intact, without ablating pathway activity completely. Here, we use a conditional allele of *Arl13b* in the mouse to show that ARL13B plays a role in cerebellar development through the regulation of proliferation and that its loss dramatically impacts SHH pathway output in a variety of conditions. Deletion of *Arl13b* effectively reduces signaling levels in the presence of constitutive pathway activation driven by an oncogenic form of SMO, and knockdown of *ARL13B* in human medulloblastoma cell lines reduces their clonogenic potential. Taken together, our *in vivo* and *in vitro* studies demonstrate that ARL13B is a novel target for the treatment of medulloblastoma.

M5086B Determining the significance of space radiation exposures: high resolution genomic mapping to determine overlap in susceptibility loci for HZE-ion induced, γ-ray induced, and spontaneous phenotypes in outbred mice. *E. F. Edmondson*[1], J. Raber[2], O. Iancu[2], D. Gatti[3], E. Garcia[1], N. Kleiman[4], D. Kamstock[1], C. Fallgren[1], M. M. Weil[1]. 1) Colorado State University, Fort Collins, CO; 2) Oregon Health & Science University, Portland, OR; 3) The Jackson Laboratory, Bar Harbor, ME; 4) Columbia University, New York, NY.

Cancer risk from galactic cosmic radiation exposure is considered a potential "showstopper" for a manned mission to Mars. Calculating the actual risks that will be confronted by spaceflight crews is complicated by our limited understanding of the carcinogenic effects of high charge, high energy (HZE) ions, a radiation type for which there are no human epidemiological data. Here, we examine some of the assumptions underpinning the current NASA model used to assess space radiation cancer risk.

To study the effects of HZE ion irradiation in a genetically heterogeneous population, 1850 HS/Npt stock mice of both sexes were genotyped for 77,808 SNPs and exposed to (1) 0.4 Gy of 240 MeV/n ^{28}Si ions or (2) 600 MeV/n ^{56}Fe ions, (3) 3 Gy of ^{137}Cs γ-rays, or (4) sham irradiated. The mice were monitored for cataractogenesis, cognitive deficits, and cancer development until they reached 800 days of age or became moribund. Comprehensive necropsies were performed on each mouse and on all organ systems. Each detected lesion was characterized histologically. Genome reconstructions, which provide the basis for genome-wide SNP imputation, were completed for each mouse using algorithms for probabilistic assembly of founder haplotypes. Polygenic covariance among related individuals was corrected for during quantitative trait loci (QTL) mapping using a kinship term and significance thresholds were determined with permutation tests. To appreciate shared susceptibility loci for multiple neoplastic phenotypes following exposure to HZE ions or γ-rays, LOD scores from each QTL were plotted as heatmaps and hierarchically clustered.

The spectrum of tumors induced by accelerator produced HZE ions is similar to the spectra of spontaneous and gamma-ray-induced tumors, though the proportions of specific tumors differ. Quantitative trait loci (QTL) controlling susceptibilities to spontaneous, γ-ray-induced, and HZE ion-induced tumors are identified, and cluster analyses based on coincident loci point to share susceptibility loci for specific tumors types regardless of their origins (how they were induced). Malignancy, as measured by decreased latency or increased metastatic density, is comparable for radiation-induced and spontaneous tumors. Female mice are at a greater risk for radiogenic tumors than male mice. These findings support the assumptions underlying the current model used by NASA to estimate fatal cancer risks from space radiation exposures.

M5087C Complex genetic regulation of immune cell composition and activity in a genetically variable population. *M. T. Ferris*, A. C. Whitmore, A. P. Morgan, C. R. Morrison, D. R. Miller, F. Pardo-Manuel de Villena, M. T. Heise. Univ North Carolina, Chapel Hill, Chapel Hill, NC.

Immune cell populations represent a first line of defense against a variety of pathogens and immune insults. The composition of these cell populations within a given organ system determines the type and fit of potential responses. Here we utilize a set of approximately 100 F1 crosses between Collaborative Cross recombinant inbred lines to assess both variation in as well as genetic control of immune cell composition and activity levels in the lungs of unperturbed animals. We identified 30 cell populations within the lungs of these animals, and were able to identify 9 significant and 12 suggestive QTL regulating individual cell populations. We conditioned on these QTL loci, and were able to identify additional loci driving the composition of the immune cell population. Furthermore, we identified a population of immune cells who are only present in a subset of strains. Multiple genetic loci contribute to the presence of this population, and C57BL/6J alleles drive the absence of this population, suggesting that this commonly used mouse strain does not have this population of cells. In order to validate the underlying relationships between various cell populations, as well as those genetic loci we have identified, we conducted an analysis of immune cell populations from 100 Diversity Outbred animals. Our results highlight both the strong and complex genetic control of basal immune compositions, as well as the importance of studying immune cell populations across a range of genetically diverse models.

M5088A Evaluation of premetastatic niche formation in a mouse model of spontaneous melanoma lung metastasis. *J. Freitas*, J. Palmer, J. Sportsman, L. Kos. Florida International University, Miami, FL.

The deadliest trait of cancer cells is their capacity to colonize other sites of the body during a complex process called metastasis. Metastasis is the ultimate cause of death in 90% of patients with cancer, and there are still many remaining gaps in our understanding of metastasis formation. A number of studies have proposed the existence of an intricate crosstalk between primary tumors and future sites of metastases in order to transform the environment of these organs into a suitable microenvironment. This microenvironment is called the premetastatic niche, and is established to receive disseminating cancer cells, and support the growth of the metastatic colony. Melanoma is a highly metastatic cancer and preferentially establishes secondary lesions in lungs and brain. We have created a mouse model of melanoma B6(Cg)-Tg(Dct-Grm1)ESzc Tg(KRT5-rtTA)1Glk Tg(tetO-Edn3,-lacZ)Kosl or *(Dct-Grm1/K5-Edn3)* that spontaneously develops melanoma tumors and metastasizes to the lung. In order to describe the premetastatic niche formation in the mouse model of melanoma metastasis we monitored the appearance of bone marrow derived cells (BMDCs) clusters and metastatic cells during tumor progression by immunofluorescence and flow cytometry. We detected both BMDCs and tumors cells in the earliest stage of tumor progression suggesting that the lung melanoma metastasis in the *Dct-Grm1/K5-Edn3* mouse model is independent of premetastatic niche formation. We also found tumorigenic cells staining positive for both melanocytic and hematopoietic markers in higher numbers early during primary tumor formation. The appearance of Melanoma-BMDC hybrids in the lung suggest they might be the metastasis initiating cells, which might explain why the premetastatic niche formation is not required in the *Dct-Grm1/K5-Edn3* mouse model. Furthermore our findings implicate that Melanoma-BMDC hybrids are potential targets for melanoma treatment.

M5089B *GNL3* modulates prostate cancer metastasis susceptibility. *M. Lee*[1], K. A. Williams[1], Y. Hu[2], J. Andreas[1], S. J. Patel[1], S. Zhang[3], N. P. S. Crawford[1]. 1) Genetics and Molecular Biology Branch, NHGRI, NIH, Bethesda, MD 20892, USA; 2) Center for Biomedical Informatics and Information Technology, NCI, NIH, Rockville, MD 20850, USA; 3) Computational and Statistical Genomics Branch, NHGRI, NIH, Bethesda, MD 20892, USA.

Prostate cancer is the second leading cause of cancer mortality in men in developed countries. However, the molecular determinants of prostate cancer metastasis remain unclear. Previously, we reported that germline variation influences metastasis in the C57BL/6-Tg(TRAMP)8247Ng/J (TRAMP) mouse model of prostate cancer. These mice develop prostate tumors similar to a subset of poor outcome, treatment-associated human prostate cancer tumors. Germline variation introduced by PWK/PhJ caused significant suppression of tumor formation and metastases in the (TRAMP x PWK/PhJ) F1 males. *GNL3*, which encodes for a binding partner of p53 and functions in cell cycle regulation, was identified as a novel candidate metastasis susceptibility gene through a systems genetics approach using 201 (TRAMP x PWK/PhJ) F2 males and multiple prostate cancer patient datasets. Quantitative trait locus (QTL) mapping identified a locus on Chromosome 14 (LOD = 4.41; genome-wide *P* = 0.032) encompassing *Gnl3* to be associated with distant metastasis-free survival. In two prostate cancer patient datasets, *GNL3* expression was associated with an increased risk of aggressive disease and poorer disease-free survival. In addition, *GNL3* harbored SNPs associated with aggressive tumorigenesis in the PLCO/CGEMS GWAS of 1,172 prostate cancer patients. Here, we aim to examine the molecular mechanisms of GNL3 as a metastasis susceptibility modifier using human prostate cancer cell lines PC-3 and LNCaP stably over-expressing *GNL3.* Over-expression of *GNL3* in PC-3 caused an increase in cell proliferation and decreased *in vitro* cell migration and invasion compared to control cells. In soft agar assays, over-expression of *GNL3* in both PC-3 and LNCaP cells increased colony count. Subcutaneous injections into the flanks of NU/J male mice of *GNL3* over-expressing PC-3 cells, but not LNCaP cells, caused a significant increase in tumor burden compared to control. Pathway analysis of microarray data from cells over-expressing *GNL3* demonstrated that over-expression of *GNL3* modulates cell cycle regulators. These results collectively demonstrate a role for GNL3 in modulating metastasis susceptibility possibly by regulating cell cycle-related gene expression. This study, in addition to our previous studies, continues to exemplify how mouse models can be used to identify metastasis susceptibility genes through a novel systems genetics approach, and gives new insight into the molecular mechanisms of fatal prostate cancer.

M5090C Molecular analysis of epidermal growth factor receptor (EGFR)-independent colorectal cancers. *C. MANTILLA ROJAS*[1], M. YU[2], D. THREADGILL[1]. 1) Texas A&M University, College Station, TX; 2) 2University of North Carolina, Chapel Hill, NC.

According to the American Cancer Society, colorectal cancer (CRC) is the second leading cause of cancer-related deaths in the United States. Early detection efforts have reduced mortality, yet approximately 50,000 deaths are expected this year. Much of the etiology underlying CRC remains unclear, which hampers efforts to design more efficacious therapies. As such, a strong need exists to better understand the molecular mechanisms governing CRC progression. One of the first targets for molecular targeted therapies was the tyrosine kinase receptor epidermal growth factor receptor (EGFR). Preclinical studies in our lab and others showed that targeting EGFR greatly reduced incidence of CRC in mouse models. However, subsequent clinical trials using EGFR inhibitors were less efficacious, suggesting that targeting EGFR alone does not result in a significant benefit in most CRC cases. Mutations in *Kras* can explain some non-responding CRCs, but even in cancers lacking *Kras* mutations, little is known about which cancers are likely to respond. In this study, we used intestine-specific genetic ablation of *Egfr* in the $Apc^{Min/+}$ (genetic) and axozymethane (carcinogenic) CRC mouse models. We discovered that 10% of colonic tumors arise independent of EGFR activity. By molecular analysis we confirmed the absence of *Egfr* in these tumors, and conclusively demonstrated the existence of an EGFR-independent mechanism by which CRC can arise and progress. Residual tumors lacking EGFR were larger in size than those developing under normal EGFR activity, suggesting these cancers may be a more aggressive form of CRC. We also have evidence that ERBB3, a related EGF receptor, mediates compensatory and alternative pathways, suggesting an important role of ERBB3 may be in EGFR-independent CRC progression. Furthermore, we have generated an additional model that conditionally inactivates ERBB3 ($Erbb3^{tm1Dwt}/Erbb3^{tm1Dwt}$), and when combined with $Egfr^{tm1Dwt}/Egfr^{tm1Dwt}$>, these mice will have EGFR and ERBB3 combined deficiency in the intestinal epithelia. The innovative models we developed will provide powerful tools to genetically dissect molecular pathways contributing to CRC, leading to novel targets and associated biomarkers for therapeutic intervention. The study will advance our understanding of EGFR biology during colonic tumorigenesis, ultimately contributing to better therapies for CRC.

M5091A Host genetic and gut microbiota variability within the C57BL/6-Apc^{Min} mouse affects the intestinal tumor phenotype. *J. Moskowitz*, S. Busi, M. Hart, C. Franklin, J. Amos-Landgraf. University of Missouri, Columbia, MO.

Colorectal cancer (CRC) is a multifactorial disease that develops as a result of well-established genetic factors such as mutation of the tumor suppressor *Adenomatous Polyposis Coli (APC)* gene. However, other poorly characterized factors such as the gut microbiota (GM) likely play an important role in tumor development and progression. Our laboratory has found significant differences in both small intestinal (SI) and colonic tumor numbers between two Apc^{Min} mouse colonies; the C57BL/6J-Apc^{Min} (B6-*Min*/J) from the Jackson Laboratories, and the C57BL/6JD-Apc^{Min} (B6-*Min/*D) closed colony that has been maintained at the University of Wisconsin. It is unclear whether underlying host genetic factors or differences in the GM are responsible for these phenotypic differences. To determine the potential impact of GM on disease phenotype, we used complex microbiota targeted rederivation (CMTR) to rederive isogenic embryos of the two *Apc* mutant colonies onto CD1 surrogate dams that possessed GM from either The Jackson Laboratory (Crl:$CD1_{GMJAX}$) or Envigo (Hsd:$CD1_{GMHSD}$). We generated a total of four Apc^{Min} groups: B6-*Min*/J_{GMJAX}, B6-*Min*/J_{GMHSD}, B6-*Min*/D_{GMJAX}, and B6-*Min*/D_{GMHSD}. At three months of age, all animals were sacrificed to determine both SI and colonic tumor multiplicity. We observed a significant increase in both SI (p=0.03) and colonic tumors (p=0.006) in the B6-*Min*/J_{GMHSD} group as compared to the B6-*Min*/J_{GMJAX} group. Additionally, we observed trending increases in SI and colonic tumor numbers in B6-*Min*/D_{GMHSD} compared with B6-*Min*/D_{GMJAX} mice. These data suggest that the GM has a critical role in the SI and colonic tumor phenotype. We also noted

that B6-*Min*/D animals had more SI tumors than B6-*Min*/J animals within each GM group. To ensure that no known C57BL/6J modifiers existed in the population, founder animals were genotyped and found negative for the B6-*Atp5a1*^{Mom2} resistance allele, indicating that the *Mom2* mutation is not responsible for the phenotypic differences between the two colonies. Importantly, there was no difference in colonic tumor numbers between groups with the same GM. Together, these data suggest that host genetic differences play a role in the SI phenotype, but not the colonic phenotype. We conclude that both the GM and host genetic factors within the C57BL/6J-*Apc*^{Min} population contribute to the SI tumor phenotype. However, the GM primarily defines the colonic tumor phenotype. In addition to revealing highly important information regarding tumorigenesis in the *Apc*^{Min} mouse, these results will have a critical impact on reproducibility of studies using this model.

M5092B Nuclear to cytoplasmic relocalization of cyclin C directs stress-induced mitochondrial fission and promotes apoptosis in yeast and mouse cell lines. *R. S. Strich*[1], J. Jazek[1], V. Ganesan[1], A. Joshi[1], A. Di Cristofano[2]. 1) Rowan University-SOM, Stratford, NJ; 2) Albert Einstein University, NY USA.

In response to cellular damage, the mitochondria undergo extensive fragmentation, exhibit mitochondrial outer membrane permeability (MOMP), and release pro-apoptotic factors. Although the basic fission machinery is required for this hyper-fission, the molecular switch that induces this process remained elusive. In response to oxidative stress, the yeast[1] and mammalian[2] transcription factor cyclin C translocate from the nucleus to the cytoplasm where they associate with the GTPase Drp1/DNM1 at the mitochondria. In both systems, cyclin C is both necessary and sufficient to induce extensive mitochondrial fragmentation. The conservation of cyclin C activity is remarkable as treating permeabilized mouse embryonic fibroblast cultures with purified yeast cyclin C rapidly induced complete mitochondrial fission without an added stress signal. Further analysis revealed that the mouse cyclin C is also required for stress-induced MOMP and apoptosis. Using a CCNC knockout MEF culture system, we found that cyclin C is required for efficient mitochondrial recruitment of the pro-apoptotic BH-3 protein BAX. This activity appears direct as cyclin C co-immunoprecipitates with activated BAX following oxidative stress. Consistent with the role in stress-induced apoptosis, we found that cyclin C suppresses hyperplasia and adenoma formation in a PTEN phosphatase thyroid tumor model. While either single mutant presents with a modest phenotype, combining *Ccnc* and *Pten* null alleles dramatically accelerates thyroid hyperplasia resulting in premature death. These results indicate that cyclin C is a previously undescribed solid tumor suppressor. These results suggest that cyclin C cytoplasmic localization alters mitochondrial dynamics and influences apoptotic sensitivity in mammals.

M5093C Combinatorial regulation of BATF and BATF2 in LPS-stimulated and Mycobacterium-infected inflammatory responses. *H. Suzuki*[1], S. Roy[1], R. Guler[2,3], S. Schmeier[4], S. Parihar[2,3], M. Ozturk[2,3], F. Brombacher[2,3]. 1) RIKEN CLST, Yokohama, JP; 2) ICGEB, Cape Town, SA; 3) Cape Town Univ., Cape Town, SA; 4) Massey Univ., North Shore, NZ.

Basic leucine zipper transcription factor *Batf* belongs to the activator protein (AP-1) family of transcription factors, consisting of *Batf*, *Batf2* and *Batf3*, and is a positive regulator of various cellular processes in DCs, T and B cells. During our recent finding that BATF2 induces inflammatory responses in classically activated macrophages, lipopolysaccharide (LPS) or *Mycobacterium tuberculosis* (Mtb) infection, we found that *Batf* expression was also induced in LPS-stimulated and Mtb-infected macrophages, but not in IFNγ-activated classical activation. In order to explore BATF function in macrophages, we assessed the effect of *Batf* knockdown in LPS-stimulated mouse bone marrow-derived macrophages and compared it with that of *Batf2* knockdown. We found that BATF and BATF2 regulate different set of genes; the gene ontology analysis revealed that BATF suppresses negative regulators of inflammatory response. Further, *Batf2* knockdown up-regulated *Batf* expression, suggesting that BATF2 is a negative regulator of *Batf* expression. Taken together with the BATF2 function, our results suggest that BATF plays an important role of augmentation of the inflammatory response in LPS-stimulated macrophages.

M5094A Susceptibility to diethylstilbestrol exposure in mice. *D. L. Aylor*, N. E. Allard, T. I. Konneker. North Carolina State University, Raleigh, NC.

Diethylstilbestrol (DES) is a drug that caused infertility and cancer in some adults who were exposed prenatally before its use was ended in 1971. Some DES-exposed mouse strains also display reproductive defects (male and female) and cancer; yet other mouse strains are unaffected. This indicates a strong genetic component to susceptibility. Our goal is to identify the gene x environment interactions (GxE) associated with clinical traits and molecular profiles in DES-exposed inbred mouse strains. To accomplish this goal, we are screening a large panel of inbred mouse strains that includes 50 lines from the Collaborative Cross (CC) genetic reference panel. We observe novel strain-specific reproductive defects in DES-exposed males, including some that lead to azoospermia and infertility. In females, we have measured the acute effects of DES exposure on uterine gene expression for a known susceptible strain (FVB/NJ) and a known resistant strain (C57BL/6J). A substantial number of genes are differentially expressed between DES-exposed and control mice in both strains, but only 61% of these genes are shared. This illustrates the large effect genetic background can have on DES-induced changes in uterine gene expression. These strain-specific responses to DES involve coordinate regulation of hundreds of genes and can help narrow down sets of genes associated with disease susceptibility. We have identified gene modules that characterize strain-specific DES response and we relate these to clinical data derived from uterine histopathology. We conclude that the combination of genetic variation with functional genomics is a powerful tool for identifying genes involved in differential susceptibility to toxicants, and we propose that this approach is broadly relevant to other toxicological studies in rodents.

M5095B Systemic metabolic effects exerted by a point mutation in the RED subdomain of PAX6. *N. F. Chhabra*[1,2], M. Wu[1,2], M. Fütterer[1,2], I. Irmler[1,2], J. Beckers[1,2,3], M. Götz[4,5], J. Rozman[1,2], G. Przemeck[1,2], M. Hrabe de Angelis[1,2,3]. 1) Institute of Experimental Genetics, Helmholtz Zentrum München, Neuherberg, Germany; 2) German Center for Diabetes Research (DZD e.V.), Neuherberg, Germany; 3) Chair of Experimental Genetics, Centre of Life and Food Sciences, Weihenstephan, Technische Universität München, Freising, Germany; 4) Institute of Stem Cell Research, Helmholtz Zentrum München, Neuherberg, Germany; 5) Physiological Genomics, Institute of Physiology, Munich University, Munich, Germany.

The paired box protein 6 (PAX6) is a major transcription factor involved in eye development. Additionally, its role in the development of the pancreas has previously been documented, although the underlying mechanisms in the homeostasis of the adult pancreas remain largely unknown.

The *ENU*-generated C3;CAnN-*Pax6*^{Leca2} mouse line with a point mutation (R128C) in the RED subdomain of the PAX6 protein, recapitulates a human mutation causing foveal hypoplasia. In addition to the retinal defects, the mutation translates into numerous observable abnormalities in the pancreas. Progressive islet distortion was discernable from the age of 4 weeks including various dysregulated genes. More specifically, up-regulation of the endocrinal progenitor marker *Neurog3* and down-regulation of several β-cell specific markers in addition to increased proliferation within the islet suggested the prevailing phenotype to be most consistent with β-cell dedifferentiation.

Moreover, glucose stimulation of isolated islets *in vitro* and an intraperitoneal glucose challenge *in vivo* indicated reduced insulin content and secretion. However, this reduction was accompanied by a decreased fasting blood glucose level and a normal glucose clearance, possibly explained through the evident increased insulin sensitivity and decreased hepatic glucose production. Additionally, increase in locomotor activity and energy expenditure indicated an effect mediated via the hypothalamus, as an effect of the mutation. Taken together, the data suggests, as yet, unknown systemic function of PAX6 affecting the overall metabolism of the organism.

M5096C Congenic localization of the *Moo1* obesity QTL to 319 kb. *S. M. Clee*, C. L. K. Leung, S. Karunakaran, J. Dong, C. S. Yan, Z. J. Wu, A. Manji, S. Mahmoodi. University of British Columbia, Vancouver, Canada.

The BTBR T+ *Itpr3*^{tf}/J (BTBR) inbred strain has increased susceptibility to obesity and diabetes compared to the C57BL/6J (B6) strain. These effects are exaggerated in the presence of an obesogenic stimulus, e.g. homozygosity for the *obese* allele of the leptin gene(*Lep*^{ob}). Prior genetic studies mapped the loci affecting body weight and metabolic traits (fasting glucose and insulin) segregating between these strains. These studies identified the modifier of obesity 1 (*Moo1*) locus on mouse Chromosome 2 as the major locus controlling the difference in adiposity between these strains in *Lep*$^{ob/ob}$ mice. Congenic strains initially identified a ~6 Mb region of Chromosome 2 where replacement of BTBR alleles with those from B6 reduces body weight ~10% (the Moo1-C strain). Work by my laboratory has shown that this locus also affects obesity induced by high fat feeding, and is associated with alterations in body fat, food intake and glucose tolerance. We have also detected an interaction between this locus and stress that affects body weight. To localize the causative genetic variation we created a panel of 10 sub-congenic strains from Moo1-C strain recombinants. Analysis of these strains revealed *Moo1* is comprised of at least 2 independent QTLs. The proximal of these, *Moo1a*, is encompassed within a strain (Moo1-V) in which B6 alleles replace only 319 kb of BTBR genome (rs27970625 – D2Mit328). Homozygosity for B6 alleles in this region reduces body weight of high fat fed BTBR mice by ~8 % (P<0.001). This region spans 2 known genes: *Itga6* and *Pdk1*. We identified numerous (non-coding) sequence changes within and near these genes and each gene has a single coding variation between the strains, although these are not predicted to affect protein function. We assessed expression of these genes in metabolically relevant tissues and found an ~50% reduction in expression of both *Itga6* and *Pdk1* in many tissues. *Pdk1* regulates the entry of glucose-derived metabolites into the Krebs cycle for oxidation. This also regulates substrate availability for the synthesis of fat, making this an obvious candidate. We obtained mice deficient in PDK1 from the KOMP repository, but found no evidence of alterations in obesity in high fat-fed heterozygous or homozygous knockouts compared to their wildtype littermates. *Itga6*, although the less obvious candidate, is an integrin that could affect obesity in several ways. Analysis of mice with reduced ITGA6 is ongoing. These data highlight the power of mouse genetics to discover novel molecular pathways affecting complex metabolic phenotypes that are highly influenced by environmental factors and to identify specific gene-environment interactions.

M5097A *Dll1*- and *Dll4*-mediated Notch signaling in adult pancreatic β-cells is essential for the structural integrity of the islets of Langerhans and maintenance of glucose homeostasis. *M. Fuetterer*[1,2], N. Chhabra[1,2], M. Irmler[1,2], J. Beckers[1,2,3], G. Przemeck[1,2], M. Hrabě de Angelis[1,2,3]. 1) Institute of Experimental Genetics, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany; 2) German Center for Diabetes Research (DZD e.V.), Neuherberg, Germany; 3) Chair of Experimental Genetics, Center of Life and Food Sciences, Weihenstephan, Technische Universität München, Freising, Germany.

The Notch signaling pathway is a short-range communication transducer involved in the regulation of many cellular processes. Genes of the pathway are expressed in different cell types and organs at different time points during embryonic development and adulthood. For example, the Notch ligand delta-like 1 (DLL1) controls the decision between endocrine and exocrine fates of progenitor stem cells in the developing pancreas; and loss of *Dll1* function leads to premature differentiation of the pancreatic endocrine cell lineage. The ligands DLL1 and DLL4 as well as other members of the pathway are also expressed in the adult pancreas. However, the role of Notch signaling in adult tissue homeostasis is not well understood. Here, we describe cell-type specific, distinct expression of Notch pathway members in the adult murine pancreas. Using ligand-specific conditional loss- and gain-of-function mouse models we demonstrate alterations in islet morphology and effects on blood-glucose regulation as well as other metabolic parameters. Hence, we provide a first impression on functional aspects of Notch signaling in the adult islet and its importance for maintenance of tissue homeostasis.

M5098B Quantitative Genetic Analysis of MUC5AC and MUC5B in a Mouse Model of Asthma. *Samir N. P. Kelada*, Alessandra Livraghi-Butrico, Lauren Donoghue, Joseph P. Thomas, Kathryn McFadden, Gang Chen, Lucas T. Laudermilk, Wanda K. O'Neal, Richard C. Boucher. UNC, Chapel Hill, NC.

Rationale Mucus hyper-secretion is a hallmark feature of asthma and other obstructive airway diseases. Two mucins, MUC5AC and MUC5B, represent the major glycoprotein components of mucus. Little is known about the genetic determinants of MUC5AC and MUC5B protein expression. We aim to identify genetic regulators of MUC5AC and MUC5B protein concentrations in a mouse model of asthma. **Methods** We applied a house dust mite allergen model of asthma to both founder lines (n=8) and incipient lines (n=154) of the Collaborative Cross (CC). We collected whole lung lavage samples 72 hours after allergen challenge and quantified MUC5AC and MUC5B by agarose gel electrophoresis followed by western blotting. Each CC mouse was genotyped on a high density Affymetrix array. Protein expression in lungs was examined using immunohistochemistry. Gene knockdown *in vitro* was accomplished using lentiviral constructs expressing shRNAs. **Results** CC founder lines sensitized and challenged with allergen exhibited statistically significant differences in both MUC5AC and MUC5B, providing evidence of heritability. Incipient CC lines exhibited a broad range of MUC5AC and MUC5B secretion, consistent with a polygenic architecture for these two phenotypes. Quantitative trait loci (QTL) for MUC5AC and MUC5B were identified on Chromosomes 13 (at 75 Mb) and 2 (at 154 Mb), respectively. We focused on the MUC5B QTL because of the large effect size and found that *musculus*-derived alleles were associated with lower MUC5B compared to alleles from *domesticus* and *castaneus*. We validated the difference in MUC5B concentrations due to QTL region genotype by performing a second set of experiments using independent CC lines of contrasting haplotypes (*musculus* vs. *domesticus*). Using additional gene expression and SNP datasets, we identified *Bpifb1* as a candidate gene. We show that BPIFB1 expression colocalizes with MUC5B in airway epithelia and is upregulated by allergen treatment. Finally, we show that knockdown of *BPIFB1* affects MUC5B secretion in primary human airway epithelial cells. **Conclusions** Concentrations of MUC5AC and MUC5B in the allergen-challenged lung are controlled by distinct genetic loci, and these loci are distinct from those that regulate mucin gene expression. Our data indicate that variation in *Bpifb1* is strongly associated with MUC5B concentration after allergen challenge.

M5099C GeneLab: A systems biology platform for spaceflight omics data. *S. S. Reinsch*. NASA-Ames Research Center, Moffett Field, CA.

NASA's GeneLab project is maximizing the science output from spaceflight experiments conducted aboard the International Space Station (ISS) by: (1) developing a unique public bioinformatics database that includes space bioscience relevant "omics" data (genomics, transcriptomics, proteomics, and metabolomics) and experimental metadata; (2) partnering with NASA-funded flight experiments through bio-sample sharing or sample augmentation to expedite omics data input to the GeneLab database; and (3) developing community-driven reference flight experiments.

The data hosted in the GeneLab data system to date represents omics data from numerous model organisms including microbes, yeast, *C. elegans*, *Drosophila*, *Arabadopsis*, rodents and human cell lines. In this presentation we will show an overview of omics data in the context of existing physiological data from spaceflight.

In 2015 GeneLab partnered with two Biological Research in Canisters experiments (BRIC-19 and BRIC-20), which examined the proteomic and transcriptomic responses of *Arabidopsis thaliana* to spaceflight. GeneLab also partnered with Rodent Research-1 (RR-1), the maiden flight to test the recently developed rodent habitat, and is generating transcriptomic, proteomic and epigenomic data from various tissues including liver, muscle, eye, kidney etc. GeneLab is establishing partnerships with other planned flights for 2016 including a comparative study of two bacterial species. GeneLab is also establishing sample sharing collaborations with multiple future rodent missions.

Overall, GeneLab will facilitate the generation and query of parallel multi-omics data, and deep curation of metadata for integrative analysis, allowing researchers to uncover cellular networks as observed in systems biology platforms. Consequently, the scientific community will have access to a more complete picture of functional and regulatory networks responsive to the spaceflight environment. Analysis of GeneLab data will contribute fundamental knowledge of how the space environment affects biological systems, and enable emerging terrestrial benefits resulting from mitigation strategies to prevent effects observed during exposure to space. As a result, open access to the data will foster new hypothesis-driven research for future spaceflight studies spanning basic science to translational science.

GeneLab is funded through NASA's Space Life and Physical Sciences Research and Applications Division (SLPSRA) and the International Space Station Research Integration Office (ISSRIO).

M5100A Rat Resource and Research Center. *E. C. Bryda*, H. Men, A. C. Ericsson, J. M. Amos-Landgraf, Y. Agca, C. L. Franklin, R. S. Prather. University of Missouri, Columbia, MO.

The Rat Resource and Research Center (RRRC) was established in 2001 with funding from the National Institutes of Health (NIH) with the goals of 1) shifting the burden for maintaining and distributing rat models from individual investigators to a centralized repository, and 2) providing the biomedical community with ready access to valuable rat strains/stocks and other related services that enhance the use of rats in research. Currently, the RRRC has close to 400 donated rat lines in its inventory. Upon importation of strains/stocks into the RRRC, sperm and embryos are cryopreserved to ensure against future loss of the model. The RRRC distributes live animals, cryopreserved sperm and embryos as well as rat embryonic stem (ES) cell lines. Quality control measures for all materials include extensive genetic validation and health monitoring. The RRRC has expertise in rat reproductive biology, colony management, health monitoring, genetic assay development/optimization, and isolation of germline competent ES cell lines from transgenic rats; our staff and researchers are readily available for consultation and collaborations and a number of services are available on a fee-for-service basis. Our website (www.rrrc.us) allows user-friendly navigation and provides information about all strains/stocks, cell lines, model donation procedures, on-line ordering, lists of services, and protocols. Current research efforts include refinement of models, characterization of the rat microbiota and its influence on model phenotypes, and generation of new rat models, including new models of Inflammatory Bowel Disease (IBD) generated using

CRISPR/Cas9 technology. In addition to the RRRC, the University of Missouri is home to two other NIH-funded animal resources: the MU Mutant Mouse Resource and Research Center (MMRRC) and the National Swine Resource and Research Center (NSRRC) as well as the newly established MU Metagenomics Center (MUMC). Together, these highly collaborative groups provide a variety of animal model-related services across species to facilitate biomedical research.

M5101B Using the web-based genome browser *gEVAL*, to evaluate and improve the draft assemblies of 18 strains for the Mouse Genomes Project. *W. Chow*, K. Howe. Wellcome Trust Sanger Institute, Cambridge, UK.

The Mouse Genomes Project used next generation sequencing technologies to sequence and assemble 16 key laboratory mouse strains and 2 wild derived mouse strains to produce a comprehensive picture of variation amongst mouse genomes. However, like many *de novo* genome projects, the initial draft assemblies revealed regions of discordance and misassemblies.

To aid in the improvement and curation of these genomes, and to incorporate new long-range datasets, the assemblies of these 18 strains were recently added to the web-based genome evaluation browser gEVAL (BioRxiv, 2016). gEVAL has been successfully used to curate the human mouse and zebrafish reference genomes, which has later led to other reference assemblies such as rat, pig, chicken, and tasmanian devil to be included in the browser.

gEVAL provides a one-stop solution to assess the compliance of a given assembly with a multitude of available data such as the correct pairing and suitable distance of mapped clone ends, the placement of markers and cDNAs, inter-comparative alignments between assemblies, long range genome/optical mapping datasets and many more.

Having these assemblies publically accessible in gEVAL, along with a whole range of supporting datasets, allows the wider mouse research community an early, easy way of accessing and evaluating the contiguity of a region of interest and view the already available gene sets.

Furthermore, gEVAL provides a platform to assist our curation groups that are tasked with improving these assemblies and the annotation of features such as genes, in hopes that these efforts will contribute to yielding full genome sequences of quality comparable to the reference standard .

Website: http://geval.sanger.ac.uk/

BioRxiv: http://dx.doi.org/10.1101/038638 (accepted in Bioinformatics, March 2016).

M5102C Phylogenetically based Gene Ontology (GO) Annotations using the Phylogenetic Annotation and INference Tool (PAINT). *K. R. Christie*[1], M. Feuermann[2], P. Gaudet[2], S. E. Lewis[3], D. Li[4], H. Mi[5], M. C. Munoz-Torres[3], P. D. Thomas[5], J. A. Blake[1], The Gene Ontology Consortium. 1) The Jackson Laboratory, Bar Harbor, ME; 2) Swiss Institute for Bioinformatics, Geneva, Switzerland; 3) Lawrence Berkeley National Laboratory, Berkeley, CA; 4) Phoenix Bioinformatics, Redwood City, CA; 5) University of Southern California, Los Angeles, CA.

A major goal of the Gene Ontology (GO) project is to describe the functions of genes from all kingdoms of life in a consistent way. For a limited set of model organisms, annotation of the functions of at least some of the genes can be done based on direct experimental data. However, for many organisms, little or no experimental data exists. Even for model organisms, there are many genes that are not directly characterized. In these situations, other methods of capturing functional data are necessary. One method utilized by the GO community uses phylogenetic trees of related sequences (via Panther) that are overlaid with experimental GO annotations from which evolutionarily based functional annotations can be inferred. The PAINT (Phylogenetic Annotation and INference Tool) curation tool has been developed to support this effort. The curator can view the distribution of GO terms that are based on direct experimental evidence for each species to infer the likely evolutionary history of functions and thus which functions can be propagated to which sequences within the tree. This phylogenetic method helps provide more complete annotations of genomes for use in term enrichment and genomic analyses, sometimes more detailed that what is provided using domain analysis, e.g. via InterPRO domains. For example, the small subunit (SSU) processome involved in biogenesis of the small ribosomal subunit is well characterized in *S. cerevisiae*, but not in the laboratory mouse. In the case of the mouse *Wdr3* gene, which is homologous to *S. cerevisiae DIP2* (aka *UTP12*), curation using phylogenetic analysis provided detailed annotations for mouse *Wdr3*. In contrast, the InterPRO domains for this gene did not provide useful annotations, and an annotation transferred by sequence similarity comparison provided a somewhat misleading annotation to an overly specific RNA binding term. Thus annotations from this phylogenetic annotation method can provide detailed GO annotations for genes based on experimental characterization of their homologs in other organisms.

This work is funded by HG 002273 to the Gene Ontology Consortium.

M5103A Catalogue of identified mutations in RIKEN ENU Mutant Mouse Library: a new approach for the studies on polygenic traits. *R. Fukumura*[1], H. Kotaki[1], S. Makino[1], Y. Ishitsuka[1], Y. Nakai[1], Y. Minakuchi[2], A. Toyoda[2], A. Fujiyama[2], Y. Gondo[1]. 1) RIKEN BRC, Tsukuba, Ibaraki, JP; 2) NIG, Mishima, Shizuoka, JP.

A model mouse for any human disease helps to elucidate the pathogenic mechanism and to develop a therapeutic application(s). Therefore, many model mice have been developed. IMPC have been in progress to phenotype KO mouse strains established by IKMC. In this international efforts, the genetic background was unified in C57BL/6N focusing on monogenic traits and diseases. Recently, the genome editing technologies, in particular, the CRISPR/Cas9 system, have made it possible to quickly introduce mutations to a few target loci in a single strain. The genetic studies of polygenic traits and disorders such as mental diseases, metabolic syndromes and life-style related diseases are, however, still limited. We have made RIKEN ENU Mutant Mouse Library of 10,000 G1 males open to public since 2002 and many users have already used and reported their outcomes. Each G1 mouse has ~5,000 mutations; thus, it is plausible to exhibit some polygenic traits due to the interaction among the thousands of mutations. Two such cases have been indeed suggested by users. In order to assess what a part of thousands of mutations interact each other in each G1 strain, we are now conducting systematic QTL analysis focusing on the body weight. Firstly, two outlier G1 strains, G1DB012260 and G1DB008748, for body weight were chosen from the 10,000 G1 Library and revived them by IVF/ET

method. We have obtained 81 and 51 G2 progenies and their intercross have given rise to 72 and 128 G3 mice so far from G1DB012260 and G1DB012260, respectively. The 8-weeks-old body weight of the G3 populations showed an increase of genetic variance comparing to the control population, which indicates the existence of some genetic interaction among induced mutations. At the same time, Whole Exome Sequencing (WES) and SNV calls of the two G1 genomes identified 159 and 182 ENU-induced mutations and the genotyping of identified mutations in G3 mice were conducted. The preliminary results of QTL analysis based on the body weight and genotyping of the G3 populations also showed several interactive peaks. We thus encourage users to apply the RIKEN Mutant Mouse Library not only for the monogenic analyses but also multigenic/polygenic studies to establish models for various complex traits and diseases. We have so far identified 944 ENU-induced mutations in 428 target regions based on user's requests. In addition, WES has catalogued 4801 ENU-induced mutations in 53 G1 strains. A total of the 5,745 mutations are also open to public.

M5104B Utilizing NCBI's Mouse Genome Resources. *Tripti Gupta*, Kelly McGarvey, Terence Murphy, Kim Pruitt. National Center for Biotechnology Information, National Library of Medicine, 8600 Rockville Pike, Bethesda, MD 20894.

Complete and accurate genome annotation is essential to researchers using genomic data. A major focus of the Reference Sequence (RefSeq) database at the National Center for Biotechnology Information (NCBI) is to provide an accurate and comprehensive annotation of the mouse genome through computational and manual curation. The RefSeq database contains annotated genomic, transcript, and protein sequence records derived from data in public sequence databases and from computation, curation, and collaboration. This combinatorial approach results in a high-quality annotation that focuses on representation of full-length, non-redundant sequence data and that is regularly updated through re-annotations every 12 to 18 months. RefSeq provides whole genome annotation of the reference strain C57BL/6J genome assembly, including variation on alternate locus scaffolds, maintained by the Genome Reference Consortium (GRC) and annotation of the mixed strain Celera assembly. In addition, complete annotations of 15 other rodents, including Peromyscus maniculatus bairdii and Rattus norvegicus, are available and can be downloaded from the NCBI RefSeq Genomes FTP site (ftp://ftp.ncbi.nlm.nih.gov/genomes/refseq/vertebrate_mammalian/). In order to provide the most consistent and comprehensive annotation possible, RefSeq scientists manually curate genes in close collaboration with the Mouse Genome Informatics database, the Consensus Coding Sequence project, and the GRC. Manual curation methods continually incorporate new data sets such as genome wide promoter-associated epigenetic data and PolyA-Seq data to improve annotation and define manually annotated features on transcript and protein sequences. RefSeq curation efforts have traditionally focused on representing full-length transcripts of protein coding genes, primarily using transcript data, protein alignments, and published data as evidence; however, in recent years, we have incorporated additional data into our computational and manual curation methods, allowing for more complete and accurate annotation. For example, changes to NCBI's eukaryotic annotation pipeline allowed the incorporation of RNA-Seq data, resulting in significant increases in the numbers of predicted protein-coding variants and non-coding transcripts. Incorporation of the RNA-Seq data has been particularly valuable to our recent efforts to expand the representation of long non-coding RNAs. The current annotation of the GRCm38 assembly includes 31,500 predicted non-coding RNAs, a 26% increase relative to the previous annotation, which did not utilize RNA-Seq data. This poster provides an overview of NCBI's mouse genome resources and highlights recent curation efforts by the RefSeq group.

M5105C Analysis of the Collaborative Cross founder strains at the German Mouse Clinic identify new and known phenotypes. *H. Kollmus*[1], M. Horsch[2], M. Gegenfurtner[2], German Mouse Clinic Consortium[2], H. Fuchs[2], V. Gailus-Durner[2], R. Balling[3], K. Schughart[1,4,5], M. Hrabe de Angelis[2,6]. 1) Helmholtz Centre for Infection Research, Braunschweig, Germany; 2) Helmholtz Zentrum München, Munich, Germany; 3) Luxembourg Centre for Systems Biomedicine, University Luxembourg, Luxembourg; 4) University of Veterinary Medicine, Hannover, Germany; 5) University of Tennessee Health Science Center, Memphis, Tennessee, USA; 6) Technische Universität München, Freising-Weihenstephan, Germany.

We performed a comprehensive and comparative phenotyping screening of the CC founder strains carried out at the German Mouse Clinic (GMC, www.mouseclinic.de). The Collaborative Cross (CC) is a large panel of mouse-inbred lines derived from eight founder strains, including three wild-derived strains (A/J, C57BL/6J, 129S1/SvlmJ, NOD/ShiLtJ, NZO/HILtJ, CAST/EiJ, PWK/PhJ, and WSB/EiJ). The phenotyping analyses cover phenotypes related to human diseases such as behavioural and cardiovascular parameters, clinical chemistry, dysmorphology, bone and cartilage, energy metabolism, eye and vision, immunology, lung function, neurology, nociception, followed by a detailed pathological examination. For each strain, at least sixteen females and males were phenotyped leading to a highly robust data set. Metadata analysis showed that the three wild-derived strains are most different from the laboratory strains. For some parameters the wild-derived strains are more similar to each other than to the laboratory strains. NZO/HILtJ, A/J and 129S1/SvlmJ were most different from all other strains. The analysis of screen-specific parameter sets recapitulated the global tendency of phenotypic similarities between laboratory strains, but also detected phenotypes that distinguished single strain from all others. Our results confirmed already known strain characteristics but also identified new phenotypes. For instance reduced hearing sensitivity was described in A/J and NOD/ShiLtJ before but not for NZO/HILtJ. This data set will be a valuable baseline for understanding phenotype effects in CC strains.

M5106A Mouse SNPs and polymorphisms data on Mouse Genome Informatics. *MeiYee Law*, Janan Eppig, Carol Bult, Mouse Genome Informatics. The Jackson Laboratory, Bar Harbor, ME.

Mouse Genome Informatics (MGI, http://www.informatics.jax.org) provides free access to mouse genetic, genomic and biological data in support of mouse as a model for human biology and disease. Here we describe MGI's newly implemented SNP searching and analysis tools that provide greater flexibility for researchers to explore and extract SNP data. The new SNPs query form includes data from 88 inbred strains from dbSNP. Using search options such as multiple genes search, genome coordinates search, strains of interest search, and comparison reference

strain, results returned highlight allele variation at each available genomic location, dbSNP, links to MGI and other genome browsers, etc. SNP results also can be filtered by additional criteria such as restricting results to coding or non-coding sequences. The application of mouse SNPs data is extensive. Due to the high sequence similarity between human and mouse at the nucleotide and amino-acid level, a knock-in of human SNPs can also be used to study the disease in mouse models. Information from SNPs data is crucial for the understanding of novel or existing mouse strains, QTL mapping for susceptibility to diseases of interest, evaluating copy number variants, applying SNP profiles to drug choices, etc. Our poster will demonstrate the SNPs search tool and function on MGI database. SNP data in MGI is supported by NIH grant HG000330.

M5107B Mouse Genome Nomenclature at MGI, Improved by Collaboration. *M. McAndrews*, D. Reed, J. Recla, C. Bult, J. Eppig. The Jackson Laboratory, Bar Harbor, ME.

The Mouse Genome Informatics (MGI, www.informatics.jax.org) group implements the rules and guidelines established by the International Committee on Standardized Genetic Nomenclature for Mice and maintains the international authoritative resource for the identity and names of mouse genes, genetic markers, alleles, chromosome aberrations, genomic features, and mouse strains. Nomenclature follows the established guidelines, but there is input from others to develop accurate and informative names and symbols that will be useful to and used by the scientific community.

Each gene and genome feature is given a genome feature type using the Sequence Ontology (SO, http://www.sequenceontology.org/browser/obob.cgi). Feature types provide information that cannot always be included in nomenclature. Example SO feature terms include protein-coding, miRNA, long noncoding RNA, and pseudogene. MGI petitions the SO to create additional feature types when new ones are necessary. Every mouse strain, allele, gene and genome feature receives a unique MGI_ID. Some, depending on the object, receive a list of synonyms including common 'lab' names, published alternate names, and previous official names. These aid researchers in identifying an object of interest in as many ways as possible. Designations have evolved for spontaneous, induced, targeted, endonuclease-mediated, and gene-trapped alleles of endogenous genes. Transgenic alleles have their own symbols distinct from the others. The different nomenclature rules for allele symbols help investigators distinguish among these types.

The representation of Quantitative Trait Loci or QTL is an area of focus undergoing refinement and expansion. QTL identified from literature need official nomenclature and mapping coordinates.

Robust homology information is crucial for translational researchers. MGI collaborates with human and rat nomenclature committees and subject matter experts to unify the nomenclature of homologs. MGI participates in the Consensus CDS (CCDS) project, a collaborative effort to identify a core set of human and mouse protein-coding regions that are consistently annotated and of high quality, hosted at NCBI https://www.ncbi.nlm.nih.gov/CCDS/CcdsBrowse.cgi. The Consensus CDS (CCDS) project is working toward convergence on a standard set of gene annotations. Updated nomenclature makes homology relationships clear.

This work is supported by NIH grant HG000330.

M5108C Informing the Genetic Basis of Disease: Informatics for The International Mouse Phenotyping Consortium. *T. Meehan*[1], A. Mallon[2], D. Smedley[3], H. Parkinson[1], on behalf of the MPI2 consortium. 1) EMBL-EBI, Hinxton, Cambridge, UK; 2) MRC Mammalian Genetics Unit, MRC Harwell, Harwell, UK; 3) Queen Mary University London, London, UK.

Attempts at correlating phenotypic aspects of disease with causal genetic variants are confounded by the lack of knowledge for most genes. The International Mouse Phenotyping Consortium (IMPC) is building the first truly comprehensive functional catalog of a mammalian genome by producing and characterizing a knockout mouse strain for every protein-coding gene. Data from a standardized, broad-based phenotyping pipeline are collected and archived for both male and female mice by the IMPC-Data Coordinating Center. Dedicated 'data wranglers' coordinate with each phenotyping center to ensure proper transfer and quality control of data. A sophisticated statistical analysis pipeline applies the best statistical test to the data and identifies knockout strains with significant changes while accounting for bias from confounding effects. In addition, hundreds of new disease models are computationally identified by analysis of phenotype overlap and automated 3-D embryo dysmorphology detection using software developed or adapted by the IMPC. With phenotype data now available for over 2600 genes at mousephenotype.org, this talk will focus on the new insights the IMPC is providing into development, fertility, disease and the wide-prevalence of sexual dimorphism.

M5109A The Systems Genetics Core Facility at UNC. *D. R. Miller*, T. A. Bell, S. E. Cates, C.-P. Fu, J. M. Holt, C.-Y. Kao, K. F. Manly, A. P. Morgan, G. D. Shaw, B. Wanstrath, L. McMillan, F. Pardo-Manuel de Villena. Univ of North Carolina at Chapel Hill, Chapel Hill, NC.

The Systems Genetics Core Facility at UNC provides Collaborative Cross mice; genotyping services using the MUGA arrays and tools to utilize both the mice and the genotypes.

The Collaborative Cross is a genetic reference population derived from eight inbred strains by an international consortium of researchers. The Systems Genetics Core Facility (SGCF; http://csbio.unc.edu/CCstatus/index.py?run=AvailableLines) at UNC distributes CC lines that have reached a defined minimum level of inbreeding. The SGCF has also reconstructed the founder mosaic of each CC line. We have combined these reconstructions with the whole genome sequence published by the Sanger Institute to generate pseudogenomes from each CC line that incorporate all high quality SNP and indel variants while retaining the extensive annotation of the mouse reference genome (http://csbio.unc.edu/CCstatus/index.py?run=Pseudo). We are currently sequencing mice from each of the distributable lines and expect to make those genomes available before the end of 2016.

The SGCF has distributed CC mice to >40 laboratories. CC projects fall into four categories: Strain surveys to determine the genetics of a wide variety of traits; Follow up experiments in smaller sets of CC strains; Development of models of human disease and Identification and genetic and molecular dissection of novel biological phenomena. Manuscripts using the CC have been published recently including a strain survey for

susceptibility of Ebola virus infection, a new mouse model for spontaneous colitis, the discovery of a meiotic drive system and a new parent of origin effect on gene expression. We will present summaries on the status of the CC population (number of lines, inbreeding and breeding performance); use of the CC and publications.

Genotyping arrays using iterations of the Mouse Universal Genotyping Array (MUGA) have been designed at UNC and implemented through GeneSeek (Neogen) in Nebraska. MUGA (7000 SNPs), MegaMUGA (70,000 SNPs) and GigaMUGA (150,000 SNPs) have each required separate and improved tools which are all available at http://csbio.unc.edu/CCstatus/index.py?run. The reissuance of the MUGA array can also be very useful for F2 analysis.

M5110B What's New in Mouse Genome Informatics (MGI)? *J. Richardson*, J. Kadin, M. Ringwald, J. Blake, C. Bult, J. T. Eppig, MGI Team. The Jackson Laboratory, Bar Harbor, ME.

Newly implemented in MGI in the last year: (1) MGI Gene Pages, the most frequently viewed pages in MGI are re-designed, including a new human disease table showing OMIM diseases with the human causitive gene, and human diseases modeled in mice with mutations in the gene being viewed, and Grid displays providing overviews of phenotypes, functional annotations, and embryonic gene expression in tissues [see poster Blake et al]; (2) Improvements to the Recombinase search, allowing users more specific parameter searching and providing autocomplete fields. The results summary also allows filtering and sorting of the data returned; (3) GO tables are enhanced to include a Category column from a GO slim subset of terms and a Context column providing details of the conditions used in the experiment [see poster Christie et al]; (4) MGI's Mouse dbSNP Query is re-designed to vastly improve performance. Users can now filter results by funtional class and re-order columns to reposition strains of interest. [see poster Law et al]; (5) A Batch Search utility has been added to the Gene Expression (GXD) Query to facilitate searches with lists of gene symbols or IDs. GXD searches return a tissue-by-gene matrix view as part of its multi-tabbed data summary [see poster Smith et al & Shaw et al].

MGI also is working with model organisms on collaborative projects: (1) A project to port individual organism InterMine instances (in MGI's case, MouseMine) to a shared Cloud environment to make accessibility across model organisms more transparent for users. (2) A project including MGI, RGD (Rat Genome Database) and DO (Disease Ontology) to enhance and improve DO depth and structure so that it can support disease annotations from mouse and rat. (3) A project including MGI and Wormbase to test and improve Textpresso as a literature triage tool that could save significant curator time in screening biomedical literature.

MGI also recently completed a major upgrade to its software infrastructure, porting nearly 200 tables in the database to Postgres and rewriting data loads, software for curation, and scripts supporting the web interface. Most MGI software now resides on the Jackson Laboratory server cloud. As a result we have improved the stability and speed of MGI and simplified future maintenance. Supported by NIH grants HG000330, HG002273, HD064299.

M5111C Mouse Genome Informatics tools for batch data searches and retrieval. *D. R. Shaw*, J. A. Blake, C. J. Bult, J. A. Kadin, J. E. Richardson, M. Ringwald, J. T. Eppig. Jackson Laboratory, Bar Harbor, ME.

Mouse Genome Informatics (MGI, http://www.informatics.jax.org) web resources provide free access to detailed information on the biology of the laboratory mouse. Searches of MGI are aided by the use of standardized nomenclatures for genes, alleles, and strains and by defined, hierarchical vocabularies: the Mammalian Phenotype (MP) Ontology, the Gene Ontologies (GO) and Mouse Developmental Anatomy. Data include over 291,000 MP annotations, 310,000 GO annotations and 1.5 million expression assay results.

MGI provides several tools for generating tab-delimited files of search results and for querying with lists of genes, alleles and IDs. Dozens of weekly database reports are available for download as well as full database dumps for MySQL and PostgreSQL. Data integration allows complex queries across multiple data sets and most web searches provide tab-delimited data export options. An easy to use Batch Query supports a variety of queries using IDs and symbols. An even more powerful tool, MouseMine, offers iterative querying, built-in enrichment analysis, and API support. A Batch Search for gene expression data returns a tissue-by-gene matrix view that facilitates a comparison of expression patterns between genes.

Live demonstrations of MGI resources are also available at the MGI Booth exhibit: 433. MGI's dedicated User Support group is available at mgi-help@jax.org.

This work is supported by NIH grants HG000330 and HD062499.

M5112A The Gene Expression Database (GXD): mouse developmental expression information at your fingertips. *C. M. Smith*, J. H. Finger, T. F. Hayamizu, I. J. McCright, J. Xu, J. T. Eppig, J. A. Kadin, J. E. Richardson, M. Ringwald. The Jackson Laboratory, Bar Harbor, ME.

The Gene Expression Database (GXD) is an easily searchable, freely available database of mouse developmental gene expression information (www.informatics.jax.org/expression.shtml). It provides researchers with critical insights into the function of genes and the molecular mechanisms of development, differentiation, and disease processes. GXD captures expression data from wild type and mutant mice. It integrates data from different assay types, including RNA *in situ* hybridization, immunohistochemistry, knock-in *in situ* reporter, RT-PCR, as well as Northern and Western blot experiments. Data are acquired from the literature and from groups engaged in large-scale expression studies. Currently GXD contains over 1.5 million expression results for over 14,000 genes. GXD contains detailed metadata recorded in standardized ways, including: time and tissue of expression (or non-expression); pattern and strength of expression; numbers and sizes of detected bands (for blots); genetic background of the samples; and a description of the probe/antibody used in the assay. These data are accompanied by over 275,000 images, allowing users to view the primary data and interpret it themselves. As an integral part of the Mouse Genome Informatics (MGI) resource, GXD integrates its expression data with other genetic, functional, phenotypic, and disease-oriented data, thus allowing researchers to evaluate expression data in the larger context; search by a wide variety of biologically- and biomedically-relevant parameters;

and discover new data connections to help in the design of new experiments. Recently developed features provide quick and intuitive access to the data. These include: interactive tissue-by-developmental stage and tissue-by-gene matrix views; image summaries defined by user search criteria; and data filters that can be used to iteratively refine search results. The expression section of MGI gene detail pages now features a graphical gene expression overview, as well as links to expression data from chicken, *Xenopus*, and zebrafish, enabling a gene-based comparison of expression information between mouse and these species. GXD is funded by NIH grant HD062499.

Population, Evolutionary & Quantitative Genetics Meeting

Poster Session Abstracts

P2001A Identifying population differentiation in the clam shrimp Eulimnadia texana through genome assembly and pooled sequencing. *J. G. Baldwin-Brown*[1], A. D. Long[1], S. C. Weeks[2]. 1) University of California, Irvine, Irvine, CA; 2) University of Akron, Akron, OH.

Identifying population differentiation at specific sites across the genome in non-model organisms has been difficult historically. Here, I present the results of a combination of approaches to convert the non-model organism Eulimnadia texana (the clam shrimp) into a practical system for genomics, and show evidence of differentiation of genomic sites apparently due to adaptive evolution. Clam shrimp are attractive for genetics because of their small genome size (150Mb), large populations, short generations (~3 weeks), and their ability to lay eggs that can remain in diapause for decades without loss of viability. I generated a whole genome, hybrid de novo assembly of the clam shrimp genome (assembly N50: 18Mb) using a combination of Illumina short read genomic data and PacBio long read data. I used Illumina RNA sequencing of both male and hermaphrodite clam shrimp in order to annotate the genome, then compared the genome to those of Drosophila melanogaster and the closest sequenced relative of the clam shrimp, the water flea Daphnia pulex, and used differential gene expression analysis to identify genes that significantly differ in expression between males and hermaphrodites. I generated allele frequency estimates from pooled sequencing data from 11 separate wild populations of clam shrimp and estimated average linkage disequilibrium, FST, and other classic population genetics statistics. Both bayesian methods and FST analysis of populations revealed candidate selection sites. I correlated these with a variety of environmental factors, including presence of predators, vernal pool dimensions, and ratio of clam shrimp males to hermaphrodites. I identified multiple sites that appear significantly diverged and that have annotated genes that may be under adaptive evolution in these populations.

P2002B Genetic characterization of populations of the African Jewelfish (*Hemichromis letourneuxi*) introduced to the waterways of Florida. *N. M. Belfiore*[1], P. J. Schofield[2]. 1) University of Tampa, Tampa, FL; 2) US Geological Survey, Gainesville FL.

The African jewelfish, *Hemichromis letourneuxi*, is an invasive, predatory cichlid that has been introduced at least once in the 1960s to Florida. Its native range is in freshwater bodies west of the Red Sea, spanning Egypt, North Sudan, and Eritrea in northeastern Africa, and thus it is likely adapted to a variety of tropical and subtropical habitats. It was first encountered, introduced by unknown means, in the Miami area in the 1960s. In subsequent decades, the fish has been encountered in waterways spreading west and north rapidly. It is tolerant of a wide range of aquatic conditions, freshwater and brackish, including shallow, vegetated or rocky areas of canals, tidal creeks, culverts, rivers, and marshes. This invasive species is a threat to other aquatic species, including native fishes, shrimp and snails because of its predatory behavior. We compare mitochondrial and nuclear DNA sequence data from jewelfish sampled in six Florida populations, spread throughout the current range of this introduced species. Using gene and species tree reconstruction methods, we are hypothesizing the historical relationships among jewelfish populations using Bayesian phylogenetic reconstruction and concordance methods. In conjunction with geographic information and the timing of arrival of this species in different drainages, we estimate the number of introductions of jewelfish from unique backgrounds, the times of introduction(s), the mode of spread, and where the initial introduction(s) occurred. Principles learned through understanding the history of this species could help to prevent future introductions of invasive species.

P2003C *Speckled feathers and bladder eyes: pleiotropic effects of the Almond mutation in pigeon*. *R. L. Bruders*[1], E. J. Osborne[2], Z. Kronenberg[2], M. Yandell[2], M. D. Shapiro[1,2]. 1) Department of Biology,University of Utah, Salt Lake City, UT; 2) Department of Human Genetics,University of Utah, Salt Lake City, UT.

The molecular basis of phenotypic diversity in wild and domesticated animals is poorly understood. My project addresses how diversity arises by identifying genetic and developmental origins of unique traits. The domestic rock pigeon (*Columba livia*) is a compelling model to understand molecular mechanisms of diversity because this species consists of over 300 different breeds with spectacularly variable phenotypes. One derived trait, “Almond,” is characterized by seemingly random sprinkling of pigmented and apigmented regions within and between feathers throughout the body. Classical genetic studies suggest Almond feather pigmentation is caused by a dominant sex-linked mutation located near the major color locus, recently identified by our lab as Tyrp1. Additionally, these studies found that homozygous Almond males (ZZ sex chromosomes) develop severe eye defects and completely lack pigmentation whereas hemizygous Almond females (ZW), which lack a wild-type copy of the Almond allele, do not develop these defects. This suggests that dosage of the mutant allele, rather than absence of the wild-type allele, is responsible for these eye phenotypes. We compared the genomes of 10 Almond pigeons to 76 non-almond pigeons of various colors using pFst in order to identify a candidate region on scaffold 6 a Z chromosome scaffold. Further investigation showed a substantial increase in coverage in this region in Almond birds, indicative of copy number variation in this region. There are 5 genes in this region including MLANA, a melanosome maturation gene. Expression analysis using Q-RT-PCR on regenerating feathers revealed a suprising decrease in MLANA expression in the light feathers of Almond birds despite a increase in copy number. Currently no coding changes have been found in the genes in this region, indicating that substantial increase in copy number of MLANA leads to the sprinkling feathers and eye defects seen in Almond pigeons.

P2004A *CYP2D6*: Detecting New Structures for Clinical Practice. *B. Carvalho Henriques*[1*], Y. Wang[1], R. Whitford[1], CJ Slomp[1], D. Rossolatos[1], J. Paya-Cano[2], S. Curran[2], P. Santosh[2], IW Craig[2], KJ Aitchison[1,2]. 1) University of Alberta Edmonton, Canada; 2) SGDP Centre London, UK.

Background

A gene that has been the focus of extensive pharmacogenomic research is the cytochrome P450 enzyme 2D6 (CYP2D6), which is highly polymorphic. Identifying how different alleles impact phenotype in terms of metabolism is desirable because CYP2D6 is involved in the metabolic pathway of up to 50 different drugs currently used in medicine. This project continues work that identified individuals with

anomalous copy number calls[1], that might indicate combinations of *CYP2D6* with its adjacent gene (*CYP2D7*), known as hybrid alleles. Our objective is to identify precisely which such hybrid variants are present. In this manner, the improvement in technology gained will enable correct identification of a wider range of variants of this enzyme than was previously possible, for translation into clinical practice in the form of more accurate pharmacogenetics testing.

Methods

The methodology applied was a long-PCR approach to identify hybrid alleles of *CYP2D6* using the technique described by Kramer *et al*. (2009)[2] and Black *et al*. (2012)[3], with fragment delineation by both agarose gel and Agilent 2100 Bioanalyzer (Agilent Technologies, Canada) electrophoresis.

Results

Results showed some successful amplification for the conditions established. Comparison made between different runs point to effective changes to the initial method. The technique employed is a modified version of that described by Kramer *et al*., using a buffer that is specific for GC-rich regions. Preliminary results have confirmed the method application in gene characterization, having successfully amplified structures inherent to *5-like genotype

P2005B Evolutionary implications of recombination rate variation among populations of *Drosophila melanogaster* . *J. Cruz Corchado*[1], J. Comeron[1,2]. 1) Interdisciplinary Graduate Program in Genetics, University of Iowa, Iowa City, IA; 2) Department of Biology, University of Iowa, Iowa City, IA.

Recombination is a crucial biological process and one of the most fundamental parameters in evolution. Under most conditions, meiotic recombination is essential for ensuring that organisms adapt to ever changing biotic and abiotic conditions and, as such, it shapes evolutionary change within and between species. Yet, and despite its importance, recombination rates are fast evolving and vary between closely related species. In this study, we estimate and compare recombination rates in five *Drosophila melanogaster* populations (Zambia, Rwanda, Cameroon, France and USA). We observe that recombination rates not only change in total magnitude but also in their relative distribution within chromosomes (recombination landscapes). We also show that differences in recombination landscapes among populations play a significant role explaining population-specific differences in nucleotide diversity without requiring adaptive events (local adaptation). Our results suggest that inter-population differences in local recombination rates and the corresponding differences in local Background Selection (BGS) need to be considered as a possible explanation for population-specific differences in nucleotide diversity at specific genomic regions.

P2006C The Effects of Demographic History on the Detection of Recombination Hotspots. *A. L. Dapper*, B. A. Payseur. University of Wisconsin - Madison, Madison, WI.

In many species, meiotic recombination is concentrated in small genomic regions. These "recombination hotspots" leave signatures in fine-scale patterns of linkage disequilibrium, raising the prospect that the genomic landscape of hotspots can be characterized from sequence variation. This approach has led to the inference that recombination hotspots evolve rapidly in some species, but are conserved in others. Historic demographic events, such as population bottlenecks, are known to affect patterns of linkage disequilibrium across the genome, violating population genetic assumptions of this approach. Such events are prevalent, yet demographic history is generally unaccounted for when making inferences about the evolution of recombination hotspots. To determine the effect of demography on the detection of recombination hotspots, we use the coalescent to simulate haplotypes with a known recombination landscape. We measure the ability of popular linkage disequilibrium-based programs to detect recombination hotspots under different demographic histories, including population bottlenecks, hidden population structure, population expansions and population contractions. We find that demographic events, and in particular, population bottlenecks and exponential population growth, have the potential to greatly reduce the power to discover recombination hotspots, in some cases by up to 90%. Furthermore, demographic events also have the potential to increase the false positive rate of hotspot discovery. In the worst-case scenario, long, slow population contractions quadruple the frequency of false positives, even under stringent significance cutoffs. We tested whether simple genomic parameters, such as nucleotide diversity or heterozygosity, could be used to predict the reduction in power due to non-equilibrium demographic histories. We found that neither the power, nor the false positive rate, of hotspot detection could be predicted without also knowing the demographic history of the sample. Our results suggest that ignoring demographic history likely overestimates the power to detect recombination hotspots and underestimates the degree to which recombination hotspots are shared between closely related species. We make specific recommendations for how demographic inference can be incorporated into population genetic inferences about recombination hotspots.

P2007A Exogenous RNA in the serum of healthy persons. *Supriyo De*[1], Douglas Dluzen[2], Alan B. Zonderman[3], Toshiko Tanaka[4], William H. Wood[1], Luigi Ferrucci[4], Michele K. Evans[2], Kevin G. Becker[1], Nicole Noren Hooten[2]. 1) Gene Expression and Genomics Unit, Laboratory of Genetics, National Institute on Aging, NIH, Baltimore, MD; 2) Health Disparities Research Section, Laboratory of Epidemiology and Population Science, National Institute on Aging, NIH, Baltimore, MD; 3) Behavioral Epidemiology Section, Laboratory of Epidemiology and Population Science, National Institute on Aging, NIH, Baltimore, MD; 4) Longitudinal Studies Section, Translational Gerontology Branch, National Institute

on Aging, NIH, Baltimore, MD.

The discovery of circulating cell-free DNA (exDNA) and RNA (exRNA) in human body fluids, including serum, has sparked great interest in using these nucleic acids as markers of disease, as diagnostic tools or as therapeutic molecules. Here, we examined the exRNA/exDNA profiles in community-dwelling individuals. Surprisingly, we found a considerable percentage of sequenced extracellular DNA/RNA remains unaligned to the human genome/transcriptome compared to DNA/RNA extracted from cells. In this project, we have tried to identify the nature of the unaligned reads after filtering out the sequencing adapters and primers. Total RNA was extracted from the serum of 10+ healthy young individuals and 10+ healthy old individuals and total RNA-seq on the Ion Torrent Proton sequencer was performed using a modified protocol to obtain both small and large sized RNAs. The reads were first aligned to the human genome (hg19) using a two-step process with Tophat2 and Bowie2 (not presented here) and unaligned reads were aligned to all known organisms in the Refseq v70 database (54,118 organisms) encompassing prokaryotes (archaea and bacteria) and eukaryotes (fungi, plants and vertebrate & invertebrate animals). Kraken software was used to align against 618.8 billion DNA sequences and 24.2 billion RNA sequences in a sequential manner of the different kingdoms of life. The results surprisingly show that different individuals have different percentages of fragments of DNA and/or RNA from numerous organisms. Some of the organisms identified are bacteria (including Clostridium sp. and Pseudomonas sp.), fungi (including Malassezia sp., Saccharomyces), plants (such as corn, tobacco, poplar etc.), insects (including mites, deer tick and body lice), vertebrates (such as turkey and cow). This suggests that the species we are identifying in serum may give important information about diet and behavior among the individuals studied. Many of the sequenced reads from the serum of different individuals align to specific regions of the genome of an organism (e.g. Pseudomonas aeruginosa), indicating that perhaps these fragments (kilobases in size) are particularly more stable, which allows them to withstand degradation in body fluids. Thus, far we have identified these organisms through computational methods, but further experimental validation will be performed.

P2008B Genetic variation, population structure, and genome assembly of the threatened Neosho madtom catfish (*Noturus placidus*). *J. E. Decker*[1,2], L. K. Whitacre[1,2], M. L. Wildhaber[3], G. S. Johnson[4], J. M. Downs[5], T. Mhlanga-Mutangadura[4], V. M. Tabor[6], D. Fenner[7]. 1) Informatics Institute, University of Missouri, Columbia, MO; 2) Division of Animal Sciences, University of Missouri, Columbia, MO; 3) U.S. Geological Survey, Columbia Environmental Research Center, Columbia, MO; 4) Department of Veterinary Pathobiology, College of Veterinary Medicine, University of Missouri, Columbia, MO; 5) The Peoria Tribe of Indians of Oklahoma, Miami, OK; 6) U.S. Fish and Wildlife Service, Kansas Ecological Services Field Office, Manhattan, KS; 7) U.S. Fish and Wildlife Service, Oklahoma Ecological Services Field Office, Tulsa, OK.

The Neosho madtom (*Noturus placidus*) is a small catfish, generally less than 3 inches in length, unique to the Neosho-Spring River system within the Arkansas River Basin. It was federally listed as threatened in 1990, largely due to habitat loss. As part of conservation efforts, we generated whole genome Illumina paired-end sequence data from ten Neosho madtom (average 39X coverage) originating from three geographically separated subpopulations to evaluate genetic diversity and population structure. One slender madtom (*Noturus exilis*) was also sequenced as an outgroup. Lack of a reference genome necessitated variants be discovered using De Bruijn graphs implemented in CORTEX v1.0.5.21. Approximately 1.64 million high confidence single nucleotide polymorphisms (SNPs) were observed. Only 86,155 SNPs were variable across the Neosho madtoms sequenced, indicating overall low level genetic diversity. While principal component analysis based on these genotypes accurately clustered individuals from the same location together, insignificant eigenvalues indicated weak population structure, suggesting these subpopulations are genetically compatible for reintroduction among these three locations. We also completed a draft *de novo* assembly of the Neosho madtom genome from 120X of sequences pooled across 3 individuals. We assembled the ~1 Gb genome into 149,885 contigs with a N50 of 12,261 bp. Using only 50X coverage of paired-end and mate pair data from a single fish, we were able to assemble the genome into 68,147 scaffolds with an scaffold N50 of 120 kb, demonstrating the value in assembling a genome from a population that is closely related to a species of economic interest (i.e., channel catfish, *Ictalurus punctatus*) but has lower genetic diversity and is easier to assemble. Ongoing efforts aim to improve the assembly by using sequences from DISCOVAR recipe libraries (250 bp paired-end reads), assembled with DISCOVAR de novo and MaSuRCA. The ability to generate a reference genome allows us to use demographic models, such as PSMC, to compare the effective population sizes between the Neosho madtom and the slender madtom. With genomic tools developed, we can now better manage this endangered species and investigate the basic biology of why such a low-diversity species can subsist.

P2010A Population Genetic Analysis of Autophagy and Phagocytosis genes in *Drosophila melanogaster*. *J. Im*, B. Lazzaro. Cornell University, Ithaca, NY.

Phagocytosis and autophagy are cellular mechanisms that recognize and eliminate pathogens from the extracellular space and cellular interior, respectively. These mechanisms, as a part of the immune system, defend the host from a wide range of ever-changing pathogens that evolve to escape, resist or compromise host immunity. Some bacteria use effector proteins that manipulate host autophagy and phagocytosis to either inhibit immune defense or to promote bacterial invasion into the interior of the cell. In response, the host may experience selective pressure to adapt. This dynamic conflict may result in coevolution, leading to recurrent positive directional selection on host genes. Therefore, we hypothesize that host phagocytosis and autophagy genes may have experienced more positive selection than other genes in the genome. We specifically hypothesize that genes that are known to interact with bacterial factors are most likely to have undergone positive selection.

To test this hypothesis, we perform population genetic analyses on a curated set of phagocytosis and autophagy genes, as well as control genes that are matched with case genes by gene length and genome location, using 197 *Drosophila melanogaster* sequences from the Drosophila Genome Nexus Project. Initial analyses suggest strong, recent selection on a subset of autophagy genes, including Atg8a and Atg13.

Atg8a is known to be involved in the expansion of autophagosome, while Atg13 is involved in autophagosome induction. Previous work has shown that an effector protein from the intracellular pathogen *Legionella pneumophila* inhibits host autophagy by blocking the proper conjugation of Atg8a with Atg3 and Atg7, supporting our hypothesis that Atg8a may be a target of host-pathogen coevolution. This is the first study to examine the evolution of non-receptor phagocytosis and autophagy genes involved in immune defense and will provide a novel insight into the evolution of the innate immune responses.

P2011B Insertion polymorphisms of mobile elements in sexual and asexual populations of *Daphnia pulex*. *x. jiang*, H. Tang, M. Lynch. Indiana University, Bloomington, IN.

Transposable elements (TEs) constitute a substantial portion of many eukaryotic genomes, and can in principle contribute to evolutionary innovation as well as genomic deterioration. *Daphnia pulex* serves as a useful model for studying TE dynamics as a potential cause and/or consequence of asexuality. We analyzed insertion polymorphisms of TEs in 8 sexual and 8 asexual isolates of *D. pulex* from whole-genome sequencing data. Our results show that the total fraction of the derived sequences of TEs is not substantially different between asexual and sexual *D. pulex* isolates. However, in general, sexual clones contain fewer common (fixed) TE insertions, and in the mean time, demonstrate higher insertion polymorphisms than in asexual clones, supporting the hypothesis that sexual reproduction facilitates the spread of TEs while limiting the deleterious load imposed by TE insertions. We identified a subset of asexual-specific TE insertions, including the insertions of 20 LTR retrotransposons, two non-LTR retrotransposons and five DNA transposons. By comparison, no sexual-specific TE insertions were observed in our analysis. Furthermore, 24 out of the 27 asexual-specific insertion sites are located in contigs from chromosomes VIII, IX, and X that are known to be associated with obligate asexuality in *D. pulex* and partially derived from *D. pulicaria.* We found that 18 out of the 27 asexual-specific TE insertions can also be detected in some *D. pulicaria* isolates, indicating only a small number of TE insertions have likely accumulated after the origin of obligate asexuals.

P2012C The Relationship between Host Genetic Architecture and Pathogen Susceptibility in Caenorhabditis elegans. *L. M. Johnson*, C. F. Baer, J. M. Ponciano, S. A. Rouse. University of Florida, Gainesville, FL.

The association between host genotype and the susceptibility to and clinical manifestation of particular pathogens is well-documented, but the particulars of this relationship are rarely understood. A vital first step in better understanding the genetic basis of pathogen susceptibility is analyzing the role of mutation. This study aims to quantify the per-generation input of genetic variance by mutation for susceptibility of *Caenorhabditis elegans* to *Pseudomonas aeruginosa*. A set of mutation accumulation (MA) lines, which have undergone 250 generations of single hermaphrodite decent, along with their ancestral parent, were infected with *P. aeruginosa*. A chain binomial model was then used to estimate the average survival age of all infected individuals. A significant difference was seen in survival probability between ancestral worms and those which had undergone 250 generations of mutation accumulation, with MA worms showing a decreased time until death. We will also report line mean and variance for MA and control lines tested.

P2013A Characterization of Genic Microsatellite Markers (EST-SSRs) in the Endangered Tree *Quercus georgiana*. *PRIYANKA KADAV*. MICHIGAN TECHNOLOGICAL UNIVERSITY, HOUGHTON, MI, USA.

Characterization of Genic Microsatellite Markers (EST-SSRs) in the Endangered Tree *Quercus georgiana*. PRIYANKA KADAV[1], MURPHY WESTWOOD[2], ANDREA KRAMER[3], JEREMIE FANT[3], ANDREW HIPP[2], RAAKEL TOPPILA[2], SEAN HOBAN[2], OLIVER GAILING[1], [1]Michigan Technological University, [2]The Morton Arboretum, [3] Chicago Botanic Garden

Quercus georgiana is an endangered endemic oak species that exists only in a few scattered populations in the southeastern US. The aim of the project is to characterize genic microsatellite markers (EST-SSRs) in this endangered tree species in four populations from Georgia. A total of 27 EST-SSRs have been tested for locus-specific amplification in eight *Q. georgiana* samples from the four different populations, out of which 12 have been selected based on the amplification of a single polymorphic gene locus for the analysis of all 300 samples. Samples were amplified in a GeneAmp PCR system 2700 using the EST-SSRs. PCR amplicons were separated on an ABI 3730 Genetic Analyzer with the internal size standard GS-LIZ-500 and scored with GeneMarker V.2. 6.7. An initial assessment of the genetic variation parameters expected heterozygosity (H_e), observed heterozygosity (H_e) and number of alleles per locus (N_a) was done in GENAlEx6 using EST-SSRs. In addition, the inbreeding coefficient F was calculated for each marker in GENAlEx. Observed heterozygosity (Ho) and expected heterozygosity (He) for individual markers ranged from 0.273 to 1.000 and from 0.247 to 0.867, respectively. The number of alleles per locus (Na) ranged from 2 to 11. Genetic differentiation among populations (F_{ST}=0.067) was comparatively high with pairwise F_{ST} values ranging from 0.024 to 0.119. The mean genetic variation for the four populations fragments was 0.677 (H_o) and 0.655 (H_e). High genetic differentiation between neighboring populations could indicate genetic drift.

P2014B Population genomics of *Fusarium graminearum* head blight pathogens in North America. *A. Kelly*, T. Ward. USDA-ARS, Peoria, IL.

In this study we utilized comparative genomics to identify candidate adaptive alleles in the fungus *Fusarium graminearum,* the primary pathogen of Fusarium head blight (FHB) in cereal crops. Recent epidemics of FHB have been economically devastating to agriculture, as *F. graminearum* reduces cereal yield and contaminates grain with harmful mycotoxins. We performed Illumina whole-genome sequencing (50X coverage) on 60 *F. graminearum* strains from the US and Canada, and then utilized a combination of reference-based mapping and *de novo* sequence assembly to assess genomic diversity and differences in gene content. Bayesian clustering and phylogenetic analyses based on 505,748 SNPs revealed three major *F. graminearum* populations. Isolates with the recently discovered NX-2 toxin type were genetically distinct

from the resident and emergent populations that are typically associated with FHB in North America. However, 8 out of 20 NX-2 isolates shared a substantial proportion of their ancestry (63% on average) with resident isolates that have the 15ADON toxin type. High-resolution genome scans of diversity revealed multiple loci that exhibited genetic signatures consistent with adaptive divergence, in that these regions were highly differentiated among populations, had an excess of rare variants and showed reduced intrapopulation diversity. Candidate selected regions included the trichothecene toxin gene cluster encoding the core metabolic enzymes responsible for structural differences among toxin types. A second locus encoded a protein kinase (PKS3) involved in fruiting body pigmentation and a type of RNA helicase that has proven critical for cold adaptation in other fungal species. A third locus encoded four uncharacterized proteins with homology to primary metabolic enzymes. *De novo* assembly of unmapped reads identified 22,788 contigs (average length 618 bp) that were missing or highly diverged from the *F. graminearum* reference genome. Though most unmapped contigs (87%) were found in a single isolate, we detected 162 genes that were widely distributed and differentially maintained across populations. These population-enriched genes showed homology to proteins in other phytopathogenic fungi with predicted functions in secondary metabolism, fungal self/non-self recognition and fungal cell-wall degradation. Our findings suggest that cold tolerance and trichothecene toxin diversity may be driving local adaptation in *F. graminearum* populations. Furthermore, differences in gene content suggest that competitive interactions with other fungi and secondary metabolite diversification have shaped the population genome of *F. graminearum*, and may be contributing to differences in how these pathogens exploit the agricultural landscapes of North America.

P2015C The effects of linked selection on *Capsella grandiflora*. *Tyler Kent*, Stephen Wright. University of Toronto, Toronto, Ontario, Canada.

The pervasiveness of the effects of selection on neutral and total genetic diversity in species is a major question in evolutionary genetics. It is becoming increasingly understood that selection can greatly alter the local coalescent histories of genomic regions linked to selected loci, which are otherwise considered to evolve neutrally. This can have major impacts on estimates of summary statistics and demography and can bias population genetic models. Additionally, in plants, linked selection studies to date have mainly focused on species-wide datasets, which may lead to underestimation of the impact of linked selection on local populations. Here we present a model fitting of linked selection to a sample of 189 individuals from a single population of the obligate outcrossing plant model species Capsella grandiflora. We show that linked selection has wide-ranging effects on genetic diversity, and compare our results to similar findings in the highly self-fertilizing Arabidopsis thaliana. Improved knowledge of local coalescent histories and landscapes of genetic diversity in this model species will improve the quality of future population genetic analyses as well as guide future studies on the relative impacts of positive and negative selection and genetic drift in a widely applicable plant family..

P2016A Exact calculation of the joint site frequency spectrum for generalized isolation with migration models. *Andrew Kern*. Rutgers University, Piscataway, NJ.

Population genomic datasets collected over the past decade have spurred interest in developing methods that can utilize massive numbers of loci for inference of demographic and selective histories of populations. The site frequency spectrum (SFS) provides a convenient framework for such analysis and accordingly much attention has been paid to predicting theoretical expectations of the SFS under a number of different models. However, to date, exact solutions for the joint SFS of two or more population under models of migration and divergence have not been found. Here we present a novel Markov chain representation of the coalescent on the state space of the joint SFS that allows for rapid, exact calculation of the joint SFS under generalized isolation with migration (IM) models. In turn, we show how our Markov chain method, in the context of composite likelihood estimation, can be used for accurate inference of parameters of the IM model using SNP data. Lastly, we apply our method to recent whole genome datasets from *Drosophila melanogaster* and human populations.

P2017B The evolution of herbicide resistance in an agricultural weed, *Capsella bursa-pastoris*. *Julia Kreiner*, John Stinchcombe, Stephen Wright. University of Toronto, Toronto, Ontario, CA.

How much is adaptive evolution driven by local *de novo* mutation, selection on standing variation, or gene flow from other populations? Weed populations regularly sprayed with herbicides generally experience stronger and more predictable selection than natural populations, and have well-characterized target loci subject to selection, making them an interesting model for understanding the population genomics of adaptation. Here we investigate the population genomics of resistance to acetolactate synthase (ALS) inhibitor herbicides in the agricultural weed *Capsella bursa-pastoris* across a broad geographic range in Alberta and Saskatchewan, Canada. We genotyped 96 individuals via genotype-by-sequencing (GBS) and sequenced whole genomes from 192 individuals distributed among two pools collected from low and high resistance geographic regions. We compared the number of independent resistance mutations and the frequency of resistance mutations from our pooled-seq data to population structure estimates from our GBS data. We infer the extent to which herbicide resistance adaptation was driven by local vs. global selective sweeps, and/or from selection on standing genetic variation. The evolution of resistant agricultural weeds in response to single target herbicides is becoming increasingly common since reports were first made in 1968 (Jasieniuk et al., 1996) and underlines the importance of understanding how the evolutionary rescue of populations proceeds under increasing levels of stress. The origins and spread of herbicide resistance alleles is important for contemporary weed management, food security, and conservation.

P2018C ***Saccharomyces eubayanus*** **population dynamics in nature and industry.** *Quinn Langdon*[1], David Peris[1], Ryan V. Moriarty[1], Kayla Sylvester[1], Guillaume Charron[2], Jean-Baptiste Leducq[2], Christian R. Landry[2], Diego Libkind[3], Chris Todd Hittinger[1]. 1) University of Wisconsin-Madison, Madison, WI; 2) Université Laval, Québec City, Canada; 3) CONICET-UNComahue, Bariloche, Argentina.

Members of the *Saccharomyces* genus have played a key role in genetic research and are widely utilized in industrial applications. However, much is sill unknown about their wild population structure, genetic diversity, and domestication for fermentation applications. One species in this genus, *Saccharomyces eubayanus*, is a parent of the hybrid lager yeasts and, despite its important role in brewing, in the wild, it has never been isolated in Europe and is mainly isolated in Asia and South America. *S. eubayanus'* role in industry and its global distribution allows us to ask evolutionary questions of domestication and wild population structure across different time scales from ancient to modern. Utilizing whole genome sequencing data and population genomic techniques, we have begun to disentangle *S. eubayanus*' current demographics and elucidate the genetic diversity at the time of hybridization to form lager yeasts. Analysis of all genomes currently available shows two major populations of *S. eubayanus;* with evidence of an ancient population split, followed by subsequent secondary contact and gene flow primarily into only one of the populations. Within one of the major populations there are several subpopulations whose genetic diversity and geography inform our understanding of its complex past and present demography. One subpopulation has only been found in the Holarctic ecozone and includes the lager lineages. From this subpopulation, we can infer the diversity of the ancient subpopulation that gave rise to lager yeasts despite having few modern representatives of this subpopulation. Another subpopulation contains closely related strains largely from Patagonia, but also Oceania and North America suggesting the potential for migration and niche expansion. Finally, adding to our understanding of recent population dynamics is enhanced by a lineage that is the result very recent admixture of the two the major populations. Interestingly this lineage is found in two locations in North America, suggesting that this admixed group can thrive outside of Patagonia and raising questions of the migratory possibilities of this yeast. *S. eubayanus'* dynamic population structure has allowed us survey ancient to modern gene flow and work back in time to illuminate our knowledge of the subpopulation that gave rise to lager yeasts. Understating the modern population structure and diversity of industrially important yeasts informs our understating of both the wild dynamics of yeasts and the different paths taken to domesticate this important genus.

P2019A A Haplotype Method Detects Diverse Scenarios of Local Adaptation from Genomic Sequence Variation. *Jeremy Lange*, John Pool. University of Wisconsin-Madison, Madison, WI.

Identifying genomic targets of population-specific positive selection is a major goal in several areas of basic and applied biology. However, it is unclear how often such selection should act on new mutations versus standing genetic variation or recurrent mutation, and furthermore, favored alleles may either become fixed or remain variable in the population. Very few population genetic statistics are sensitive to all of these modes of selection. Here we introduce and evaluate the Comparative Haplotype Identity statistic (χ_{MD}), which assesses whether pairwise haplotype sharing at a locus in one population is unusually large compared with another population, relative to genome-wide trends. Using simulations that emulate human and *Drosophila* genetic variation, we find that χ_{MD} is sensitive to a wide range of selection scenarios, and for some very challenging cases (*e.g.* partial soft sweeps), it outperforms other two population statistics. We also find that, as with F_{ST}, our haplotype approach has the ability to detect surprisingly ancient selective sweeps. Particularly for the scenarios resembling human variation, we find that χ_{MD} outperforms other frequency and haplotype-based statistics for soft and/or partial selective sweeps. Applying χ_{MD} and other between-population statistics to published population genomic data from *D. melanogaster*, we find both shared and unique genes and functional categories identified by each statistic. The broad utility and computational simplicity of χ_{MD} will make it an especially valuable tool in the search for genes targeted by local adaptation.

.

P2020B How a Framework for Evolutionary Systems Biology Can Accelerate Reproducible Modeling of Mechanistic Fitness Landscapes. *Laurence Loewe*. Laboratory of Genetics and Wisconsin Institute of Discovery, University of Wisconsin-Madison, Madison, WI.

Systems approaches are becoming increasingly important, as population genomics aims to understand factors shaping the reproduction and survival of genotypes based on the phenotype they encode and their environment. Current interest in personalized medicine, disease prediction and understanding GxPxE interactions can easily be frustrated by the computational work required and by the limitations of current tools, which often excel at the specialized tasks they were written for, but are of little use for closely related tasks that often only differ in minor details. Considering the computational challenges of mechanistically predicting phenotypes, diseases or fitness in non-trivial systems raises the question, how often it will be possible to extract reliable biology from simulations in which signals can be hard to separate form the noise of mishandling data, numerical errors, bugs, logic errors and more. Sound programming and modeling advice emphasize the importance of good questions to solve specific problems. This often leads to results or tools that are highly specific to some type of question, ignoring other closely related questions. Asking such questions often triggers so much code-wrestling, data shoveling, version wrangling and other silicon digging, that little time remains for considering big picture questions, such as how the relentless New Evolutionary Synthesis that started in the 1920s can be advanced to the point where fitness landscapes become useful in the real world.

To facilitate the development of computational tools for ultimately enabling interactive "flight simulators for mechanistic fitness landscapes", it is pivotal to understand the corresponding requirements and to provide a sound and usable conceptual framework that is stable enough to serve as a solid basis for writing long-term backwards compatible code that is reproducible enough to enable efficient model-reuse, so researchers can focus again on the biology instead of resolving tedious computational problems.

Earlier work, discussions at a series of EvoSysBio meetings, and newer advances enabled the development of such a framework for

Evolutionary Systems Biology that combines the rigor and expertise of molecular biology and other Intra-Organism Biology results with the rigor of models in Population-Genetics Biology and other Trans-Organism Biology. The result is a redefinition of EvoSysBio that lays out in much improved clarity and precision the long road to enabling fully automated mechanistic predictions of phenotypes and diseases from genotypic information. Cancer cell evolution will used as an example.

P2021C Program number not assigned.

P2022A Genotype calling from population-genomic sequencing data. *T. Maruki*, M. Lynch. Indiana University, Bloomington, IN.

Genotype calling plays important roles in population-genomic analyses. Although many statistical methods have been developed, the performance of the widely used genotype-calling methods is not understood well, especially when the population deviates from Hardy-Weinberg equilibrium (HWE). In this study, we develop a maximum-likelihood (ML) method for calling genotypes that incorporates population-level prior estimates of genotype frequencies and error rates to improve the accuracy of genotypes called from low-coverage sequencing data. We compare the performance of the proposed method with that of GATK and Samtools using computer simulations under genetic conditions where the population may deviate from HWE. The results show the proposed method yields more accurate called genotypes than the currently widely used methods.

In addition to the method for low-coverage sequencing data, we develop another ML method for calling genotypes from high-coverage sequencing data, which does not require prior population-level estimates and enables identification of polymorphisms with arbitrary number of alleles. Using computer simulations, we examine when the coverage is high enough to accurately characterize polymorphisms using the proposed method. Taking the results of the performance evaluation into account, we apply the proposed method to high-coverage (mean 18×) whole-genome sequencing data of 83 clones from a population of *Daphnia pulex*. Our results using multiple procedures for minimizing analyzing sites with mismapped reads indicate that a nonnegligible fraction of polymorphisms in this species is triallelic, demonstrating the importance of relaxing the assumption of biallelic polymorphisms. Because of the efficiency and flexibility, the proposed method can in principle be extended to population-genomic analyses of polyploid data. As an example, we extend it to analyses of triploid sequencing data. Using computer simulations, we examine the performance of the proposed method. Our results show that calling accurate genotypes from triploid sequencing data requires much higher coverage than that from diploid sequencing data, which will help researchers to design sequencing strategies for population-genomic studies in polyploid organisms.

P2023B Whole animal genetics-by-sequencing approaches to investigate starvation resistance. *B. T. Moore*[1], J. M. Jordan[1], E. A. Bowman[2], R. Chitrakar[1], A. Hung[1], R. E. W. Kaplan[1], J. D. Hibshman[1], L. R. Baugh[1]. 1) Duke University, Durham, NC; 2) Vanderbilt University, Nashville, TN.

The advent of high coverage and low cost sequencing technologies has allowed for newer and more powerful approaches in molecular and population genetics. Transposon sequencing, where genome-saturated mutant populations' allele frequencies are measured before and after selection, functionally characterizes each and every gene in the genome in a single experiment. The approach has been successfully applied to a variety of phenotypes in a variety of unicellular systems: growth and motility in *E. coli*, synthetic genetic interactions in yeast, and pathogen-resistance in mammalian cell lines. However, transposon insertion typically produces null alleles, which can be valuable to identify gene function, but evolutionary insight relies on identification of naturally occurring polymorphisms affecting the trait of interest. Genome-wide association studies (GWAS) can be used to study the effect of natural genetic variation on a trait, but they grow prohibitively expensive if the number of individuals to genotype and phenotype becomes large. Techniques such as pool-GWAS, where individuals are pooled prior to genotyping, and restriction site-associated DNA sequencing (RAD-seq), where a subset of the genome is targeted for sequencing, have lowered the cost and increased the power of GWAS.

Here we describe the application of transposon sequencing and pool-GWAS (with RAD-seq genotyped natural variants) in the whole metazoan model, *C. elegans*. Transposon sequencing has not been previously implemented in an animal model. Specific challenges we have solved include the lack of high-throughput transformation (in contrast to unicellular models) and creation of a representative transposon-insertion sequencing library. We are using our new transposon-sequencing and pool-GWAS methods to study the genetic underpinnings of starvation survival in the nematode. When a *C. elegans* larva hatches in the absence of food its development must be halted and its metabolism changed, requiring precise coordination within cells and between tissues. We present preliminary data of a transposon sequencing screen for starvation survival. Furthermore, we present preliminary data of a pool-GWAS experiment of 96 *C. elegans* wild isolates for starvation survival.

P2024C Two locus allele frequency statistics with demography and selection using a diffusion approach. *Aaron Ragsdale*, Ryan Gutenkunst. University of Arizona, Tucson, AZ, USA.

Patterns of polymorphism within and between populations are determined by the demographic and evolutionary history of those populations. By measuring the present genetic diversity and patterns of linkage disequilibrium within a population, we may infer its demographic history and patterns of selection. The allele frequency spectrum (AFS) is an informative summary statistic of observed genetic variation within a sample, and has been widely used in demographic inferences for single and multiple populations, as well as to infer the effects of selection on that observed variation. AFS-based methods assume independence between sites, and the AFS does not describe levels of linkage disequilibrium between nearby sites. However, frequencies of neighboring alleles are correlated, and selection on linked sites affect patterns of observed variation, so observed levels of linkage disequilibrium are informative about the demographic and evolutionary history of

the population. We present a novel numerical approach to the forward-in-time diffusion model for the joint distribution of two-locus allele frequencies and linkage disequilibrium, which can model the simultaneous effects of demography and selection on one or both loci. This allows for improved inferences on single-population demography, and describing the expected patterns of allele frequencies subject to natural selection at linked sites, including the effects of background selection and hitchhiking events.

P2026B Frequency, variance and power: how genetic model and demography impact association studies. *J. S. Sanjak*. UC Irvine, Irvine, CA.

To understand the genetic architecture of complex traits we need theoretical models that make useful predictions that are consistent with empirical observation. Simulations of complex traits are widely used for inference of population parameters and in-silico testing of new experimental or analytical methods. Despite this, the approaches in the field of complex trait simulation are very heterogeneous. One common thread is that classic models consider particular mutations ("SNPS") as separate loci. However, we wish to model a genomic region as a functional unit or gene. As such, there are important implications of the structure of the relationship between mutations in the region and it's functional output in a diploid individual. Also, it is well known that demography plays an important role in shaping patterns of DNA sequence variation, but the specifics of how demography interacts with underlying genetic model are unknown. We use forward-time simulation to explore the properties of a co-dominant model and two different recessive models, in constant-sized and recently expanded populations, in the context of heritability estimation and genetic association studies. In particular, we find that the population frequency by effect-size distribution and statistical properties of association studies are both impacted by genetic model. Consequently, when explicitly modeling DNA sequence variation underlying a complex trait it is critical to differentiate between sites within a functional unit (gene) and those in distinct functional units. Comparing the effect of population growth across multiple genetic models suggests that, perhaps, the genetic model is more important than the demographic model.

P2027C Robust identification of hard and soft sweeps in humans via machine learning. *Daniel R. Schrider*, Andrew D. Kern. Rutgers University, Piscataway, NJ.

Detecting the targets of adaptive natural selection from whole genome sequencing data is a central problem for population genetics. Numerous approaches have been devised to detect the population genetic signature of a *de novo* beneficial mutation sweeping rapidly to fixation (a hard selective sweep). To date most of these methods to detect sweeps show poor performance under realistic demographic scenarios. Moreover, over the past decade there has been a renewed interest in determining the importance of selection from standing variation (soft sweeps) in adaptation of natural populations, yet few methods are sensitive to this mode of selection. Here we introduce a new tool, S/HIC, which uses supervised machine learning to precisely infer the location of both hard and soft selective sweeps. We show that S/HIC has unrivaled accuracy for detecting sweeps under demographic histories that are relevant to natural populations, and distinguishing sweeps from linked as well as neutrally evolving regions. Moreover we show that S/HIC is uniquely robust among its competitors to demographic misspecification: even if the true demographic model of a population differs catastrophically from that specified by the user, S/HIC still retains impressive discriminatory power. Next, we apply S/HIC to resequencing data from human European and African population samples from the 1000 Genomes Project. S/HIC reliably recovers selective sweeps that have been identified earlier using less specific and sensitive methods, and identifies several compelling novel candidates, including a tumor suppressor gene that is often mutated or deleted in breast tumors. Lastly we perform the first genome-wide examination of the prominence of hard versus soft sweeps in human populations, finding a much greater frequency of soft sweeps in Africa. This result confirms theoretical predictions that larger populations will more often respond to adaptive challenges by selecting on previously standing polymorphisms.

P2028A Comprehensive genome-wide disease characterization (URSA(HD)) and tissue-specific networks (GIANT) guide discovery and functional elucidation of novel predicted disease-associated genes. *Chandra Theesfeld*[1], Young-suk Lee[1], Casey Greene[3], Arjun Krishnan[1], Aaron Wong[1,2], Emanuela Ricciotti[3], Rene A. Zelaya[4], Daniel S. Himelstein[5], Ran Zhang[1], Boris M. Hartmann[6], Elena Zaslavsky[6], Stuart C. Sealfon[6], Daniel I. Chasman[7], Garrett A. FitzGerald[3], Kara Dolinski[1], Tilo Grosser[3], Olga Troyanskaya[1,2]. 1) Princeton University, Princeton, NJ; 2) Simons Foundation, New York, NY; 3) University of Pennsylvania, Philadelphia, PA; 4) Geisel School of Medicine at Dartmouth, Hanover, NH; 5) University of California, San Francisco, San Francisco, CA; 6) Icahn School of Medicine at Mount Sinai, New York, NY; 7) Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

Complex diseases are driven by multiple genetic changes and characterized by genome-wide perturbations of cellular pathways and functions. Gene expression profiling experiments comparing normal to disease samples while useful in uncovering molecular pathology of diseases, are limited in that they cannot discern similarities between related diseases. Discovery of truly-disease specific attributes requires a comprehensive approach comparing many diseases and many normal samples. We have developed URSA(HD), a unified probabilistic framework to identify and quantify distinctive disease signals for 309 human diseases based on gene expression profiles of clinical samples. URSA(HD) can uncover subtle differences between similar diseases and highlights identifiable aspects of rare diseases. URSA(HD) outperforms other approaches of using individual disease genes or the typical normal/disease differential expression analyses. URSA(HD) can also be used by researchers to make sample predictions(both cancerous and non-cancerous) for a given clinical gene expression profile (ursa.princeton.edu).

URSA's resulting biological models constitute feature sets specific to each disease: different from those for all other diseases (including similar diseases), and different from all normal tissue. In the biological model for neuroblastoma, a pediatric cancer, 16 of the top 20 genes are documented causal or biomarker genes, and the remaining four genes are uncharacterized. We tested the relevance of these four genes and

found clear growth or cell migration phenotypes for three genes in one or two different human neurobastoma cell lines. Since literature is limited or non-existent for these four genes, further characterization of their roles will require consideration of potential roles in cell and tissue physiology. URSA(HD) models retain only the tissue signatures that are relevant to the disease over and above normal tissue signal. Genome-wide functional studies and access inclusive tissue information and predictions, we have developed human genome-wide tissue-specific networks: GIANT.princeton.edu. With these networks, known and predicted tissue-specific roles played by proteins, including widely expressed proteins, are accessible. Associations within these networks are directly usable by scientists for hypothesis generation and testing and will be useful**.**

P2029B Polygenic adaptation to an optimum shift. *K. R. Thornton*. Univ California, Irvine, CA.

The design and interpretation of genome scans for selection have been largely influenced by models that assume either continuous directional selection on unconditionally beneficial new mutations ("hard" or "classic" sweeps) or fluctuating selection on a previously neutral or weakly-deleterious mutation ("soft" sweeps). However, many examples of adaptive phenotypes in natural population involve complex traits, and the above models may not be adequate descriptions of how such complex polygenic traits evolve. Here, I use forward-time simulation to examine the dynamics of adaptation to a sudden environmental shift, which is modeled as a shift in the optimum value of a complex trait with a broad-sense heritability less than one. The model integrates the existing concepts of "soft" sweeps from standing variation and "classic/hard" sweeps from new mutations, but the strength of selection on individual mutations changes over time as the mean trait value approaches the new optimum value. Adaptation initially proceeds via soft sweeps, fixing mutations of relatively large effect that arose prior to the optimum shift. Subsequent evolution involves hard sweeps of mutations whose effect sizes decrease as time goes on. The site frequency spectrum (SFS) and linkage disequilibrium (LD) show time-dependent deviations from equilibrium values, providing a means of inferring the magnitude of the optimum shift. Finally, the genetic variation for fitness takes a long time to return to equilibrium, and there is continued directional selection after the new optimum phenotype is reached as the population is loses mutations that increase variance in fitness.

P2030C Genome wide association in presence of high density marker panels and genotyped causal variants. *S. Toghiani*[1], L. Y. Chang[1], S. Aggrey[2,3], R. Rekaya[1,3]. 1) Department of Animal and Dairy Science, The University of Georgia, Athens, GA, USA; 2) Department of Poultry Science, The University of Georgia, Athens, GA, USA; 3) Institution of Bioinformatics, The University of Georgia, Athens, GA, USA.

Genome wide association studies (GWAS) rely on estimating the association between phenotypic variation and a large number of SNPs often within the framework of a linear regression (LR) or mixed linear (ML) models. Although both models have a certain level of statistical equivalency, they differ in the manner of associating phenotypic variation to genetic polymorphisms. Linear regression models directly associate the phenotype with SNP genotypes allowing for a direct dissection of the trait especially if causal variants are included on the panel. However, these models suffer from the excessive high dimensionality of the parameter space and co-linearity between SNPs. ML models remove some of the issues associated with LR methods and allow for straightforward accommodation of confounding due to population structure and family relationships. ML models rely on the estimation of the realized genetic similarity matrix (GM) between individuals using all available SNP genotypes. It is well known that the GM matrix change very little with the increase in the number of markers in the panel once a certain density threshold is reached even when causal variant genotypes are available. As the density of genotyping panels continuous to increase in density so does the probability of causal variants being genotyped. In order to investigate the robustness of ML models in the era of next generation sequencing, a simulation study was carried out for a trait with heritability of 0.4. One chromosome with 75,000 SNPs and 35 casual variants explaining 5% of total genetic variance was simulated mimicking a 2 million SNP marker panel and 1000 casual variants at the genome level. Simulated data was analyzed using LR and ML models either including or excluding causal variants. Using ML models, prediction accuracy defined as the correlation between true and estimated genetic values was the same independently of panel density, exclusion (0.293) or inclusion (0.294) of causal variants. Genetic variance was under estimated (0.013 vs. 0.02). Prediction accuracy increased by around 3% when a LR model was used and causal variants were included. Genetic variance was more accurately estimated (0.017 vs. 0.02). LR model used all available SNPs and its performance is expected to increase if a model averaging (BayesB) or SNPs prioritizing approaches were applied. As density increases and more causal variants are include in the marker panels, ML models will need some improvements mainly in the calculation of GM matrix.

P2031A Detecting patterns of microgeographical adaptation to a patchy saline environment of a single popupation of *Medicago truncatula*. *w. vu*[1], P. Chang[1], K. Moriuchi[4], E. von-Wettberg[2], M. Friesen[3], S. Nuzhdin[1]. 1) Univ Southern California, University Park Campus, Los Angeles, CA 90089; 2) Florida International university 11200 SW 8th St, Miami, FL 33199; 3) Michigan State University 220 Trowbridge Rd, East Lansing, MI 48824; 4) University of California, Davis 1 Shields Ave, Davis, CA 95616.

Divergent selective pressures across a heterogeneous environment can result in the maintenance of genetic variation and adaptation to local environmental conditions. While this process has been well documented at larger geographical scales, it remains unknown whether micro-environmental variation can result in the maintenance of genetic variation. Therefore we aim to understand the genetic basis of plant response to micro-environmental variation. Our study examines the patterns of micro-scale adaptation to a saline habitat within a single population of *Medicago trucatula*—an annual selfing legume that is native to Mediterranean regions.

Early flowering is a predictor of increased plant performance and reproductive output in saline conditions. We observe that flowering time is

negatively correlated with soil salinity levels in the field, indicating that the variability in soil patches can maintain phenotypic variation and potentially genetic variation. This suggests that variable selective pressure between soil patches is likely driving divergent flowering time responses within a single selfing population. Furthermore, SNP frequency is strongly associated with latitude, longitude, elevation and soil salinity levels. Some of the polymorphisms correlated with environmental variability cause functional changes in genes associated with flowering time, disease resistance, salt and osmotic stress. Overall, these results suggest that micro-scale environmental variation can potentially shape patterns of adaptation to heterogeneous environments.

P2032B Genome-wide divergence among microhabitats in *Fundulus heteroclitus*. *D. N. Wagner*, T. Baris, D. Dayan, X. Du, M. Oleksiak, D. Crawford. University of Miami, Miami, FL.

Selective differences among environments rely on isolation or selection coefficients that exceed migration, thus in a highly connect environment there is little expectation of genetic divergence among habitats. The teleost fish *Fundulus heteroclitus* lives in *Spartina* saltmarshes along the eastern coast of North America where the tide flushes and then drains these saltmarshes, typical of a well mixed population. The natural history supports this supposition: these fish have small home range of 36m and they reproduce in a common part of the saltmarsh, laying their eggs at the highest tides in the upper tidal regions in mussel shells or among leaves of *Spartina alterniflora*. Yet, within a single marsh are three microhabitats: 1) tidal basins, 2) intertidal creeks, and 3) tidal ponds, that have meaningful environmental differences in their daily maximum temperatures and oxygen concentration. Based on mark-recapture studies, individuals are often associated with a single habitat. These environmental differences and site fidelity could select for different genotypes. To examine any microhabitat differences in genotypes, individuals from the 3 different microhabitat types from 3 replicate saltmarsh populations along the New Jersey Coast (Mantoloking, Rutgers Field Station, and Stone Harbor) were genotyped at more than 4,000 SNPs using genotyping-by-sequencing (GBS). GBS identified between 2.2-4.4% of single nucleotide polymorphisms (SNPs) with significant outlier F_{ST} values between microhabitats of resident fish (p-value < 0.01, FDR = 1%). These SNPs may be adaptively important, and suggest that selection is surprisingly effective in altering allele frequencies over very small geographical distances.

P2033C Essential proteins evolve slower than non-essential ones during evolution experiments. *D. Alvarez-Ponce*[1], B. Sabater-Muñoz[2], C. Toft[3,4], M. X. Ruiz-González[2,5], M. Fares[2,5]. 1) University of Nevada, Reno, Reno, NV; 2) Department of Genetics, Smurfit Institute of Genetics, University of Dublin, Trinity College Dublin, Dublin, Ireland; 3) Department of Genetics, University of Valencia, Valencia, Spain; 4) Departamento de Biotecnología, Instituto de Agroquímica y Tecnología de los Alimentos (CSIC), Valencia, Spain; 5) Instituto de Biología Molecular y Celular de Plantas (CSIC-UPV), Valencia, Spain.

The Neutral Theory of Molecular Evolution is considered the most powerful theory to predict the evolutionary behavior of proteins. One of the main predictions of this theory is that essential proteins should evolve slower than dispensable ones owing to increased selective constraints. Comparison of genomes of different species, however, have revealed only small differences between the rates of evolution of essential and non-essential proteins. It has been argued that comparing relatively distant genomes may entail a number of limitations. For instance, many of the genes that are dispensable in controlled lab conditions may be essential in some of the conditions faced in nature. Moreover, essentiality can change during evolution, and rates of protein evolution are simultaneously shaped by a variety of factors, whose individual effects are difficult to isolate. Here, we conducted two parallel mutation accumulation experiments in *Escherichia coli*, during 5500–5750 generations, and compared the genomes at different points of the experiments. Our approach (a short-term experiment, under highly controlled conditions) enabled us to overcome many of the limitations of previous studies. We observed that essential proteins evolved significantly slower than non-essential ones during our experiments. Strikingly, rates of protein evolution were not affected by expression level, protein abundance, or protein length.

P2034A Subpopulation structure in long-term cultures of *Escherichia coli* K-12. *M. Behringer*, B. Choi, S. Miller, T. Doak, M. Lynch. Indiana University, Bloomington, IN.

Inexpensive whole genome sequencing now permits us to look at genome-wide patterns of adaptation within populations, but this approach is only starting to be used to examine the extensive population structure that arises under long-term evolution studies. To determine the effects that effective population size and variable mutation rates have on genome evolution, we conducted a long-term evolution experiment using *Escherichia coli* populations with six different genetic backgrounds, carried through 3 years of continuous culture. After whole-population sequencing of these lines, we identified recurring mutations across populations—specifically genes associated with biofilm formation, global regulation, and peptidoglycan recycling.

To further investigate this phenomenon, we isolated eight random clones from twelve long-term evolution populations polymorphic for mutations in *fimE* (biofilm formation), *hns* (global regulation), and *nlpD/mppA* (peptidoglycan recycling). These twelve populations also represent three of the genetic backgrounds used: wild-type (WT), Δ*mutL*, and a *mutL*+ line preloaded with mutations for ~4000 generations of mutation accumulation. Genomic sequence of the clones, finds genetic evidence for subpopulation structure in the long-term evolution populations. Further, we find phenotypic differences within populations for lag-time, maximum growth rate, diauxic growth, auxotrophy, and biofilm formation.

For our wild-type focus population—where mutation rate is low—we identified three major haplotypes among the eight clones. Associated with these haplotypes, we identified genetic and phenotypic evidence of auxotrophy for thiamine in five clones. Additionally, these five clones displayed slower maximum growth rates, but shorter lag times and diauxic growth curves (indicating resource prioritization), presenting one

possible adaption to coexistence in a fluctuating environment.

In our Δ*mutL* focus population, with mutation rates ~150 times greater than wild-type, we identified six major haplotypes. Furthermore, because of the increased mutation rate, we were able to conduct pathway analyses shedding light on the specialization of each clone. Interestingly, because of the potential for non-competing niches, independent evolutionary changes within identical pathways occurred in clones belonging to different haplotypes. We conclude that our methods gives us the mutational resolution to describe evolutionary changes within hetrogenous, intraspecies communities, an important step toward understanding intraspecies communities in both nature and disease.

P2035B Phenotypic variation in individuals isolated from *Escherichia coli* long-term evolution populations. *Brian Choi*, Megan Behringer, Samuel Miller, Thomas Doak, Michael Lynch. Indiana University, Bloomington, IN.

How organisms evolve and/or adapt is one of the central questions in population genetics. While evolution can be driven by four major forces: mutation, recombination, natural selection and random genetic drift, when investigating experimentally evolved cultures it can be difficult to determine if shared genotypes occur due to mutational hotspots in the genome or parallel adaptive evolution. Previous long-term evolution experiments conducted by Richard Lenski and collaborators have demonstrated multiple avenues of adaptation for *Escherichia coli* strain B in liquid culture (Elena and Lenski, 2003). Using a similar long-term investigation, we aimed to explain how ancestral genetic background, starvation, and an environment where subpopulations can inhabit their own niche affects population dynamics and long-term evolution. As such, we characterized 96 clones isolated from 12 out of 200 populations involved in a long-term evolution experiment. Our 12 focus populations were propagated from one of three possible *E. coli* K-12 ancestors, and transferred every 24 - 48h for 2.5 years (~4000 generations) in liquid LB medium. Among clones, auxotrophic, behavioral, morphological, and growth variations were identified. We additionally evaluated each of the clones for improved or worsened fitness compared to the wild-type ancestor through relative growth curve assays. Lastly, we applied a bioinformatics approach for lineage and mutation analysis to identify patterns and commonalities between the varied phenotypes and their respective genotypes. Here, we are able to trace homologous changes in bacterial evolution to suggesting parallel response to pressures due to their respective conditions, background, or ecological niche. The complex structuring of ecological niches among the long-term populations is reflective of the shifts in gene polymorphisms.

P2036C Quantifying host genome response to gene drive using experimental evolution. *K. Fisher*, G. Lang. Lehigh University, Bethlehem, PA.

Gene drives—selfish alleles that bias inheritance in their favor—have great potential for solving epidemiological and agricultural problems. Seeding populations with transgenic individuals containing drive elements linked to a trait of interest, such as resistance, has been proposed as strategy to control disease vectors and agricultural pests. The most predictable, and consequently useful, of these elements are targeted endonucleases that recognize and insert themselves into homologous alleles in which they are absent by cleaving a target sequence and allowing homologous recombination to result in gene conversion. Homing endonucleases and CRISPR endonucleases have been demonstrated to be effective knockout drivers with reliable activity and specificity in laboratory populations (Windbichler et al. 2011; DiCarlo et al, 2015; Gantz & Bier, 2015), and thus are possible tools for this type of population level genetic manipulation in the field.

Models of gene drive suggest that the gains from distorting inheritance can overcome selection such that even strongly deleterious alleles can spread through drive (Deredec et al. 2008; Unckless et al. 2015). These studies, however, do not consider coevolutionary dynamics between drive elements and host genomes. Homing endonucleases rarely exert deleterious effects in their native hosts, suggesting that coevolution readily occurs in response to drive to lessen intragenomic antagonism. Changes in response to selection on the part of either drive elements or host genomes could potential derail the intended effects of synthetic gene drives. To date, no studies have assessed the efficacy and reproducibility of gene drive in evolving populations or to the predictability of host genome response.

Here we propose to directly test the efficacy of gene drive in evolving populations of the budding yeast, *Saccharomyces cerevisiae.* We have successfully constructed several drive elements. Alleles have been designed so that we can vary the fitness cost of drive across experimental replicates. Drive and target alleles will be fluorescently tagged to quantify their frequencies over time. Whole genome sequencing will be used to characterize reproducibility of host genome responses. We predict that host genomes will evolve in response to drive and that fates of drive elements will be predictable as a function of increasing selection, but unpredictable between replicate populations of the same selective regime due to the stochastic nature of molecular adaptation.

P2037A Leveraging haplotype-aware inference for evolve-and-resequence studies. *S. Greenblum*[1], S. Tilk[1], A. Bergland[1,2], P. Schmidt[3], D. Petrov[1]. 1) Stanford University, Stanford, CA; 2) University of Virginia, Charlottesville, VA; 3) University of Pennsylvania, Philadelphia, PA.

In the face of sharp environmental fluctuations, massive adaptive change has been observed in metazoan populations on timescales of just tens of generations. Despite the importance of rapid adaptation for predicting the dynamics of critical health threats such as host-pathogen co-evolution and viral outbreak, the genetic basis of this phenomenon remains unclear. Large-scale evolve-and-resequence (E+R) experiments, entailing serial sequencing of pooled samples from populations subject to selection, hold enormous promise for studying the dynamics of rapid adaptation in a controlled yet realistic setting. However, more work is needed to devise experimental and analytic frameworks that maximize the power and precision of these studies, given available technologies, resources, and informatics tools.

Here we leverage both data from the experimental evolution of *Drosophila melanogaster* populations, as well as simulated data, to demonstrate how various experimental designs incorporating fully-sequenced founder lineages influence the detection resolution of alleles under strong short-term selection. In particular, we focus on the tradeoff between experimental schemes that minimize linkage disequilibrium

among founder haplotypes to uncouple the trajectories of strongly adaptive alleles and nearby sites, and schemes that incorporate new computational tools that *make use* of founder linkage to increase the precision of individual allele frequency measurements, thereby reducing sequencing costs and facilitating higher levels of replication.

We demonstrate how this tradeoff informs best practices for E+R, and quantify the increased power afforded by linkage-informed analyses in detecting the genomic targets of rapid adaptation. Improved frameworks building on these results will immediately benefit future studies of experimental evolution in many model organisms, and will help clarify the true extent of the *Drosophila* genome that is subject to short-term seasonal selection as well as the broader impact of rapid adaptation on genome architecture.

P2038B Genome-wide Analysis of Starvation-selected *Drosophila melanogaster*- a Genetic Model of Obesity. *Christopher Hardy*[1], Molly Burke[2], Mira Han[1], Logan Everett[3], Kathryn Lantz[1], Allen Gibbs[1]. 1) University of Nevada Las Vegas, Las Vegas, NV; 2) Oregon State University, Corvallis, OR; 3) North Carolina State State University, Raleigh, NC.

Experimental evolution affords the opportunity to investigate adaptation to stressful environments. Combining experimental evolution with recent developments in whole-genome sequencing has elevated the field by providing insight into the dynamics of evolution as well as a new tool to discriminate genes involved in polygenic traits. Here, we performed an "Evolve and Resequence" (E&R) study where we selected for starvation-resistance in populations of *Drosophila melanogaster* for over 80 generations. In response to selection, the starvation-selected lines have developed an obese condition, storing nearly twice the level of fats than their unselected controls. While the excess fats provide a ~3-fold increase in survival time upon starvation, the imbalance in lipid homeostasis incurs evolutionary cost. Some of these tradeoffs resemble obesity-associated pathologies in mammals including metabolic depression, low activity levels, dilated cardiomyopathy and disrupted sleeping patterns. To determine the genetic basis of these traits we sequenced genomic DNA from the selected lines and their controls. We found 1,046,373 polymorphic sites, many of which diverged between selection treatments. In addition, we found a wide range of genetic heterogeneity between the replicates of the selected lines, suggesting multiple mechanisms of adaptation. Genome-wide levels of heterozygosity in the selected lines were low, with many large blocks of SNPs nearing fixation. To find loci under selection, we generated a new algorithm to control for the effects of genetic drift. We mapped these loci to a set of 1,453 genes, which were enriched for genes related to morphogenesis, development, tissue differentiation and regulation of metabolism. The results of our study speak to the evolutionary origins of obesity and provide new targets to understand the polygenic nature of obesity in a unique model system.

P2039C Investigation of the prevalence of antagonistic pleiotropy. *L. Herissant*[1], D. Yuan[2], P. Humphrey[3], M. Johnson[3], A. Agarwala[4], D. Fisher[4], M. Desai[3], D. Petrov[2], G. Sherlock[1]. 1) Department of Genetics, Stanford University, Stanford, CA; 2) Department of Biology, Stanford University, Stanford, CA; 3) Department of Organismic and Evolutionary Biology and of Physics, and FAS Center for Systems Biology, Harvard University, Cambridge, MA; 4) Department of Applied Physics, Stanford University, Stanford,CA.

Pathogenicity, drug resistance and cancer progression are examples of mutation-driven processes, where increased selective advantage is conferred upon cells carrying new mutations. While these mutations may be beneficial in one specific condition, they may be deleterious in other conditions, a phenomenon known as Antagonistic Pleiotropy (AP). AP is thought to lead to evolutionary trade-offs and the persistence of deleterious alleles. But what is the prevalence of AP? Which genes or pathways are more likely to be involved in AP, and under which conditions? Is there any specific type of mutation that results in AP? One study investigated AP and observed ~14% of non-essential gene deletions display AP (Qian et al., 2012) but the prevalence and nature of AP for beneficial mutations is largely unexplored.

To answer these questions, we are using an experimental system that allows us to track and measure the fitness values of ~500,000 separate lineages within an evolving yeast population via DNA barcodes (Levy et al 2015). We performed evolution on haploid population as well as on diploid population. One preliminary observation is that, diploids arise in the haploid population and have some fitness advantage depending on the growth conditions.

With this barcoding system, we are able to identify lineages that gain a beneficial mutation, based on how their frequencies increase over time. We will select clones that harbor beneficial mutations in order to measure their fitness in alternate conditions. We will infer AP for any clones that carry beneficial mutations in the first environment that now show a fitness lower than wild-type in at least one alternate environment. On clones of interest, we will perform whole genome sequencing to determine the mutation that induces AP in those clones.

These data will result in the largest set of fitness measurements for adaptive mutations ever collected across multiple environments. It will allow us to determine, for example, the extent of AP among new beneficial mutations and any correlations between the magnitude of the beneficial effect a mutation confers in one environment and whether it exhibits AP in other environments. The results will indicate whether beneficial mutations in certain pathways are more likely to exhibit AP and will provide the first insight of how mutation-driven processes can confer selective evolution or why deleterious alleles can be conserved upon evolution.

P2040A Analyses of Breast Cancer Type 1(BRCA 1) Gene Of Different Mammalian Species. *E.VictorI. Ikpeme*, O.Ogbu Udensi, H.Edim Etta, U.Benjaimin Ekaluo, M. Ozoje, B.Bendiwhobel Ushie, E. Echea, M.Edem Kooffreh, E.Archiebong Okon. University of Calabar, Calabar, Cross River, Nigeria.

Breast cancer type 1 (BRCA1) gene also known as breast cancer type 1 susceptibility protein homologue plays important role in DNA double-strand break repair, homologous recombination, chromatin remodeling, cell cycle regulation and transcription regulation. Considering the importance of this protein, the present study was undertaken to analyse BRCA1 gene of different mammalian species by assessing the identity and similarity, phylogenetic relationship, physicochemical properties, predict the motifs, secondary and the tertiary structures. Seventeen

nucleotide and protein sequences of BRCA1 gene of different mammalian species were retrieved from National Centre for Biotechnology Information (NCBI). Multiple sequence alignment was done using CLUSTAL W software, while identity and similarity was determined by constructing a pairwise comparison. Results obtained at the end of the experiment showed that there was no percentage Identity or similarity that was less than 70%. The phylogenetic relationship of BRCA1 gene of the mammalian species clustered into aquatic, herbivores, carnivores and omnivores, respectively. The highest time of divergence (95MYA) of the BRCA1 gene was observed between the BRCA1 gene of killer whale and human, while the least time of divergence (4.6MYA) was observed between the BRCA1 gene of cattle and American buffalo. Physicochemical properties of BRCA1 proteins in the five mammalian species (cattle, sheep, pig, American buffalo and human) were found to be unstable, hydrophilic and intracellular in nature. The following motifs were present at various positions in the BRCA1 gene of the five mammalian species; zinc finger RING, BRCT domain, N-myristoylation site, N-glycosylation, cAMP and cGMP dependent protein kinase phosphorylation site, Tyrosine kinase phosphorylation and cell attachment sequence, but leucin zipper pattern and microbodies c-terminal motifs were found in only human BRCA1 gene. The BRCA1 secondary structure contained the alpha helix, extended strand and random coil. Based on the results obtained, it can be deduced that BRCA1 gene has identical homologue, functional similarity and highly conserved in these mammalian species.

P2041B Experimental evolution of drift robustness in digital organisms. *T. LaBar*, C. Adami. Michigan State University, East Lansing, MI.

Both recurring deleterious mutations and mutation accumulation due to genetic drift can reduce a population's average fitness. To counteract these effects, selection should favor genetic architectures that are robust and limit these deleterious effects. For instance, populations can evolve mutational robustness by reducing the average deleterious effect of a mutation so as to minimize the mutational load. Here, we test whether populations can evolve to limit the reduction in fitness caused by deleterious mutation accumulation and genetic drift in small populations (i.e., the drift load) using experimental evolution with digital organisms. In other words, we ask whether populations can evolve robustness to genetic drift ("drift robustness") when adapting to survive in small populations, similar to populations evolving mutational robustness to survive high mutation rates. We found that small populations do evolve drift robustness, while large populations evolve drift fragility. Drift robustness emerges from the evolution of genetic architectures that reduce the likelihood of deleterious mutations with small effect sizes. We discuss specifically the role selection plays in the spread of drift robust genotypes, and show that drift robustness can arise from mutations that drastically decrease the likelihood of deleterious mutations while significantly increasing the likelihood of lethal mutations. These findings may have implications for genome evolution of organisms with small population sizes, such as bacterial endosymbionts and eukaryotic organelles.

P2042C A gene's view of a long-term evolution experiment with *Escherichia coli*. *Rohan Maddamsetti*[1], Philip Hatcher[2], Barry Williams[1], Jeffrey Barrick[3], Richard Lenski[1]. 1) Michigan State University, East Lansing, MI; 2) University of New Hampshire, Durham, NH; 3) University of Texas at Austin, Austin, TX.

In my dissertation research, I used genomic data from a long-term evolution experiment with *Escherichia coli* (LTEE) to answer two questions, among others. First, what do the evolutionary dynamics in the LTEE look like? Second, what kinds of genes evolve in the LTEE? These studies share the same cast of characters: *pykF, iclR, spoT, nadR, topA,* and *malT*. These genes make the strongest contribution to adaptive evolution in the LTEE. I use these genes to show that the evolutionary dynamics that play out in the LTEE involves two processes that are often difficult to tell apart: clonal interference and negative frequency-dependent selection. I then show that even though these genes evolve rapidly and repeatedly in the LTEE, they are well-conserved across *E. coli* isolates and have diverged slowly since the *Salmonella–Escherichia* split. In fact, adaptive evolution in the LTEE largely involves mutations at conserved protein residues within conserved core genes such as *pykF*. The apparent simplicity of LTEE belies considerable complexity, making the LTEE a powerful model system for evolutionary genomics.

P2043A The fitness spectrum in adaptation of diploid yeast. *David Yuan*[1], Lucas Herissant[2], Atish Agarwala[3], Daniel Fisher[3], Gavin Sherlock[2], Dmitri Petrov[1]. 1) Department of Biology, Stanford University, Stanford, CA; 2) Department of Genetics, Stanford University, Stanford, CA; 3) Department of Applied Physics, Stanford University, Stanford, CA.

Adaptation is one of the central processes in evolution. Not only does adaptation drive phenotypic change in organisms, it also underlies many human diseases, such as cancer and the emergence of drug resistance in their treatment. Yet our current understanding of adaptation suffers from a major limitation.

While many organisms of interest to biology and medicine are diploid, many studies characterize adaptive mutations—the agent of evolutionary change—only in haploids. Mutations driving adaptation likely have very different properties depending on whether they arose in diploids or haploids. For instance, diploid adaptive mutations cannot be fully recessive and may be gain-of-function more often than haploid ones. This can lead to profoundly different adaptation dynamics between diploids and haploids. We previously investigated this difference using a theoretical model [Sellis et al. 2011], though little empirical data on adaptation in diploids exist to date. Thus, our understanding of adaptation in diploid populations often requires extrapolating parameters from haploid experiments. This is particularly troubling in studies of cancer—an adaptive process in diploids.

To overcome this limitation, we are isolating and characterizing a statistically representative number of adaptive mutations in both diploids and haploids. To achieve this, we have used experimental evolution in yeast coupled with a high-resolution molecular barcoding system that enables us to measure and track the fitness of ~5x105 lineages over time [Levy et al. 2015]. We carried out experimental evolution in barcoded S. cerevisiae diploid and haploid populations in multiple evolutionary conditions. Results from haploids provide a basis of comparison, while

multiple conditions take us towards generalizability of results.

As a first step towards understanding how adaptation differs between diploids and haploids, we will identify lineages that acquire adaptive mutation by increases in the frequencies of their barcodes. We will then estimate the distribution of fitness among thousands of adaptive clones for each evolution experiment. These adaptive clones will be taken from time point(s) in which most have one causal adaptive mutation. This data will be the largest and most precise to date on the dynamics of adaptation in diploid populations. The results will inform us on how diploids differ from haploids in terms of speed of adaption and effect size of adaptive change. In the future, we will identify the causal adaptive mutations to deeply characterize how diploids differ from haploids in terms of target and pathway of adaptation, dominance, and environmental pleiotropy.

P2044B Genomic Basis of Craniofacial Diversity in Lake Malawi Cichlids. *K. Abdilleh*, C. Patil, J. T. Streelman. Georgia Institute of Technology, Atlanta , GA.

Craniofacial disorders represent some of the most common birth defects affecting ¼ of the human population worldwide. Many causal mutations implicated in craniofacial malformations are also responsible for generating the natural craniofacial trait variation observed between species. The advancement of next generation sequencing technologies has allowed for rapid acquisition and identification of genome-wide variants mediating adaptive craniofacial differences between species. Rock dwelling and sand dwelling cichlid fishes of Lake Malawi (LM) exhibit extensive variations in craniofacial morphologies, specifically in jaw size and length making them an outstanding model for the study of craniofacial morphological evolution. Here, we performed whole-genome re-sequencing of 16 rock and sand dwelling LM cichlids and identified regions of genomic differentiation between the groups. We show evidence that (1) regions of genomic differentiation are enriched for genes involved in pathways and processes relating to cranial neural crest cell differentiation and development (2) alternately fixed SNPs between rock and sand species are within and around crucial genes of the cranial neural crest cell gene regulatory network and (3) alternately fixed SNPs between rock and sand species are also within enhancer elements regulating craniofacial and neural crest development. Taken together, our comparative genomic analysis provides a global picture of the key genomic changes likely modulating species-specific craniofacial differences between rock dwelling and sand dwelling LM cichlids.

P2045C Repeated horizontal transfer of a fused gene encoding adjacent metabolic enzymes. *N. M. Anderson*[1], S. W. Roy[1,2]. 1) University of California, Merced, Merced, CA; 2) San Francisco State University, San Francisco, CA.

We report a case of gene fusion and horizontal gene transfer (HGT), two noncanonical molecular evolutionary processes whose functional significance remains obscure. Diffusion of products between enzymes can be a limiting step in metabolic pathways, a problem that can be mitigated in part by the physical association of enzymes that act in adjacent steps of the pathway. A manual search of the 1000 Fungal Genomes Project revealed 10 species within the large Pezizomycotina (Ascomycota) containing a single gene that encodes both aconitate hydratase (aconitase family) and isocitrate/isopropylmalate dehydrogenase (IsoDH), two enzymes that are adjacent in the citric acid cycle and other pathways. Surprisingly, the species containing this fusion were found to be distantly related, a finding that could be due to either: a) repeated independent fusion of these two genes; or b) a single gene fusion event and repeated horizontal transfer of the fused gene.

To distinguish between these possibilities, we reconstructed phylogenetic trees for each of the enzymes separately and compared these gene trees to the consensus species tree. Our results strongly support a grouping of the fused genes, implying multiple cases of HGT. Expanding this search to other fungal groups revealed additional species harboring aconitase-IsoDH fusions in a pattern that suggested additional HGT events, but also suggested a fusion event independent from those within Pezizomycotina. The striking propensity for HGT of these fused genes suggests that they impart a fitness advantage, likely through increased efficiency of metabolic pathways, revealing the ways that HGT can disseminate useful molecular innovations throughout the tree of life.

P2046A Mapping the Origins of Inter-Population Skin Color Variation with Admixed Indigenous Populations . *K. C. Ang*, V. A. Canfield, T. C. Foster, K. C. Cheng. Penn State College of Medicine, Hershey, PA.

The genetic basis of population-specific differences in human skin color is a fascinating, socially relevant, and enduring mystery of human biology. For Europeans, we now know about two genes that together account for much of their lighter skin color as compared with Africans, and other genes that affect intra-population variation in skin, eye and hair color. However, the genes responsible for the lighter skin color of East Asians and Amerindians (as compared with West Africans) remain unknown. To map those genes, we searched for populations admixed for either East Asian or Amerindian ancestry and a darker-skinned ancestry. The only populations with such an admixture that also lack significant European admixture that would confound our analysis were two indigenous populations, the Orang Asli of Malaysia and the Kalinago of Dominica. Both groups exhibit large variation in skin pigmentation. The Orang Asli of Peninsular Malaysia consist of three tribes, Senoi, Proto-Malay, and Negrito, who have a complex ancestry. The Kalinago have primarily Amerindian and West African ancestry. DNA samples and skin reflectance measurements were collected from a total of >1000 individuals. Skin pigmentation, expressed as Melanin Index, ranged from 20 to 80 units, averaging 45.5 and 45.8 for the Senoi and Kalinago, respectively (as compared with 25 and 21 for East Asian and European and 55, and 56 for Negrito and West African, respectively). Samples containing European *SLC24A5*^{A111T} or *SLC45A2*^{L374F} alleles will be excluded from our downstream analysis to minimize interference with East Asian and Amerindian pigmentation alleles. For the same reason, we identified and are excluding individuals with an *OCA2* albinism allele found in the Kalinago population. SNP genotyping of subsamples of 92 Kalinago and 78 Orang Asli samples revealed that the Negritos are distinct, that the six Senoi tribes show significant diversity, and that a highland Senoi subtribe is distinct from the rest of the Senoi. Analysis of a Kalinago subsample showed 61% Amerindian, 31% African, and 8% European ancestry, which

is considerably higher Amerindian ancestry than has been reported for other Caribbean populations. Progress will be reported towards screening of whole-genome sequences from phenotypic extremes from these samples for polymorphisms that are nearly fixed in East Asians but nearly absent in Africans. CRISPR-mediated zebrafish knockouts, morphants, and RNA rescue are being used to validate candidate genes.

P2047B Genomic deletion and silencing on the Y chromosomes of Rumex hastatulus. *F. Beaudry*, S. Wright. University of Toronto, Toronto, ONTARIO, CA.

Our support of evolutionary theory depends greatly on the empirical ubiquity of its effects. Although old sex chromosomes in animal systems are well characterized, the young sex chromosomes of plants are sparsely investigated. Here, we determine the amount of chromosomal degeneration observed in the XYY chromosomal system of the dioecious annual plant Rumex hastatulus. Using both RNAseq and genomic Paired-End data, we observe both deletion and silencing of single copy hemizygous genes on the Y chromosomes, where more genes are deleted than silenced. Genes in high copy number are enriched for copies of genes from the chloroplast genome. We conclude that using transcriptome and genome data together allow for the ascertainment of the most complete set of sex-linked and hemizygous genes.

P2048C Horizontal transfer can drive a greater transposable element load in large populations. *J. P. Blumenstiel*, S. B. Groth. University of Kansas, Lawrence, KS.

Genomes are comprised of contrasting domains of euchromatin and heterochromatin and transposable elements play an important role in defining these genomic regions. Therefore, understanding the forces that control transposable element abundance can help us understand the chromatin landscape of the genome. What determines the burden of transposable elements in populations? The standard model suggests that drift plays a determining role. In small populations, mildly deleterious transposable element insertion alleles are allowed to fix, leading to increased copy number. However, it is not clear how the rate of exposure to new transposable element families, via horizontal transfer, can contribute to broader patterns of genomic TE abundance. Here, using simulation and analytical approaches, we show that when the effects of drift are weak, exposure rate to new transposable element families via horizontal transfer can be a critical determinant of genomic copy number. Since larger populations are expected to have a higher rate of exposure to rare horizontal transfer events, this leads to the counter-intuitive prediction that larger populations may carry a higher transposable element load. This work has implications for our understanding of the evolution of chromatin landscapes, genome defense by RNA silencing and recombination rates. It may also have implications for devising methods for pest control by gene drive.

P2049A Defining microRNA molecular origins to facilitate target prediction. *Glen Borchert*. University of South Alabama, Mobile, AL.

MicroRNAs (miRs) are small noncoding RNAs that typically act as regulators of gene expression by base pairing with the 3' UTR of messenger RNAs (mRNAs) and either repressing their translation or initiating degradation. Descriptions of the molecular origins of independent miR molecules currently support the hypothesis that many miR hairpins were generated by the adjacent insertions of two related transposable elements (TEs) at one genomic locus. Thus transcription across such TE interfaces establishes many, if not the majority of functional miRs. We have recently completed an in depth analysis of the genomic origins of annotated miR loci, detailing the formations of 3,605 distinct miR loci primarily from TEs. Interestingly, our analyses also identify evidence for a second, novel mechanism of miR locus generation through describing the formation of 273 miR loci from mutations to other forms of noncoding RNAs. The implications of these findings are substantial for understanding how (in particular) TEs confer increased genomic fitness, describing miR transcriptional regulations, and making accurate miR target predictions. As such, hypothesizing that a miR and its mRNA target sites might actually be formed in parallel by the ongoing colonization of a common ancestral transposable element, led us to develop a novel miR target prediction strategy in which we limit miR target searches to mRNAs containing the TE (or noncoding RNA) initially giving rise to a miR: OrbId (Origin-based Identification of microRNA targets). In stark contrast to the principal miR target algorithms (which rely heavily on target site conservation across species and are therefore most effective at predicting targets for older miRs), we find OrbId is particularly efficacious at predicting the mRNA targets of miRs formed more recently in evolutionary time.

P2050B *Cis*-regulatory enhancers of social insects share ultraconserved core elements flanked by taxa specific modifications. *Thomas Brody*, Ward Odenwald, Neural Cell-Fate Determinants Section. NINDS/NIH, Bethesda, MD.

Ultra-conserved sequence elements in vertebrate enhancers suggest that fundamental gene regulatory mechanisms are shared across phylogenetically diverse species. Our previous studies took advantage of the availability of the assembled genomic sequences of the Mediterranean fruit fly *Ceratitis capitata*, the domestic housefly *Musca domestica*, and *Drosophila* to explore the integrity of regulatory sequences across the ~100 million years of divergence between these dipterans. We have shown that many of the conserved sequence blocks (CSBs) that constitute *Drosophila* enhancers, identified using the multispecies alignment algorithm EvoPrinter, are often nearly completely conserved in both *Ceratitis* and *Musca*. Analysis of the linear positioning of these CSBs with respect to the associated structural genes is also conserved. Availability of the genomic sequence the bumble bee *Bombus impatiens*, honey bee *Apis mellifera* and the European bee *Megachile rotundata* reveals conserved sequence elements bearing strong structural resemblance to those found in flies. Surprisingly, alignment of regulatory sequences from bee species with those of 10 ant species, representing two families of social insects of the order *Hymenoptera*, revealed widespread alignment of the bee sequences with orthologous ant sequences. These alignments also revealed bee- and ant-specific

sequences intermingled with CSBs common to both taxa. We conclude that comparison across ant and bee species reveals ultra-conserved enhancers that bear taxa specific sequence modifications. These studies allow for a greater understanding of enhancer evolution and constitute a first step in the comparative analysis of gene regulation in these species.

P2051C Single molecule real time sequencing reveals the detailed structure of a Y-autosome fusion in *Drosophila pseudoobscura*. *C. Chang*, A. Larracuente. U of Rochester, Rochester, NY.

Fusion events between sex chromosomes and autosomes are an important part of karyotype evolution in animals. In some cases, ancestral sex chromosomes revert back into autosomes, for example the dot chromosome of *Drosophila* is an ancient X chromosome. However, there are few documented cases of Y chromosome reversals to autosomes. *D. pseudooscura* is well-suited to study Y chromosome reversal: a fusion between the ancestral Y chromosome and an autosome (Y-to-dot) occurred ~15 MYA making the ancestral Y chromosome now autosomal. To gain insight into the evolutionary forces shaping this Y chromosome reversal, we used single molecule real time sequencing reads generated with Pacbio to assemble the dot chromosome of *D. pseudoobscura,* including the Y-to-dot region. This contig has all identified ancestral Y-linked genes, ~100 conserved dot-linked genes and telomere sequences. Surprisingly, the ancestral Y and the conserved part of the dot chromosome are only ~70kb apart, suggesting centromere is not located in the fusion region. Notably, the Y-to-dot does not contain many tandem repeats or satellite DNAs in both its intergenic and intron regions and is only 340 kb—one tenth of the size of the Y chromosome in *D. melanogaster*. Our analysis of transcriptomic data revealed that Y-to-dot genes expression remain testis-specific, even after becoming autosomal for ~15 MY. In addition, both Y-to-dot and conserved dot regions showed lower nucleotide diversity, consistent with the low recombination rates on dot chromosome in *D. pseudoobscura* and *D. miranda*. Because Y chromosomes lack recombination and have a reduced efficacy of natural selection, they tend to accumulate repetitive elements and other deleterious mutations through Muller's ratchet. As a consequence, Y chromosomes tend to have large introns including some that are megabases long. The Y-to-dot region does have longer introns than other parts of the dot chromosome and other autosomes. However, except for the absence of Y-linked mega-introns, there are no significant reductions in intron sizes on Y-to-dot of *D. pseudoobscura* compared to the Y chromosome of *D. melanogaster*. While previous studies suggest that recurrent selective sweeps favoring shorter introns shaped the Y-to-dot region, an alternative hypothesis is that the ancestor of the *obscura* group had a much smaller Y chromosome than *D. melanogaster*. Consistent with this hypothesis, our cytological survey of Y chromosomes in *obscura* group suggests that most species in this group have small Y chromosomes. Therefore, the smaller size of the Y-to-dot region may be at least in part due to a small Y chromosome in the ancestor of the *obscura* group.

P2053B Transposase genes are actively expressed in vespertilionid bat somatic tissues. *Rachel Cosby*, Ellen Pritham. University of Utah, Salt Lake City, UT.

Transposition is often deleterious, and is generally repressed by the host in both germline and somatic tissues. Despite this, transposition does occur, and studies of various elements from fly (P element, *hobo*) indicate that transposition is most common in the germline. Recent studies have challenged this idea in mammals, demonstrating that transposition occurs in somatic tissues, such as brain and tumor tissue. Most of these studies were done in human, where only LINE-1 retrotransposons remain active. Thus, the extent of somatic transposable element (TE) activity in mammals is unexplored. DNA TE activity in mammals is understood even less, due to their recent extinction in most lineages. DNA transposons are active in many other vertebrates, indicating that mammals are the exception, rather than the rule. Notably, the Vespertilionid (vesper) bat family, has experienced numerous, recent waves of DNA TE activity in conjunction with retrotransposon activity. Here we identify expressed, full-length, putatively active transposase genes in vesper bat tissues. We performed RNA-sequencing and *de-novo* transcriptome assembly on liver, kidney, and testis tissues and fibroblast cell lines obtained from four vesper bat species, *Myotis lucifugus, M. occultus, M. velifer,* and *Eptesicus fuscus.* We also incorporated publicly available datasets for kidney, liver, and brain from another vesper bat, *M. brandtii*. We then compared existing transposase protein coding sequence to predicted open reading frames (ORFs) in our transcriptome dataset in order to identify transcripts with intact transposase ORFs. We also searched for intact transposase domains using HMMER. In doing so, we identified several expressed transposase transcripts, including both DNA TEs *(hAT, PiggyBac,* others) and retrotransposons (endogenous retroviral *pol*, *gag*, and *env* genes, and LINE-1 transposase), across all vesper bats examined. Many of these elements have been predicted to be active in vesper bats previously, but often no full-length elements were found, indicating that utilizing *de-novo* transcriptome data may identify low frequency events in the population as well as overcome difficulties due to poor genome assemblies. Overall, our data strongly implies that somatic transposase expression is common in bats, and that these TEs may be actively transposing in somatic tissue, perhaps due to a lack of regulation in somatic tissues. Thus, the contribution of TE expression and transposition to the somatic transcriptome and genome of mammals may be greater than initially anticipated. Further, expression in somatic tissues may favor horizontal transfer, granting TEs another avenue to propagate outside the germline.

P2054C Cytogenetics in the post-genomic era: *Standing chromosomal variation* associated with rapid divergence in a young species pair. *A.-M. Dion-Côté*[1], R. Symonová[2], F. C. Lamaze[3], S. Pelikánová[4], P. Ráb[4], L. Bernatchez[1]. 1) Université Laval, Québec, Canada; 2) University of Innsbruck, Mondsee, Austria; 3) Ontario Institute for Cancer Research, Toronto, Ontario; 4) Institute of Animal Physiology and Genetics, Liběchov, Czech Republic.

The role of chromosome rearrangements in speciation and reproductive isolation remains a debated topic, although certain conditions associated with divergence should promote their emergence. We examined chromosome changes in two Lake Whitefish (*Coregonus clupeaformis*) lineages that recently diverged after the colonization of post-glacial lakes following allopatry. A dwarf limnetic form evolved

repeatedly from the normal benthic form, becoming reproductively isolated. We applied conventional and molecular cytogenetic methods to three such pairs of sympatric Lake Whitefish populations, in order to i) test the null hypothesis of no difference in chromosomal rearrangements between pure lineages and ii) test the hypothesis of chromosomal instability in healthy and unfit backcross embryos.

While the dwarf and normal karyotypes were highly similar, more detailed cytogenetic analyses revealed an extensive polymorphism partly shared by the three species pairs. Multivariate analyses on cytogenetic markers revealed ongoing genomic rearrangements between these incipient species, consistent with chromosomal divergence initiated in allopatry. Our results also support the hypothesis of mitotic instability in healthy backcross embryos. We found extensive aneuploidy in unfit backcross embryos, indicating meiotic breakdown in their F1 parent.

Thus, intra-chromosomal differentiation in the Lake Whitefish system may contribute to divergence by destabilizing mitotic and meiotic chromosome segregation in hybrids. Importantly, the fine chromosome structures detected here, such as centromeres, repetitive elements and heterochromatin remain difficult to sequence and assemble. Therefore, cytogenetics is highly complementary to genomics, and should be integrated with population and quantitative genetic studies towards a better understanding of speciation.

P2055A Catching *de novo* genes as they arise in natural populations. *E. Durand*, I. Gagnon-Arsenault, L. Nielly-Thibault, G. Charron, C. R. Landry. Institut de Biologie Intégrative et des Systèmes, Département de Biologie, PROTEO, Pavillon Charles-Eugène-Marchand, 1030 avenue de la Médecine - Université Laval - Québec (QC) G1V 0A6, Canada.

The emergence of new genes is a driving engine for the acquisition of adaptive innovations. New genes may arise *de novo* from previously non-genic regions or from pre-existing gene structures such as gene duplication. The *de novo* origination is the initial source of genetic novelties and comparative studies between and within species brought to light the potential contribution of intergenic regions in this process. D*e novo* gene origination involves the acquisition of an intergenic ORF by mutations conferring a gain of in frame start and stop codons, and regulatory sites to allow its transcription and translation. Here we explore the dynamics of recently emerging *de novo* genes in natural *Saccharomyces paradoxus* populations. We first characterized intergenic ORF diversity in 24 *S. paradoxus* strains, sampled in North America, that are structured in 3 lineages. These lineages are used to investigate an on ongoing speciation event, making them a perfect model in the context of recently emerging genes and their role in adaptation and potentially speciation [1]. We annotated intergenic ORFs and classified them according to the conservation of their positions. In total, 73,657 ORF families were identified: some (2%) are conserved between *S. cerevisiae* and *S. paradoxus* while 28 and 8% are fixed and specific to *S. cerevisiae* or *S. paradoxus* respectively. Interestingly, the remaining 62% of intergenic ORFs still segregate within and among the *S. paradoxus* lineages. This diversity illustrates the power of using population data to investigate the emergence of *de novo* genes from scratch, which is expected to be rare. We are now characterizing the coding potential of intergenic ORFs at the transcriptional and translational levels to compare the rate of transcription/translation gain or loss versus ORF birth and death. Our results show that intergenic regions contain a large pool of ORFs readily available for natural selection to draw from during species formation.

Leducq JB. *et al.* (2016) Speciation driven by hybridization and chromosomal plasticity in a wild yeast. Nature Microbiol. 1: 15003. doi:10.1038/nmicrobiol.2015.3.

P2056B Few Nuclear-Encoded Mitochondrial Gene Duplicates Contribute to Male Germline-Specific Functions in Humans Compared to *Drosophila*. *M. Eslamieh*, A. Williford, E. Betrán. University of Texas at Arlington, Arlington, TX.

The analysis of nuclear-encoded mitochondrial genes (N-mt genes) in *Drosophila* has shown that most of the duplicated N-mt genes acquired testis-biased expression. These genes tend to be old and have energy-related functions. They are often relocated and many originate through retroposition, a duplication mechanism that appears to facilitate the acquisition of testis expression. These specific patterns reveal strong selection for retention of these duplicates in flies. Since selection could be different for mitochondrial functions in male germline because males do not pass the mitochondria to the offspring and are under strong male-male competition to fertilize the females, we predict that the same selective pressures could operate in other species lineages. To test this, we analyzed the entire set of genes annotated as N-mt genes in the human genome. We found 290 N-mt genes (i.e., 18%) that can be grouped into gene families which are the product of 164 gene duplication events. While around 32% of the new genes showed tissue-specific expression and testis had the highest number of tissue-specific duplicates, the percentage of this kind of duplicates was small (6%) compared to *Drosophila* (54%). Unlike *Drosophila* duplicates, human testis-specific duplicated genes are young and have diverse functions. These differences might reflect differences in the selective pressures for mitochondrial function during spermatogenesis and fertilization between *Drosophila* and humans, differences in the response to these pressures or differences in the efficiency of selection between these species.

P2057C Reconstruction of gene regulatory networks in the developing gonad of the common snapping turtle using ARACNe opens new perspectives for the study of temperature-dependent sex determination. *L. Guo*, T. Rhen. University of North Dakota, Grand Forks, ND.

For many reptiles, sex is determined by the incubation temperature of the egg during embryonic development, a process known as temperature-dependent sex determination (TSD). Previous studies in reptiles with TSD have examined homologs of genes that play a role in sex determination in mammals. However, the traditional candidate gene method lacks the ability to discover novel sex-determining genes and sometimes can be misleading. To complement the candidate gene method and accelerate progress in the field of TSD, we conducted a transcriptome-wide analysis of gene expression and gene function using next generation sequencing technology. We constructed and annotated a reference transcriptome for the common snapping turtle, *Chelydra serpentina*, one of the most widespread and abundant turtles in North America. With differential gene expression analysis comparing gonadal transciptomes between male-producing and female-producing

temperatures, we identified several hundred candidate genes for TSD. With these genes, we reconstructed a gene regulatory network underlying TSD using the algorithm for the reconstruction of accurate cellular networks (ARACNe), an algorithm that is able to identify direct gene-gene interaction with high precision and sensitivity. Our transcriptome analyses not only shed new light on the study of TSD but also offer important insights into sexual development in all vertebrates and sex associated disorders in humans.

P2058A Investigating the evolutionary pathways towards extremely AT rich genomes. *W. Hao*. Wayne State Univ, Detroit, MI.

Genomic nucleotide content (usually measured as GC content) varies widely among species, the most extreme (AT-rich) of which is in the mitochondria of yeasts. These extreme genomes provide a unique opportunity to study the evolution of genomic nucleotide landscape. In this study, we sequenced six complete mitogenomes of the *Saccharomycodes ludwigii* yeast, all of which have <10% GC content. Our comparative genomics analyses observed variable intron presence/absence patterns in the large ribosomal subunit (*rnl*) gene and cytochrome *c* oxidase subunit I (*cox1*) gene, and variable lengths of AT-rich tandem repeats. The whole genome alignments among these mitogenomes showed mosaic sequence patterns, suggesting perhaps frequent mitochondrial DNA recombination. We found no evidence of accelerated substitution rates in these *Saccharomycodes ludwigii* mitogenomes, when compared against other yeast mitogenomes. Thus, mutational pressure and reduced recombination, both of which can lead to increased AT content, are unlikely the main driving force leading to the extreme AT mitogenomes in *Saccharomycodes ludwigii.* We tend to believe that the proliferation of AT-rich tandem repeats via replication slippage and/or unequal crossing-over plays an important role in driving the extreme AT richness in these mitogenomes.

P2059B Evolution of gene regulation in nutrient starvation response between free-living and commensal yeast. *Bin He*, Xu Zhou, Erin O'Shea. Harvard University, Cambridge, MA.

The genomic processes behind local adaptation can be revealed by applying functional genomics in a comparative framework. Here I present work on the evolution of phosphate starvation response bewteen the model organism, *S. cerevisiae*, and a close relative, *Candida glabrata*. *C. glabrata* is a *post-genome-duplication* species, same as *S. cerevisiae.* Yet since their divergence, it has acquired abilities to colonize mammal gut. Preliminary studies of its phosphate starvation response revealed a puzzling difference in the regulation of the pathway. While the master transcription factor PHO4 in *S. cerevisiae* requires a co-factor (PHO2) to function, *this dependence is lost* in *C. glabrata*. Interestingly, the ortholog of the PHO2 in *C. glabrata* still functions and binds adjacent to most of the Pho4 sites, yet its Pho4 is able to bind and activate gene expression independent of Pho2. Using transcriptome profiling and chromatin IP, we mapped genome-wide binding sites of both PHO4 and their co-factor in each species' genome, and identified PHO4 dependent genes, respectively. We found that (1) loss of dependence on the co-factor results in expansion of PHO4's targets. (2) accompanying cis co-evolution modulates the extent of target expansion in *C. glabrata*. (3) functional annotation of PHO4 targets in *C. glabrata* suggests cross-activation of genes involved in other stress responses. Remarkably, a survey of PHO4 orthologs in divergent yeast species revealed two independent events for loss of PHO2-dependence, both in commensal species, suggesting the change is likely beneficial in that context.

P2060C Dynamics of mitochondrial genome evolution during speciation by hybridization. *Mathieu Henault*[1], Jean-Baptiste Leducq[1,2], Guillaume Charron[1], Yves Terrat[2], Jesse B. Shapiro[2], Christian R. Landry[1]. 1) Institut de Biologie Intégrative et des Systèmes, Département de Biologie, PROTEO, Université Laval, Québec, Canada; 2) Département des Sciences Biologiques, Université de Montréal, Montréal, Canada.

Hybridization between species or diverged populations may lead to individuals with mixed ancestry that are reproductively isolated from their parents, resulting in species formation. Although the genomic outcomes of speciation by hybridization have been extensively investigated, the dynamics of organelle genome evolution and its contribution to speciation in this context remain to be fully investigated. Here we study the dynamics of mitochondrial evolution during hybrid speciation in species where mitochondrial genomes are bi-parentally inherited. We used North American lineages of *Saccharomyces paradoxus* that are characterized by partially overlapping distributions and distinct responses to environmental conditions that suggest ecological divergence. The lineage SpC* was recently discovered and shown to be an incipient species that resulted from hybridization between the sister lineages SpC and SpB in their overlapping distribution. Analysis of three SpC* mitochondrial genomes revealed two mostly SpC-like haplotypes and one mostly SpB-like haplotype that all contain introgressed regions, showing extensive mitochondrial genetic admixture in the process of hybridization. These data suggest that mitochondrial genomes readily recombine in hybridizing lineages. We tested this hypothesis experimentally by analyzing the mitochondrial genomic haplotypes of experimental F1 SpB-SpC hybrid strains and showed that frequent recombination events occur within few generations. We are currently examining the adaptive potential of the new mitochondrial haplotypes produced by recombination. Our results show that mitochondrial genomes recombine in hybridizing species where mitochondria are bi-parentally transmitted.

P2061A Detailed structure and variation of complex satellite DNA loci in *Drosophila melanogaster*. *D. E. Khost*, D. Eickbush, A. M. Larracuente. University of Rochester, Rochester, NY.

Large blocks of tandemly repeated heterochromatic sequences called satellite DNAs (satDNAs) can make up a substantial fraction of most eukaryotic genomes. SatDNAs evolve rapidly and may contribute to genetic incompatibilities between closely related species. The variation in heterochromatic sequences, including satDNAs, within species is associated with variation in fitness, genome-wide gene expression and male fertility. Despite their prevalence, satDNAs remain poorly understood and understudied, largely due to the technical difficulty in sequencing and assembling such large, highly repetitive areas of the genome. Advances in single-molecule real-time (SMRT) Pacific Biosciences (PacBio) sequencing help overcome the limitations of traditional sequencing methods for some repeat-rich sequences. We use PacBio sequencing to

reveal the detailed structure and organization of two complex satDNA loci in *Drosophila melanogaster:* a 120 bp repeat called *Responder (Rsp)* and a 260 bp repeat in the *1.688* gm/cm^3 satellite family (*260-bp*). We report on the optimal assembly strategies for regions rich in complex tandem repeats and the complete assemblies of *Rsp* and 260-bp as supported by computational and molecular validation. Both *Rsp* and *260-bp* show high levels of repeat homogenization within their arrays, particularly over the center, indicating that they are undergoing concerted evolution. Sequence variants of the repeats are non-randomly distributed, tending to be located near the distal and proximal ends of their arrays. The *Rsp* locus possesses several additional interesting levels of organization: two islands of transposable elements occur approximately 100 kb apart near the proximal and distal boundaries of the *Rsp* locus, but in an inverted orientation. The *Rsp* sequences in their vicinity have identical partners on opposite sides of the array. This structure suggests several recent, complicated duplication/inversion events and/or recent gene conversion have helped shape the *Rsp* locus. We also use Illumina sequence reads to investigate polymorphism in the organization and abundance of these satDNAs in population samples of *D. melanogaster* from across the globe. We show that the size and composition of the *Rsp* and *260-bp* loci vary across populations and infer the mechanism and location of array expansion/contraction to be through unequal crossing over at the array center. We find an approximately tenfold and fourfold variation in locus size for *Rsp* and *260bp*, respectively. Overall, the unprecedented level of detail that we have in our assemblies allows us to begin to answer fundamental questions about the evolution and dynamics of repetitive regions.

P2062B The Rate and Spectrum of Spontaneous Mutations in Social Amoeba *Dictyostelium discoideum.* . *S. Kucukyildirim*[1,4], W. Sung[3], T. G. Doak[1,2], M. Lynch[1]. 1) Indiana University, Bloomington, IN; 2) University of North Carolina Charlotte, NC; 3) National Center for Genome Analysis Support, Indiana University, Bloomington, IN; 4) Hacettepe University Ankara, Turkey.

Background: In this study we determine the rate and spectrum of spontaneous mutations for the social amoeba, *Dictyostelium discoideum*, a key model organism in molecular and cell biology. Like many other microbial eukaryotes, *D. discoideum* has unusual life history and genome features, for example its AT-rich genome (77.5%) and high percentage of simple sequence repeats, including in coding sequence. This work enables us to explore evolutionary forces and molecular mechanisms that may have shaped the mutation rate and spectrum of *D. discoideum*.

Results and Discussion: Whole-genome sequencing of 19 mutation accumulation lines of *D. discoideum* after an average of 3,000 cell divisions yielded a base substitution mutation rate estimate of 3.55×10^{-11} per site per generation, substantially lower than that observed for most eukaryotic and prokaryotic organisms. Transversions biased transitions and base-substitution changes yielded a mutation rate in the AT direction. The deletion rate is higher than the insertion rate, which is inconsistent with the previous studies showing an insertion bias in unicellular eukaryotes. The base-substitution mutation rate in *D. discoideum* is on the same order of magnitude of that of the ciliates *Paramecium tetraurelia* and *Tetrahymena thermophila.* Like ciliates, *D. discoideum* maintains a large effective population size, reducing the power of random genetic drift, such that selection is relatively unhindered to reduce mutation rates. This observation is consistent with the drift barrier hypothesis that mutation rates are inversely proportional to effective population sizes, and furthers our understanding of the evolutionary forces and molecular mechanisms shaping the evolution of mutation rate.

P2063C Mitochiondrial genome comparisons across major sea urchin families, with special focus on the emerging model *Tripneustes gratilla*. *A. Laruson*, F. Reed. University of Hawai'i at Mānoa, Honolulu, HI.

The sea urchin genus *Tripneustes* has historically served as a model species for theories on population divergence due to its impressive pan-tropical distribution with few well documented barriers to dispersal. While showing very little localized variation, analysis of microsatellite markers and mitochondrial COI sequences suggests that greater isolation exists within the Pacific Ocean than previously believed. A draft transcriptome has allowed for the generation of a full mitochondrial genome sequence from the central Pacific *T. gratilla,* and is compared to mitochondrial genome assemblies across major sea urchin families. The genus *Tripneustes* is placed in a broader phylogenetic context and tree node calibrations are used to date the origin of the lineage. Rates of codon variation in the 13 coding sequences of the mitochondrial genomes across the families are assessed, and pairwise d_N/d_S (ω) ratios highlight variable contraints on coding regions among the sea urchins. Increased understanding of the genomics of such a broadly distributed animal, with an available reference genome in *Strongylocentrotus purpuratus*, and an effectice Wright-Fisher approximating population, could allow for *Tripneustes* to be an effective model organism for population genomics.

P2064A Comparative Methylome Analyses Identify Epigenetic Loci of Transcriptional Regulation in the Human Brain. *I. Mendizabal*[1,3], L. Shi[2,8], T. E. Keller[1], G. Konopka[4], T. M. Preuss[5], T. Hsieh[6], E. Hu[2,7], Z. Zhang[2], B. Su[2], S. Yi[1]. 1) School of Biology, Institute of Bioengineering and Bioscience, Georgia Institute of Technology, Atlanta, GA 30332, USA; 2) School of Biology, Institute of Bioengineering and Bioscience, Georgia Institute of Technology, Atlanta, GA 30332, USA; 3) Department of Genetics, Physical Anthropology and Animal Physiology, University of the Basque Country UPV/EHU, Barrio Sarriena s/n, 48940 Leioa, Spain; 4) Department of Neuroscience, University of Texas Southwestern Medical Center, Dallas, TX. 75390, USA; 5) Division of Neuropharmacology and Neurologic Diseases & Center for Translational Social Neuroscience, Yerkes National Primate Research Center, Emory University, and Department of Pathology and Laboratory Medicine, Emory University School of Medicine. Atla; 6) Department of Plant and Microbial Biology and Plants for Human Health Institute, North Carolina State University, North Carolina Research Campus, Kannapolis, NC 28081, USA; 7) Kunming College of Life Science, University of Chinese Academy of Sciences, Beijing 100101, China; 8) The Molecular & Behavioral Neuroscience Institute, University of Michigan, Ann Arbor, MI 48109-2200, USA.

Elucidating the impact of epigenetic modifications in the evolution of phenotypes remains as a fundamental yet unresolved question in biology. In particular, the role of epigenetic divergence on the evolution of human brains, which underwent an unparalleled degree of recent evolutionary innovation, may have deep implications for human cognition and neuropsychiatric diseases. Systematic analyses employing

unbiased epigenome-wide methods, and including outgroup species and large panel of individuals are needed to fully understand the role of epigenetic divergence on human brain evolution. Here we report comprehensive identification and analyses of differentially methylated regions (DMRs) in human brains. We used comparative whole genome bisulfite sequencing (WGBS) of human, chimpanzee and rhesus macaque prefrontal cortices (n=8), unbiased non-parametric tests, as well as targeted deep genomic and bisulfite sequencing in an independent panel of 37 individuals across six primate species. We identify 278 DMRs using conservative cutoffs. These DMRs conspicuously co-localize with functional genomic indicators of transcriptional regulation, including chromatin features and transcription factor binding profiles. In particular, we identify many loci annotated as intergenic yet exhibiting conspicuous chromatin signatures of active transcription in brains, indicating that they represent currently unannotated loci of human brain-specific transcription. Remarkably, a large number of DMRs are found in a spatially clustered manner and tend to participate in active chromatin loops, indicating evolutionary remodeling at the higher-order chromatin structure. Analyses of previously generated gene expression and epigenetic data also support a role of DMRs in regulation of transcription. In summary, we identify hundreds of human brain specific DMRs and demonstrate that the unique epigenetic profiles of the human brain are supported in a large number of samples across multiple species. We unravel human brain specific epigenetic changes at regulatory regions that shape gene expression divergence. Substantial reprogramming of the epigenomic landscape appears to contribute to the evolutionary specializations in our brains.

P2065B Exploring the last chromosome: Y-linked sequence variation in the house mouse. *Andrew Morgan*, Fernando Pardo-Manuel de Villena. University of North Carolina, Chapel Hill, NC.

Over 180 million years since their divergence from autosomes, mammalian Y chromosomes have evolved a gene repertoire highly specialized for male reproduction. Y chromosomes are also a valuable tool for population genetics and phylogeny because they are inherited without recombination from a single parent. The Y chromosome of the house mouse (*Mus musculus*) is exceptional in that it is almost entirely euchromatic and has important roles in speciation. However, its complex repetitive structure has hindered analyses by high-throughput sequencing. We sought to fill this gap by performing a systematic survey of Y-linked variation in mouse. We have compiled whole-genome sequencing data for 132 male samples including wild-caught and laboratory representatives of each of the three subspecies of the house mouse (*Mus musculus domesticus*, *M. m. musculus* and *M. m. castaneus*) and transcriptome data from outgroup specices. First, we show that both the short and long arms of the Y chromosome of the three subspecies are differentiated by megabase-sized structural variants. Next we apply several complementary approaches to obtain a catalog of sequence variants in the non-ampliconic portion of the Y chromosome. Using laboratory strains with known pedigree relationships, we estimate the average mutation rate on Y to be $9.1 \pm 1.8 \times 10^{-9}$ per site per generation. Finally we use approximate Bayesian computation to compare patrilineal and matrilineal demographic patterns in wild mice. We find evidence for increased geographic differentiation and reduced effective population size on the Y compared to the mitochondria, and attribute this to the combined effects of background selection and variability in male reproductive success.

P2066C The evolution of sexual dimorphism of recombination rate in house mice. *April Peterson*, Bret Payseur. The University of Wisconsin-Madison, Madison, WI.

Although most studies of genetic diversity assume that the recombination rate is constant, this important parameter varies among individuals. Heterochiasmy, or - the sexual dimorphism in recombination rate - is one of the most striking forms of this variation. The theoretical foundation for recombination rate and heterochiasmy evolution is well established, yet these theoretical models remain largely untested due to a lack of empirical data. We aim to remedy this gap by expanding the range of empirical measurements and developing a framework for interpretation of observed patterns within an evolutionary context. Using an immunohistochemical approach that enables measurement in single oocytes and spermatocytes, we quantify variation across three wild-derived inbred strains of house mice (*Mus musculus*) in the genome-wide recombination rate, the synaptonemal complex length and the position of crossovers. We observe faster evolution in the genomic recombination rate of male house mice and divergence in the synaptonemal complex length across inbred strains. These data represent a subset of a larger panel of divergent inbred strains to be sampled across the murine phylogeny. When complete, these measures of heterochiasmy will enable us to test hypotheses for sex-specific evolution of genome-wide recombination rate.

P2067A Genomic disintegration in woolly mammoths on Wrangel island. *Rebekah L. Rogers*, Montgomery W. Slatkin. University of California, Berkeley, Berkeley, CA.

Woolly mammoths (*Mammuthus primigenius*) populated Siberia, Beringea, and North America during the Pleistocene and early Holocene. Recent breakthroughs in ancient DNA sequencing have allowed for complete genome sequencing for two specimens of woolly mammoths (data from Palkopoulou et al. 2015). One mammoth specimen comes from mainland populations ~40,000 years ago when mammoth populations were robust. The second, a 4300 yr old specimen, is derived from an isolated population on Wrangel island where mammoths formed an isolated population with an effective population size 50-fold smaller than previous populations. These extreme differences in effective population size offer a rare opportunity to test nearly neutral models of genome architecture evolution within a single species. Using these previously published mammoth sequences, we identify deletions, retrogenes, and non-functionalizing point mutations in the genomes of these two specimens. In the Wrangel island mammoth, we identify a larger number of deletions, a larger proportion of deletions affecting gene sequences, and an increased number of premature stop codons. We also identify more retrogenes, consistent with elevated retroelement activity. This accumulation of detrimental mutations is consistent with genomic meltdown in response to low effective population size in the dwindling mammoth populations on Wrangel island, consistent with nearly-neutral theory.

P2068B *Cis*-acting variation in gene expression dynamics within and between *Saccharomyces* species. *Ching-Hua Shih*[1,2], Justin Fay[1,2]. 1) Dept. of Genetics, Washington University in St. Louis, MO; 2) Center for Genome Science and Systems Biology, Washington University, St. Louis, MO.

Variation in *cis*-regulatory sequences has been shown to modulate gene expression levels or developmental patterns. However, temporal control of gene expression may be as important to fitness as steady-state levels. To determine whether *cis*-regulatory sequence variation contributes to gene expression dynamics as well as steady-state levels we measured allele-specific expression within multiple yeast hybrids during the transition from fermentative to respiratory growth.

We found 961-3045 genes with allele-specific differences in expression that changed over time. In comparison, we found 466-863 genes with allele-specific differences in expression either during growth on glucose or ethanol. Using logistic regression, we found that single nucleotide polymorphisms (SNPs) in promoters regions are associated with a 1.02-1.04 odds ratio (OR) of allele specific expression. In contrast, insertions and deletions (InDels) are associated with a 1.11-1.15 OR of allele-specific expression.

We conclude that there is nearly as much *cis*-acting variation that affects temporal changes in gene expression as affects steady-state levels alone. Our observation that InDels have a stronger association than SNPs suggests a difference in how expression levels and dynamics are modulated.

P2069C Degeneration and positive selection of a non-recombining chromosomal inversion underlying behavioral polymorphism in the white-throated sparrow. *D. Sun*[1], I. Huh[1], D. Maney[2], S. Yi[1]. 1) Georgia Institute of Technology, Atlanta, GA; 2) Emory University, Atlanta, GA.

The white-throated sparrow is a common North American songbird with two adult plumage morphs known as white- and tan-striped. The morphs differ in behavior, with white birds exhibiting more aggression and exhibiting less parental care than tan birds during the breeding season. The phenotypic differences are associated with multiple chromosomal inversions in the second chromosome. White birds are heterozygous for the inversions (ZAL2/ZAL2^m), whereas tan birds are homozygous (ZAL2/ZAL2). Tan and white morphs are maintained in relatively equal proportions in the population via a strong disassortative mating (nearly all mating pairs consist of one white and one tan bird). To elucidate the genetic and molecular basis of these fundamental phenotypic differences between the morphs, we compared the whole genome sequences of a rare superwhite bird (ZAL2^m/ZAL2^m) to the reference tan genome (ZAL2/ZAL2). We also incorporated RNA-seq data from a sample of 22 individuals that included tan, white and superwhite birds. Utilizing such rich genomic and transcriptomic resources, we can distinguish genomic scaffolds that reside within and outside the inversions. As expected, F_{ST} analyses indicate little recombination between the ZAL2 and ZAL2^m chromosomes within inversion. The inverted scaffolds are on average 1% divergent at the nucleotide level. Despite such small genetic differences, ZAL2^m scaffolds exhibit signs of degeneration via accumulation of slightly deleterious nonsynonymous substitutions, as expected due to the suppression of recombination. On the other hand, we also found signatures of adaptive evolution in both protein-coding and regulatory regions. Intriguingly, regions that exhibit signs of positive selection in ZAL2 and ZAL2^m chromosomes can be assigned to distinctive functional categories. Positively selected genes in ZAL2 are related to the immune system, whereas those in ZAL2^m are enriched for muscle structure development, locomotion and neuron differentiation. Our study provides new insights into how genetic differentiation can lead to phenotypic divergence in this unique vertebrate model system.

P2070A Enhancer activity of vertebrate ultraconserved elements in fruit flies. *T. Takano-Shimizu*, T. Ohsako, T. Matsuda, M. Tomaru. Kyoto Institute of Technology, Kyoto, Kyoto, JP.

Comparative genomics has identified a large number of non-coding segments that have been highly conserved over hundreds of millions of years of vertebrate evolution. To examine their functions *in vivo*, we generated over 300 Drosophila transgenic lines, each containing a unique human conserved noncoding segment inserted upstream of a core promoter fused to a GAL4 or a QF gene, and then assessed their enhancer activities. We observed reporter GFP expression in one or more tissues of embryos and larvae in all segments tested. Therefore, it is evident that human conserved segments can function as enhancer in Drosophila. Indeed, our assay system is more powerful and effective than the previously described mouse assay, which detected reporter gene expression only in a half of tested segments. What is more, induced GFP expression is biased toward the brain and central nervous system of Drosophila. This result may imply that human conserved segments share some unknown enhancer functions despite lacking sequence homology.

P2071B Divergent patterns of marsupial-eutherian genomic imprinting revealed from RNA-seq analysis in the opossum, *Monodelphis domestica* . *Xu Wang*[1], Kory Douglas[2], John VandeBerg[3], Paul Samollow[2], Andrew Clark[1]. 1) Cornell Univ, Ithaca, NY; 2) Texas A&M Univ, College Station, TX; 3) Southwest Primate Research Center, San Antonio, TX.

Among the ~150-200 imprinted genes identified in mouse and human, only 20 marsupial orthologs have been examined to date, and eight of these were found to be imprinted. Here we ask, what is the marsupial imprinting status for the remaining 130 eutherian imprinted genes, and are there any marsupial-specific imprinted genes? We profiled genome-wide allele-specific expression (RNA-seq), histone modifications (ChIP-seq) and DNA methylation (PyroMark) in fetal brain and extra-embryonic membranes from reciprocal crosses of two opossum lines, providing an unbiased survey of parent-of-origin effects. Among 68 genes known to be imprinted in eutherians (and having an opossum ortholog), 52 were covered with sufficient informative SNPs to score allelic expression. Only three (<6%) were found to be imprinted in opossum, and 48 display biallelic expression, reflecting a striking lack of conservation of imprinting status. We also discovered and validated eight marsupial-specific imprinted genes that are not known to be imprinted in any other species. Surprisingly, three of these are non-coding lincRNA genes with no homology to any eutherian sequences, but they are present and are highly conserved in other marsupial species and non-mammalian

vertebrates including chicken. Three of the rest five protein-coding imprinted genes were paralogous to eutherian genes, resulting from recent gene family expansions in opossum. Mechanistically, our epigenetic profiles confirmed that opossum-specific imprinted genes are regulated in the same way as eutherians by differential promoter methylation, despite the evolutionary fluidity of the imprinting profile. We estimate that opossums imprint only 30-40 genes, or about one-fifth the number imprinted by eutherian mammals. The smaller number and non-overlapping nature of imprinted genes could be due to the primitive placentation and shorter gestation time in marsupials compared to eutherians. Our study provides the first imprinting profile in a marsupial and sheds light on the regulation and evolution of genomic imprinting in mammals.

P2072C Comparative genomics of the *Daphnia pulex* species complex. *Z. Ye*[1], S. Xu[1,2], K. Spitze[1], J. Asselman[3], X. Jiang[1], M. Pfrender[3], M. Lynch[1]. 1) Indiana University, Bloomington, IN; 2) 2Great Lakes Institute for Environmental Research, University of Windsor, Windsor, Ontario, Canada; 3) University of Notre Dame, Notre Dame, Indiana.

Comparison of closely related genotypes from populations with distinct population sizes can help us understand the impact of effective population size on genome evolution. For this purpose, we present a high-quality genome assembly of *Daphnia pulex* (PA42) and perform comparative analysis with the previously sequenced genome of *Daphnia pulex* (TCO) in the same species. PA42 is similar with TCO at the orthologous gene level, with average protein identity 98.8% and more than 60% of orthologous proteins identical. Nonetheless, there is a highly elevated number of genes in the genome annotation of TCO, with ~8,000 excess of the genes being due to inclusion of genes of bacterial origin or inaccurate annotation . This view is supported by the high GC content, lack of introns, and high sequence coverage of these suspicious genes. The reduced effective population size of the source population of TCO relative to that of PA42 makes the comparison of these two genomes an excellent platform to understand the short-term impact of effective population size on eukaryotic genome architecture. Consistent with the view that reduced effective population size can facilitate the fixation of transposable elements (TEs) and newly gained introns, we observe more proliferation of TEs and higher frequency of gained introns in the TCO genome.

P2073A Origin and spead of *de novo* genes in *Drosophila*. *Li Zhao*, David J. Begun. Department of Evolution and Ecology, UC Davis, Davis, CA.

The traditional view of evolutionary mechanism holds that novel functions result from the modification of ancestral functions by natural selection. *De novo* gene origination was considered to be almost impossible until recent studies revealed that genes may arise from ancestrally non-genic sequence. Though such genes have been observed in several species, the dynamics of their origin and subsequent spread within populations remain completely obscure. Here I present results on the abundance, properties, expression genetics, and population dynamics of segregating and fixed *de novo* gene in *Drosophila melanogaster* populations from multiple tissues and developmental stages. These genes appear to derive primarily from ancestral intergenic, unexpressed sequences. Natural selection appears to play a significant role in the spread of these genes. These results reveal a heretofore unappreciated dynamism of gene content.

P2074B Evolution trajectories of snake genes and genomes revealed by comparative analyses of five-pacer viper. *Q. Zhou*. Zhejiang University, Hangzhou, Zhejiang, CN.

Snake's numerous fascinating features distinctive from other tetrapods necessitate a rich history of genome evolution that is still obscure. To address this, we report here the first high-quality genome of a viper, *Deinagkistrodon acutus* and comparative analyses to other species of major snake lineages and lizard. We mapped the evolution trajectories of transposable elements (TEs), developmental genes and sex chromosomes onto the snake phylogeny. Besides the dynamic lineage-specific expansion, many TEs may have been rewired into the regulatory network of brain genes in viper, indicated by the associated expression of TEs and nearby genes restricted to the brain. We characterized signatures of adaptive evolution in olfactory, venom and thermal-sensing genes, and also functional degeneration in genes associated with vision and hearing. Phylogenetic distribution of the degenerating *Hox* and *Tbx* limb-patterning genes support a successive loss of forelimbs then hindlimbs during snake evolution. Finally, we showed snake Z and W sex chromosomes have undergone at least three times of recombination suppression at the ancestor of advanced snakes, with the W chromosomes forming a gradient of degeneration from basal snakes to advanced snakes. These results, together with all the genes identified as undergoing adaptive or degenerative evolution episodes at respective snake lineages forge a framework for our deep understandings into snakes' molecular evolution history.

P2075C The Genomics of Drug Consumption in *Drosophila melanogaster*. *B. Baker*, T. F. C. Mackay. Department of Biological Sciences, Program in Genetics and W. M. Keck Center for Behavioral Biology, North Carolina State University, Raleigh, NC 27695-7614.

Abuse and addiction to psychostimulants like cocaine and methamphetamine present a worldwide health issue. *Drosophila melanogaster* presents a model system to identify genetic and transcriptional networks that underlie variation in effects of drug exposure that can serve as a blueprint for subsequent studies on humans. We have derived an outbred advanced intercross population (AIP) from 37 of the sequenced inbred wild-derived lines of the *Drosophila melanogaster* Genetic Reference Panel (DGRP). The lines are maximally genetically divergent, have minimal residual heterozygosity, are not segregating for common inversions and are not infected with *Wolbachia pipientis*. We assessed voluntary consumption of 4% sucrose, 4% sucrose + 1 μg/μL cocaine and 4% sucrose + 0.3 μg/μL methamphetamine among 11 of the 37 DGRP lines that were parents of the AIP. We found significant variation among the lines, in both sexes, for consumption of both drugs, with estimates of broad sense heritability for cocaine consumption of H^2 = 0.57 (females) and 0.63 (males) and for methamphetamine consumption of H^2 = 0.45 (females) and 0.39 (males). Thus, there is genetic variation in the DGRP lines used to construct the AIP for voluntary drug consumption. Further, several DGRP lines consume over twice as much drug + sucrose as sucrose alone, and this phenomenon is both sex- and drug-specific.

We will present data from extreme quantitative trait locus genome wide association mapping of cocaine and methamphetamine consumption using the AIP.

P2079A Moving beyond the joint-scaling test for line cross analysis: An information-theoretic approach to estimating the composite genetic effects contributing to variation among generation means. *J. P. Demuth*[1], H. Blackmon[2]. 1) University of Texas at Arlington, Arlington, TX; 2) University of Minnesota, Saint Paul, MN.

The pace and direction of evolution in response to selection, drift, and mutation are governed by the genetic architecture that underlies trait variation. Consequently, much of evolutionary theory is predicated on assumptions about whether genes can be considered to act in isolation, or in the context of their genetic background. Evolutionary biologists have disagreed, sometimes heatedly, over which assumptions best describe evolution in nature. Methods for estimating genetic architectures that favor simpler (i.e., additive) models contribute to this debate. Here we address one important source of bias, model selection in line cross analysis (LCA). LCA estimates genetic parameters conditional on the best model chosen from a vast model space using relatively few line means. Current LCA approaches often favor simple models and ignore uncertainty in model choice. To address these issues we introduce Software for Analysis of Genetic Architecture (SAGA), which comprehensively assesses the potential model space, quantifies model selection uncertainty, and uses model weighted averaging to accurately estimate composite genetic effects. Using simulated data and previously published LCA studies, we demonstrate the utility of SAGA to more accurately define the components of complex genetic architectures, and show that traditional approaches have underestimated the importance of epistasis.

P2080B Genetic variation in male attractiveness: it's time to see the forest for the trees. *S. Drobniak*[1], Z. M. Prokop[2]. 1) Jagiellonian University, Krakow, PL; 2) Jagiellonian University, Krakow, PL.

The studies of sexual attractiveness are notoriously univariate. Quantitative genetics has repeatedly emphasized the need for considering multivariate phenotypes, especially if their undelrying traits are involved in genetic correlations of varying sign and magnitude. This bias arises mainly in situations when female preference (which defines the selection gradient acting on attractive male traits) is not aligned with the direction of the dominant axis of genetic variance in the complex of attractive traits.

Here we reiterate the important conclusion about considering full multivariate phenotypes instead of univariate isolated traits. We demosntrate how not accounting properly for a multivariate character of attractiveness traits may significantly bias conclusions that are drawn from studies of sexual selection. We discuss the influence of the number of traits, the imbalance of their attractiveness (i.e. difference between female selection gradients acting on specific traits) and their genetic correlations on the outcome of sexual selection for indirect genetic benefits. We provide also a short review of the existing literature that demonstrates how the published estimates of heritabilities in male attractiveness reflect this bias. Among the published accounts of genetic variance in male attractiveness those obtained using specific, isolated traits have substantially higher heritabilities than genuine attractiveness traits (measured as the female response to male phenotypes). We also review existing studies that publish G-matrices of multiple male attractiveness traits and demonstrate that the heritability of the true multivariate male attractiveness in those trait complexes can be an order of magnitude lower than the observed haritability of isolated characters.

Our results have important implications for the evolutionary genetics of sexual selection. They suggest that in many cases the indirect genetic benefits from mating may be greatly overestimated if one uses only isolated univariate male phenotypes. They also emphasize the need for using truly multivariate assays of male attractiveness, ideally by subjecting males to direct assessment by females, and scoring female responses as the male attractiveness index.

P2081C A comparison of PCR-based and GBS-based methodologies to fine-map anthracnose resistance loci in sorghum. *T. J. Felderhoff*[1], L. M. McIntyre[1], A. Saballos[2], J. W. Olmstead[1], W. Vermerris[1]. 1) University of Florida, Gainesville, FL; 2) Chromatin, Inc, Alachua, FL.

Colletotrichum sublineola is an aggressive fungal pathogen that causes the disease anthracnose in the bioenergy crop sorghum. The resulting leaf blight and stem rot can cause yield reductions of up to 70%. The sorghum acreage in the southeastern U.S. is increasing steadily due to the species' ability to produce high yields under limited inputs. Successful cultivation of sorghum in this region, where *Colletotrichum sublineola* is endemic, is contingent upon anthracnose resistance. We generated a biparental mapping population of 135 F_4 and F_5 sorghum lines to identify anthracnose resistance genes in the highly resistant line 'Bk7'. The population was phenotyped in three Florida environments and genotyped by sequencing (GBS) following a customized filtering procedure that retained informative markers. Two resistance loci were identified - on chromosomes 7 and 9 - using association analysis between the GBS-derived markers and phenotype using Fisher's exact test. Both loci contained multiple candidate resistance genes. Fine mapping of the locus on chromosome 9 was performed on a BC_1S_1 population generated from four sweet sorghum cultivars derived from the sorghum lines 'Bk7' (also used as parent in the abovementioned mapping population) and 'Mer 81-4'. The efficacy of fine-mapping with PCR-based SNP markers was compared to that using GBS. In both instances the size of the resistance locus could be reduced substantially, but the GBS procedure provided much greater resolution, at a substantially higher cost. This case formed the basis for a comparison of the merits of both genotyping methods under a number of different scenarios (population size, marker density, labor cost) to assist in deciding on the most effective genotyping procedure. Supported by the Southeastern Sun Grant Center/USDA-NIFA Award No. 2010-38502-21854, USDA-BRDI Award No. 2011-10006-30358, and US DOE award No. DE-SC0014439.

P2082A An additive genetic model is often not sufficient for predicting individual phenotypes. *S. Forsberg*[1], Ö. Carlborg[1,5], J. Bloom[2], M. Sadhu[2], L. Kruglyak[2,3,4]. 1) Division of Computational Genetics, SLU, Uppsala, SE; 2) Department of Human Genetics, University of California, Los Angeles, Los Angeles, California 90095, USA; 3) Howard Hughes Medical Institute, University of California, Los Angeles, Los Angeles, California 90095, USA; 4) Department of Biological Chemistry, University of California, Los Angeles, California 90095, USA; 5) Division of Computational Genetics, Uppsala University, Uppsala, SE.

Ever since Mendel, genotypetophenotype (GP) mapping has been the defining feature of genetics. The complete GPmap for a trait provides the expected phenotype (genotype value) for all possible combinations of alleles across all genes affecting it. Thus, instead of looking at the effect of every allele averaged across all genetic backgrounds (the marginal effect), the GP-map provides the phenotypic effect of each unique allele combination. If the joint effect of two or more loci departs from simply adding up the marginal effects at each locus, a simple additive model will fall short in predicting the phenotypic effects revealed in the GP-map. Geneticists have for many years debated whether such non-additive patterns are of importance, or if additive models are enough to describe the genetic architecture of a studied trait. The perhaps most important piece of information needed to resolve this debate, i.e. what the true multilocus GPmaps that are modeled actually look like, is however largely missing. Here, we use a large experimental yeast population to perform an extensive, empirical estimation of highorder GP-maps affecting a large number of quantitative traits. Using these as a basis, we illustrate how the estimates obtained from statistical quantitative genetic models will depend on various features of the underlying GPmaps. Specifically, we show that a large additive genetic variance does not necessarily imply that genetic interactions is of little importance, thereby illustrating how variance component analyses can be missleading when making inferences about the genetic architecture of complex traits. We also show how additiveonly genetic models can lead to poor predictions of individual phenotypes.

P2083B Estimation of genetic parameters for growth, yield and carcass quality traits in a fast-growing strain of Atlantic salmon. *J. A. Gallardo*[1], C. J. Soto[2]. 1) Escuela de Ciencias del Mar, Pontificia Universidad Católica de Valparaíso, Valparaíso, CL; 2) Salmones Camanchaca S.A., Puerto Montt, CL.

In this study, the heritability and genetic correlations of the principal productive traits of interest related to growth, yield and carcass quality in a population of domesticated Atlantic salmon (Salmo salar) of Lochy strain were estimated. To do this, 199 families belonging to the company Salmones Camanchaca's breeding program were selected. Salmon were growed in a mariculture center as well as a freshwater fish farm. Regarding the fish farmed at sea, heritabilities of medium and high magnitude were established, for traits associated to growth (0.29 ± 0.04 to 0.43 ± 0.05) and for yield traits when were quantified based on carcass weight (0.39 ± 0.04 to 0.40 ± 0.04). Yield traits in terms of percentage and quality had low heritabilities (0.06 ± 0.01 to 0.02 ± 0.03), except for the color trait of TRIMD fish fillet, which had an average heritability (0.22 ± 0.05). Genetic and phenotypic correlations were high between the main growth and yield traits of ranges 0.79 to 1.0, but low and medium - some even negative -between them and those associated with quality, ranging from 0.13 to -0.69. In the particular case of fish fillet color, this trait should be regarded in the selection criteria, but others traits like gaping or descaling have not suficient genetic variation to be included in the selection criteria.

P2084C Tracing the signature of gene expression across time in *D. melanogaster* artificially selected for long and short sleep duration. *S. T. Harbison*, Y. Lin, Y. Serrano-Negron. National Heart, Lung, & Blood Inst, Bethesda, MD.

Sleep is highly conserved across taxa, and thought to be crucial for life. The suite of genetic factors that contribute to variation in sleep in natural populations, however, remains unknown. We conducted an artificial selection study coupled with RNA-Seq in order to identify gene networks associated with phenotypic changes over time. Using a previously created outbred population of flies constructed from ten *Drosophila* Genetic Reference Panel lines having extreme long and short night sleep duration, we constructed six selection populations. Two populations were designated as short-sleeper populations, two as long-sleeper populations, and two populations served as an unselected control. Each generation, we assayed sleep in each population. We chose the 25% most extreme sleepers as parents for the subsequent generation in the short- and long- sleeper populations; we chose 25% of the flies at random to be parents in the subsequent generation of controls. After 13 generations of selection, night sleep duration in the long-sleeper populations averaged 642.2 ± 3.83 and 667.8 ± 2.97 minutes; 104.3 ± 6.71 and 156.2 ± 8.76 minutes in the short-sleeper populations; and 563.4 ± 7.62 and 542.3 ± 7.91 minutes in the control populations. Night and day average bout length and sleep latency exhibited a correlated response to selection for night sleep across generations, while night and day bout number, day sleep, and waking activity did not. We harvested total RNA from homogenates of 10 flies of each sex per generation and sequenced poly-A selected libraries. We are currently analyzing the sequence data to detect patterns of expression across selection scheme, sex, and generation. Our goal is to detect gene expression networks that are crucial to these phenotypic changes.

P2085A Functional validation of loci contributing to nicotine resistance in *Drosophila*. *C. A. Highfill*, S. K. T. Nguyen, J. Tran, X. Wang, T. R. Moldenhauer, S. J. Macdonald. University of Kansas, Lawrence, KS. 66045.

All species posses detoxification pathways enabling them to respond to environmental toxins. Given the widespread use of pesticides, and the frequent development of resistance to these compounds by crop pests, it is critical to understand the genetic basis of xenobiotic resistance in insects. Previously, we used the *Drosophila* Synthetic Population Resource to map four QTL contributing to resistance to nicotine, a compound employed as a natural insecticide by some plants. RNA-seq showed that both cytochrome P450 genes under QTL1, *Cyp28d1* and *Cyp28d2*, and one of ten UDP-glucuronosyltransferase (Ugt) genes under QTL4, *Ugt86Dd*, were differentially-expressed between susceptible

and resistant strains. Here we carry out RNAi, quantitative complementation tests, overexpression experiments, and mutant analysis to functionally validate the effects of these loci on nicotine resistance, and attempt to identify causative sequence variants. Ubiquitous RNAi knockdown of *Cyp28d1* and *Ugt86Dd*, as well as targeted knockdown in the anterior midgut, reduced nicotine resistance, providing evidence these genes are involved in the phenotype. To determine whether these loci harbor segregating variation influencing resistance we crossed susceptible and resistant strains to a range of deficiencies and insertional mutants. These quantitative complementation tests revealed functional allelic variation at *Cyp28d1* and *Cyp28d2*, and suggested that multiple nicotine resistance factors are present within the QTL4 region, consistent with the idea that several of the Ugt genes are involved. Sequencing the *Ugt86Dd* open reading frame revealed a 22bp coding deletion segregating in our multi-parental mapping panel, with the four most susceptible founder haplotypes at the QTL all harboring the deletion allele. We constructed overexpression genotypes using both *Ugt86Dd* alleles, and found that nicotine resistance is significantly greater following anterior midgut overexpression of the insertion allele compared to the deletion allele, implying the variant has a functional role. To further test the effect of this polymorphism we generated two mixed populations derived from *Drosophila* Genetic Reference Panel; one founded with all seven DGRP strains homozygous for the deletion allele, and one founded with a random seven strains homozygous for the insertion. Flies from the population fixed for the deletion allele were more susceptible for nicotine, supporting the idea that this variant directly contributes to nicotine resistance. We have now successfully generated custom *Ugt86Dd* mutants using the CRISPR-Cas9 system, and future experiments will help elucidate the effect of the locus on nicotine resistance.

P2086B Analyzing the Effects of Naturally Occurring Genetic Variants in the Sphingosine-1-Phosphate Receptor Family. *J. T. Hornick*[1], S. Nguyen[2], P. Benegal[3], Y. I. Kawasawa[1], G. L. Moldovan[1], J. R. Broach[1]. 1) Pennsylvania State University College of Medicine, Hershey, PA 17033; 2) University of Pennsylvania, Philadelphia, PA 19104; 3) Princeton University, Princeton, NJ 08544.

The sphingosine-1-phosphate receptor (S1PR) family has been identified to be critical to a multitude of cellular functions including: cytoskeletal rearrangement, cellular motility and invasion, angiogenesis, immunological processes, and vascular maturation. In addition, the family is ubiquitously expressed throughout cell types. S1P receptors are also clinically relevant, being targeted in multiple sclerosis, cancers and recently COPD. Here we have used multiple model systems to explore how natural variants (SNPs) in human populations affect the sphingosine-1-phosphate (S1P) family of G protein-coupled receptor receptors. Variants rs61734752 (A11D) in the N-terminus of S1PR1 and rs3745268 (R60Q) and rs117064827 (V286A) in transmembrane domains 1 and 7, respectively, of S1PR2 significantly decreased the potency of the natural ligand, S1P. Variant rs35483143 (L318Q), in the C-terminus of S1PR5, disrupts the ability of the receptor to couple to Gα12, one of the two cognate Gα proteins through which the receptor elicits downstream responses. RNA sequencing analysis of transfected HEK293T cells showed decreases in transcripts pertaining to cytoskeletal rearrangement, cell motility, and RhoGEF effector signaling when comparing the variant and wild type receptors. Analysis of F-actin dynamics reveal a substantial decrease in overall F-actin in variant receptor transfected cells. Further analysis of variants is being undertaken to investigate the signaling defects to cellular and developmental homeostasis.

P2087C Integrated Genetic Analysis Platform (IGAP) for Web-based Interactive Association Analysis and Visualization of Large Scale Genotype/Phenotype Data. *G. Jun*. UTHealth School of Public Health, Houston, TX.

Modern genetic association studies require analysis of millions of variants often with hundreds or thousands of phenotypic variables. Association analysis typically involves many steps of human interventions, such as parsing variant annotation, unification of missing data identifier, sample ID matching, identification of population or family structures, stratification of input data according to population or other structural batches, and parsing phenotypic labels for traits of interest and covariates. Genotype and phenotype data are usually provided in human readable formats, but not with strictest format guidelines for automated pipelines. Due to these issues, a significant amount of analysts' time is spent on rectifying input files both for genotypes and phenotypes, and also on visualizing and parsing various quality metrics. These tasks typically require a fair amount of computer programming, and such (often in-house) programs are not being reused widely because every project has a slightly different data structure from each other. It is important to automate these steps, because computing time is cheap, and will get cheaper in the future, while an analyst's time is not. We propose a new web-based interactive pipeline for genetic association analysis, named Integrated Genetic Analysis Platform (IGAP) that provides automated, re-usable framework for large-scale genetic association analysis. IGAP is a web-based front-end environment that provides encapsulation of a collection of external tools and pipelines including PLINK, Merlin, and EPACTS. It accepts and provides easy data conversion tools between common genotype formats (VCF, PLINK and Merlin) from web browser interface, and also parses metadata from VCF file's INFO field to generate functional groups with minimal user interventions. A user can easily visualize population structures using PCA or MDS using back-end tools and data converters, and resulting plot is dynamically loaded onto the web browser. Phenotype data are stored in MySQL database together with meta-data from genotypes, and provides an interactive interface for common tasks such as matching sample IDs and defining subsets of samples for a given project. It invokes association analyses and visualizes results on the web browser. IGAP provides a flexible and easy-to-use interactive environment for various types of genetic analyses.

P2088A Automated tracking and analysis of sleep-like behavior in *Drosophila* larvae. *C. Kim*[1], S. Harbison[1], Q. Gaudry[2]. 1) National Heart Lung and Blood Institute, Bethesda, MD; 2) University of Maryland, College Park, MD.

Sleep is universally conserved among animals and invertebrates, but its purpose remains elusive. Although many studies have provided insights into the genetic architecture of sleep in adult flies, little is known about this behavior in the early developmental stages of the fly. Here we introduce a method based on machine vision to continuously measure kinematic parameters in third instar larvae during the first 4 hours of the dark cycle. We are measuring larvae from the *Drosophila* Genetic Reference Panel (DGRP) in order to associate genetic polymorphisms

with rest and activity correlates. Preliminary results indicate that significant genetic variation among the lines is present for activity and rest measurements. This powerful approach enables the construction of behavioral profiles of individual larvae using high-throughput behavioral screening.

P2089B The genetic basis of the Drosophila IIS pathway response to changing nutrition. *Elizabeth G. King*, Patrick D. Stanley, Anna M. Perinchery, Vincent S. Farinella. University of Missouri, Columbia, MO.

Given a finite amount of resources, a central requirement of all organisms is optimizing the allocation of those resources to competing anatomical structures and physiological functions, which necessitates the coordination of multiple organ systems within the nutritional environment. The insulin/insulin-like growth factor signaling (IIS) pathway is known to influence the coordination of nutrition with metabolism and allocation of nutrients, but little is known about the genetic basis of standing variation in the pathway. Most studies to date of the IIS pathway have followed a "one gene at a time" approach. In this regard, they have been very successful at determining the pathway's role in the regulation of metabolism and resource allocation and of the effects of altering each gene in isolation. In stark contrast to this success, we know little about the genetic basis of *natural* variation in the IIS pathway, metabolism, and resource allocation. We utilize a large multiparental mapping population, the *Drosophila* Synthetic Population Resource to map QTL for transcript levels of the genes encoding the core components of the IIS pathway in three different nutritional environments. We identify the loci responsible for the response of IIS expression in different nutritional conditions and discuss the extent to which different loci control IIS expression in different environmental conditions.

P2090C A decrease in soybean seed protein is associated with an increase in domestication traits. *E. E. Large*, E. Beche, T. La, X. Niu, G. Shannon, A. Scaboo. University of Missouri, Columbia, MO.

Domesticated soybeans (*Glycine max*) are an important source of protein for livestock in the Americas and an increasingly popular food source for humans around the world. Soybeans were originally domesticated 6,000-9,000 years ago in China and share a common ancestor with wild soybeans (*G. soja*). Both species share the same number of chromosomes (2n = 40) and crosses between the two species generate fertile hybrids. The two species exhibit distinct phenotypes with most modern domesticated *G. max* having large yellow seeds with upright plants and most *G. soja* having small black seeds with weedy vines. The past eighty years of soybean breeding in the United States has led to significant increases in yield but at the cost of producing less protein per seed. Furthermore, there is a growing demand to produce soybean seeds with increased cysteine, methionine, and lysine content in order to optimize monogastric animal growth. Eighty *G. soja* soybean lines, representing the broadest possible diversity of wild soybean germplasm, were screened for seed protein and amino acid composition. We identified a handful of elite *G. soja* lines with high seed protein and favorable amino acid profiles. The sixth generation of two populations derived from elite *G. soja* crosses with *G. max* were subsequently evaluated for domestication traits and seed protein. Preliminary results suggest protein content is linked or overlapping with loci controlling soybean domestication. These hybrid populations, therefore, provide clues to locate genetic determinants of protein and amino acid composition in domesticated soybeans.

P2091A The genetic basis of temperature sensitivity in a mutationally induced trait. *Jonathan Lee*[1], Matthew Taylor[1,2], Amy Shen[1], Ian Ehrenreich[1]. 1) University of Southern California, Los Angeles, CA; 2) University of Washington, Seattle, WA.

Determining how genetic variation alters the expression of heritable phenotypes across conditions is important for agriculture, evolution, and medicine. Central to this problem is the concept of genotype-by-environment interaction (or 'GxE'), which occurs when segregating genetic variation causes individuals to show different phenotypic responses to the environment. While many studies have sought to identify individual loci that contribute to GxE, obtaining a deeper understanding of this phenomenon may require defining how sets of loci collectively alter the relationship between genotype, environment, and phenotype. Here, we identify combinations of alleles at seven loci that control how a mutationally induced colony phenotype is expressed across a range of temperatures (21, 30, and 37°C) in a panel of yeast recombinants. We show that five predominant multi-locus genotypes involving the detected loci result in trait expression with varying degrees of temperature sensitivity. In analyzing the genetic basis of GxE in our system, we demonstrate that the involved alleles contribute to temperature sensitivity in different ways. While alleles of the transcription factor *MSS11* specify the potential temperatures at which the trait can occur, alleles at the other loci modify temperature sensitivity within the range established by *MSS11* in a genetic background- and/or temperature-dependent manner. We are now working to characterize how different combinations of these causal alleles modulate temperature sensitivity at the molecular and systems levels. Our goal is to establish a clear portrait of how genetic variation and the environment together alter global gene regulation, thereby resulting in GxE.

P2092B Genome-wide association mapping identifies SNPs influencing the plastic response of lifespan and age-specific fecundity to diet in *Drosophila melanogaster*. *J. Leips*[1], M. Durham[1], E. Stone[2], M. Magwire[2], P. Daya[1]. 1) University of Maryland Baltimore County, Baltimore, MD; 2) Department of Genetics, North Carolina State University, Raleigh, NC.

Many phenotypes exhibit a plastic response to variation in environmental conditions, and genetic variation in this plastic response provides the opportunity for selection to act on plasticity itself. Although genetic variation in plasticity is well documented in many taxa, the genes that regulate plasticity are largely unknown. In this study, we investigated the genetic basis of natural variation in the plastic response of age-specific fecundity and lifespan to changes in dietary protein content using the *Drosophila melanogaster* Genetic Reference Panel. Variation in the plastic response of fecundity to diet was associated with 491 polymorphisms and 292 genes, and variation in the plastic response of lifespan to diet was associated with 29 polymorphisms and 15 genes. We used our data to test predictions of two hypotheses on the genetic

mechanisms of plasticity, the allelic sensitivity hypothesis (the plastic response of traits is regulated by the genes that affect the trait means) and the gene regulation hypothesis (plasticity is regulated by genes that are independent of those contributing to trait variation). We found evidence to support both mechanisms; however, our data suggest that the gene regulation mechanism is the more common mechanism. This decoupling of trait genes from those regulating their plastic response reduces the potential constraints of pleiotropy, facilitating adaptive independent evolution of the trait means and their plastic response to environmental variation.

P2093C A Bayesian approach for the imputation of genotypes on observed markers in complex pedigrees. *D. Leroux*, S. Jasson. MIAT, Université de Toulouse, INRA, Castanet-Tolosan, FR.

We present a method to tackle the challenges posed by the modern genotype data sets in quantitative genetics and allow for quick imputation of parental origin probabilities (POP) in complex populations, for each marker, and given any number of allelic observations.

QTL analysis and genetic cartography software traditionally use parental origin (PO) data on a set of observed markers to perform their computations. This data used to be easily encoded in simple pedigrees such as backcrosses, bi-parental series of selfings, or the like. The most common encoding, introduced by Mapmaker, uses the letters ABHCD to denote PO in populations with two ancestral lines and is the result of a hand-made inference: restricting the data to markers that are homozygous on both ancestors yet distinct, one can immediately derive the PO for any individual in the population. Unfortunately this method doesn't generalize to the multi-parental population designs that are the modern trend. With complex population structures such as multi-parental generalized intercrosses (MAGIC), the allelic observations are often not informative enough to simply derive PO the old way, mainly due to limited polymorphism in regard to the number of ancestral lines.

We present a technique to infer the POP on all individuals in a given pedigree of any size and structure given observations on any subset of individuals. We represent the pedigree as a Bayesian network with discrete variables. Each variable corresponds to an individual in the pedigree and its domain is the Cartesian product of the possible PO and observed alleles (typically SNP data). This paradigm makes full use of all the available information for each individual, including the information from its relatives, to compute the POP. We also provide an algorithm to efficiently compute in amortized linear time the junction tree corresponding to the pedigree, which leads to exact inference on each marker of the PO/allele probabilities by means of simple belief propagation. This algorithm takes into account non-trivial reentrant individuals to compute the proper joint probabilities where required. We finally show how these results can be used in QTL analysis by extracting the POP for the individuals that have also been phenotyped and to genetic cartography by extracting the selection variable of each meiosis in the pedigree to create datasets that can be treated like back-crosses by the cartography software. An implementation of this method is in progress and will be made available soon to the research community.

P2094A Genetic basis of thermal tolerance in *Saccharomyces* species. *Xueying Li*, Ping Liu, Kim Lorenz, Justin Fay. Washington University in St. Louis, St. Louis, MO.

The genetic basis of phenotypic evolution is one of the central questions in evolutionary biology. It still remains unresolved how many mutations underlie species' divergence and what is the distribution of their effect sizes. The challenge of genetic analysis between species lies in their reproductive barriers and besides candidate gene studies, few large-scale, high-resolution studies have characterized the genetic basis of species' differences. Here, we performed two genome-wide screens to systematically dissect the genetic architecture of phenotypic divergence between two yeast species, *S. cerevisiae* and *S. uvarum*. These two species differ in a number of traits, the most prominent of which is thermal tolerance. In the first screen, we transformed a library of *S. cerevisiae* genes into *S. uvarum* and measured their phenotypic effects by competitive growth assays, aiming to identify single genes with independent effects underlying phenotypic divergence. We also carried out a non-complementation screen by crossing the *S. cerevisiae* deletion collection to *S. uvarum*, in order to identify genes with effects that depend on a complete complement of the *S. cerevisiae* genome. Our preliminary results suggest no single genes of large effect underlies the divergence, with the exception of mitochondrial DNA. The results of our interspecific genetic analysis are consistent with a model of multiple changes of small effect and contrast with those of intraspecific genetic analysis.

P2095B Comparison of normalization and differential expression analyses using RNA-Seq data from 726 individual *Drosophila melanogaster*. *Y. Lin*[1], K. Golovnina[2], Z.-X. Chen[2], H. Lee[2], Y. Serrano Negron[1], H. Sultana[2], B. Oliver[2], S. Harbison[1]. 1) National Heart Lung and Blood Institute, Bethesda, MD; 2) National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, MD.

In order to determine whether heritable differences in gene expression could be detected among individual flies, we performed a multi-factor experiment using RNA extracted from 768 flies. We harvested RNA from individual flies using 16 inbred lines from the *Drosophila* Genetic Reference Panel. These flies were reared in three separate biological replicates. The RNA was successfully sequenced for more than 98% of the flies, and the genotype and sex of each sample were verified by using a 'bar code' and Spearman correlation respectively. Application of this verification procedure resulted in 726 sequences remaining for further analysis. To identify the optimal analysis approach for the detection of differential gene expression among genotype, sex, environment, and their interactions, we investigated the effects of three different filtering strategies, eight normalization methods, and two statistical approaches. We assessed differential gene expression among factors and also performed a statistical power analysis using the eight biological replicates per genotype, environment, and sex in our data set. We found that two to five biological replicates were required in order to have adequate statistical power depending upon the factors analyzed. Some common normalization methods, such as Total Count, Quantile and RPKM normalization, did not align the data across samples. Analyses applying the Median, Quantile, and Trimmed Mean of M-values normalization methods were sensitive to the removal or retention of genes with low expression in the data set. The two statistical approaches, a generalized linear model with a negative binomial distribution and an ANOVA

model, yielded strikingly different results. Our favored analysis approach was to normalize the read counts using the *DESeq* method, to apply a generalized linear model assuming a negative binomial distribution using either *edgeR* or *DESeq* software, and to remove genes with very low read counts after the statistical analysis.

P2096C Genetic dissection of variation in sleep using the *Drosophila* Synthetic Population Resource. *S. J. Macdonald*, B. R. Smith. Department of Molecular Biosciences, University of Kansas, Lawrence, KS.

In humans there is considerable genetic variation for the duration and quality of sleep, and studies have implicated a lack of sleep as a risk factor for a range of health problems. *Drosophila*, in addition to being widely employed as a model genetic system to understand fundamental aspects of the control of complex trait variation, is recognized as an important translational model for the study of human health and disease. Flies exhibit a sleep-like state, and similar to mammals show increased rest following a period of sleep deprivation, an age-related decline in the duration of sleep, and reduced rest following exposure to caffeine. Here, we use *Drosophila* to dissect natural variation in sleep, identify loci for future functional testing, and facilitate experimental exploration of the mechanistic basis of variation in sleep. As with all complex, polygenic traits identifying the molecular pathways and causative genes responsible for phenotypic variation is challenging. Thus, we employed a multi-tiered approach, encompassing high-resolution QTL mapping, expression QTL (eQTL) data, and functional validation with RNAi. We initially measured a battery of sleep traits in multiple individuals from each of 600 heterozygous genotypes derived from the *Drosophila* Synthetic Population Resource (DSPR). The DSPR is a large set of multiparental advanced generation intercross lines that facilitates powerful mapping of QTL to small genomic regions. We observed extensive genetic variation in sleep traits in the population, and successfully mapped a number of QTL that collectively explain significant fractions of variation in sleep. Under the assumption that some fraction of phenotypic variation is due to changes in gene regulation, true causative genes implicated by QTL may often additionally segregate for *cis*-eQTL. Merging sleep QTL data with a large *Drosophila* head transcriptome eQTL mapping dataset from the same population allowed us to refine the list of plausible candidate causative sleep loci. This set includes genes with previously characterized effects on sleep (e.g., *timeless*), in addition to novel candidates. Subsequently, we employed adult nervous system specific RNAi to functionally test the effects of several loci, identifying significant effects on sleep following knockdown of the *Dopa decarboxylase* and *dyschronic* genes. The genes we identify are highly likely to harbor causative, regulatory variation contributing to variation in sleep-like phenotypes.

P2097A The genetics of giant sperm in *Drosophila*. *M. Manier*[1], S. Pitnick[2], J. Belote[2], S. Dorus[2]. 1) George Washington University, Washington, DC; 2) Syracuse University, Syracuse, NY.

Spermatozoa are the most morphologically variable cell type among Metazoa, and the *Drosophila* lineage displays the greatest variation in sperm length, ranging from 0.3 mm to 5.8 cm. Available evidence suggests that sperm length in this group is evolving rapidly, driving by postcopulatory sexual selection via sperm competition and cryptic female choice. Longer sperm outcompete shorter sperm and especially in longer female sperm storage organs. To investigate the genetic basis of sperm length in *Drosophila*, we used a QTL sequencing approach that identified ~500 SNPs enriched within or near ~300 protein coding genes. We prioritized candidate genes based on known patterns of expression during spermatogenesis, GO functions, patterns of rapid evolution, and number of SNPs identified within the gene. The effect of candidate gene disruption on sperm length was assessed using GAL4/UAS RNAi or insertion mutation lines. We also characterized allelic variation and differential gene expression for a subset of candidate genes in populations previously selected for long or short sperm.

P2098B *IRF4* haplotype diversity and associations with hair, eye and skin pigmentation in a Brazilian admixed population. *C. T. Mendes-Junior*[1], A. L. E. Pereira[1], N. C. A. Fracasso[2], L. Marcorin[1], G. Debortoli[2], J. D. Massaro[3], A. L. Simões[2], E. A. Donadi[3], E. C. Castelli[4], M. L. G. Oliveira[2]. 1) Universidade de São Paulo (Departamento de Química, FFCLRP-USP), Ribeirão Preto, SP, Brazil; 2) Universidade de São Paulo (Departamento de Genética, FMRP-USP), Ribeirão Preto, SP, Brazil; 3) Universidade de São Paulo (Departamento de Clinica Médica, FMRP-USP), Ribeirão Preto, SP, Brazil; 4) Universidade Estadual Paulista (Departamento de Patologia, FMB-UNESP), Botucatu, SP, Brazil.

The *Interferon Regulatory Factor 4* gene, located at chromosomal region 6p25-p23, encodes a DNA-binding transcription factor, expressed exclusively in immune system cells and melanocytic lineages. The rs12203592 SNP (intron 4) has been associated with presence of freckles, hair, eye and skin color. Functional studies in human and mice melanin-containing cells revealed that this SNP is directly involved in the regulation of *IRF4* expression, suggesting a clear role in melanocyte pigmentation. In spite of these findings, the *IRF4* diversity in admixed populations has not been evaluated so far. In order to verify if other variation sites spread across the *IRF4* gene may be associated with human pigmentation, the regulatory and coding (9 exons and part of their flanking introns) regions were analyzed by next-generation sequencing in a Brazilian admixed population sample. The population sample was composed of 228 unrelated individuals from São Paulo State, which were stratified according to eye (blue, green, hazel, light-brown, and dark-brown), hair (red, blond, dark-blond, light-brown, dark-brown and black) and skin (light, intermediate and dark) pigmentation, as well as regarding the presence of freckles and intensity of hair greying. DNA libraries, including other pigmentation genes, were prepared using the Haloplex Target Enrichment System (Agilent) and sequenced at the MiSeq platform (Illumina). CutAdapt, BWA and GATK packages were used for trimming adaptor sequences, alignment and genotype calling, respectively. Missing alleles and haplotypes were inferred by using the PHASE method. A total of 105 variation sites were identified. Eighteen of these SNPs presented strong association (OR > 10) with at least one pigmentation feature. However, if the Bonferroni correction for multiple tests is taken into account, only two associations, both of them involving the rs12203592 SNP, remain significant: allele T associated with light skin and blue eyes. This result is in agreement with previous reports that the rs12203592*T allele leads to reduced IRF4 activation and reduced tyrosinase expression, leading to sun sensitivity and blue eyes. A total of 101 different haplotypes were inferred. When haplotypes were

subdivided in promoter, coding and 3'UTR haplotypes, 17, 29 and 37 different haplotypes were observed, respectively. Various associations were identified, particularly involving the most frequent promoter haplotype, the two most frequent coding (only one of them with allele rs12203592*T) and the most frequent 3'UTR, all of them with light skin, blue eyes, brown hair and hair greying. These results suggest that other variation sites besides rs12203592, when considered in a haplotype background, are associated with human pigmentation. Financial Support: CAPES, CNPq (309572/20142 and 448242/2014-1) and FAPESP (2013/15447-0).

P2099C Genetic constraints on the learning of a complex song phenotype. *D. G. Mets*, M. S. Brainard. HHMI/Univ California, San Francisco, San Francisco, CA.

Learning reflects the influence of experience on genetically determined circuitry. Both the ways in which experience shapes behavior during learning and the ways in which genetics shape non-learned phenotypes have been widely studied. However, little is known about how experience and genetics interact to determine complex learned phenotypes. Vocal learning in songbirds provides a rich system for investigating experiential and genetic contributions to learning; the output of learning (song) is quantifiable and we can manipulate both the experiential contributions (through computer tutoring) and genetic contributions (through breeding). Here we examine the relationship between experiential and genetic contributions to learning of an ethologically relevant phenotype, the tempo of song production (quantified in syllables produced per second). Distinct genetic lines of the Bengalese finch (*Lonchura striata domesitca)* were bred from parents with different song tempos. When juvenile birds of a given line were tutored with synthetic songs that varied only in tempo, they developed adult songs with tempos that varied with the tutor song. Hence, as expected, the structure of song was shaped by experience. However, when the tempo of the tutor song was held constant, juveniles from different genetic lines developed song tempos that strongly correlated with those of their fathers, even though these juveniles had never heard their fathers sing. Thus, under controlled tutoring conditions, we found an unexpectedly strong genetic contribution to the mean song tempo. We further investigated the interaction between genetics and experience by tutoring several genetic lines (that expressed slow, medium and fast songs) on a set of synthetic songs that differed only in tempo. We again found that, across all lines, tutoring experience influenced song tempo. However, each line learned different amounts of the stimulus tempo, revealing a significant gene by environment interaction (GXE; a non-linear interaction between genetic and experiential contributions to song tempo). Taken together, these findings demonstrate a strong genetic contribution both to the mean tempo of song and to the degree to which tempo is influenced by experience. Our results provide a striking demonstration of how genetics can both shape and constrain the influence of experience on a complex learned phenotype.

P2100A The genetic basis of the coordination of nutrition and energy allocation in a synthetic population of *Drosophila melanogaster*. *E. Ng'oma*, M. A. Reed, W. Fidelis, E. G. King. University of Missouri, Columbia, MO.

Allocation of energy is critical to biological structure and function. Availability of nutrients to support life varies tremendously across time and environments. Given a limited resource pool, organisms allocate differentially to functions such as somatic maintenance, reproduction and storage. This differential allocation has a direct bearing on, for instance, how and why organisms age, why species differ extensively in reproductive output, and is thought to constrain the evolution of fitness. We use a multiparental mapping population to explore the genetic basis of the coordination of allocation with resource availability. We phenotyped a suite of interrelated allocation phenotypes in multiple dietary regimes to uncover a complete picture of the genetic basis of the coordination between resource availability and resource allocation, using the DSPR resource lines. We identify several genomic locations that influence how resources are partitioned differently when resource availability varies. These loci will also serve as focal candidates we will track over time in a future selection experiment for divergent allocation strategies.

P2101B Proteome-wide association studies identify biochemical modules associated with a wing size phenotype in *Drosophila melanogaster*. *H. Okada*, A. Ebhardt, S. Vonesch, R. Aebersold, E. Hafen. Institute of Molecular Systems Biology, ETH Zurich, Zurich, Switzerland.

The manner by which genetic diversity within a population generates individual phenotypes is a fundamental question of biology. To advance the understanding of the genotype-phenotype relationships towards the level of biochemical processes we perform the first proteome-wide association study (PWAS) of a complex quantitative phenotype. We quantify the variation of wing imaginal disc proteomes in *Drosophila* genetic reference panel (DGRP) lines using SWATH mass spectrometry. In spite of the very large genetic variation (1/36 bp) between the lines, proteome variability is surprisingly small, indicating strong molecular resilience of protein expression patterns. Proteins associated with adult wing size form tight co-variation clusters that are enriched in fundamental biochemical processes. Wing size correlates with some basic metabolic functions, positively with glucose metabolism but negatively with mitochondrial respiration and not with ribosome biogenesis. Our study highlights the power of PWAS to filter functional variants from the large genetic variability in natural populations.

P2102C Genetics of skeletal evolution in unusually large mice from Gough Island. *Michelle Parmenter*[1], Melissa Gray[1], Caley Hogan[1], Irene Ford[1], Richard Cuthbert[2], Peter Ryan[3], Karl Broman[1], Christopher Vinyard[4]. 1) University of Wisconsin-Madison, Madison, WI, USA; 2) The Royal Society for the Protection of Birds, The Lodge, Bedfordshire, UK; 3) University of Cape Town, Cape Town, South Africa; 4) Northeast Ohio Medical University, Rootstown, OH, USA.

The letter preceding the number is the community. A, B, C after the number is presentation time.
W – *C. elegans*, C – Ciliates, D – Drosophila, M – Mouse, P – PEQG, Y – Yeast, Z – Zebrafish

Organisms on islands often undergo rapid morphological evolution, providing a platform for understanding mechanisms of phenotypic change. One example is the skeleton, which shows unusual patterns in island populations and forms an integral part of the vertebrate body plan. Although the genetic basis of skeletal variation has been studied extensively in laboratory strains, particularly in the house mouse *Mus musculus domesticus*, the genetic determinants of skeletal evolution in natural populations remain poorly understood. We used house mice living on the remote Gough Island, the heaviest wild house mice on record, to understand the genetics of rapid skeletal evolution in nature. Compared to a mainland reference strain from the same subspecies (WSB/EiJ), the skeleton of Gough Island mice has enlarged considerably. We used X-ray images to measure 16 skeletal dimensions (at 5, 10, and 16 weeks of age) that are designed to capture major changes in skeletal anatomy. Quantitative trait locus (QTL) mapping in a large F_2 intercross between Gough Island mice and WSB/EiJ reveals a total of 198 QTL that control skeletal dimensions. QTL exhibit modest, mostly additive effects and Gough Island alleles are associated with larger skeletal size at most QTL. A large proportion of QTL co-localize across skeletal traits and body weight, an observation that may be explained by a high degree of pleiotropy. Our results provide a rare portrait of the genetic basis of skeletal evolution in an island population, and position the Gough Island mice as a model system for understanding the mechanisms of rapid evolution in nature.

P2103A Validation of candidate anthracnose resistance genes in sorghum via Brome Mosaic Virus-mediated gene silencing. *S. P. Rao*, T. J. Felderhoff, L. Stutts, W. Vermerris. University of Florida, Gainesville, FL.

Sorghum (*Sorghum bicolor* (L.) Moench) is the fifth most widely grown crop in the world and provides food, feed, fuel and fiber in over a hundred countries. Sorghum is an ideal bioenergy crop for the southeastern United States due to its high biomass potential on poor soils with limited inputs. Expansion of sorghum in this region, however, is contingent on resistance to the aggressive fungal pathogen *Colletotrichum sublineolum* (Henn.), the causal agent of anthracnose that can reduce grain, sugar and biomass yield by as much as 70%. We have identified a major anthracnose resistance locus on chromosome 9 using a biparental mapping population derived from the inbred lines Bk7 (resistant) x Early Hegari-Sart (susceptible). The population was genotyped by sequencing and phenotyped in three environments. The locus is 1.2 Mb in size and contains 12 candidate resistance genes. The genetic proof that one or more of these genes are responsible for conferring resistance requires showing that inactivation of the gene in a resistant line results in a susceptible phenotype, or introducing the allele of the resistant parent in a susceptible line and demonstrating acquisition of resistance. As few sorghum lines are amenable to transformation, and genome editing is not yet feasible, the best alternative is virus-induced gene silencing (VIGS) of candidate resistance genes with the help of the tripartite Brome Mosaic Virus (BMV). We are in the process of cloning short fragments of cDNA in one of the viral sequences and will generate infectious RNA transcripts through *in vitro* transcription. Three-week old resistant sorghum seedlings will be inoculated with a mixture of transcripts. Two weeks post viral inoculation, the plants will be challenged with *Colletotrichum* conidia to assess the effect of different constructs on host-pathogen interaction. Elucidating the identity of the resistance gene(s) will facilitate the breeding of disease-resistant sorghums, and provide information on the mechanism of disease resistance. Supported by USDA-BRDI Award No. 2011-10006-30358 and US DOE award No. DE-SC0014439.

P2104B Species diversity and sexual dimorphism of ethanol sensitivity in Drosophila. *M. H. Reich*, R. M. Graze. Auburn University, Auburn, AL.

Drosophila is a key model system in the genetics of ethanol sensitivity and tolerance. Ethanol sensitivity is defined as the overall sensitivity to the effects of ethanol exposure, ultimately resulting in sedation. Tolerance occurs when sensitivity is reduced after one or more initial ethanol exposure/s. Molecular studies have identified genes involved in sensitivity and tolerance in *Drosophila melanogaster*, with the aim of understanding their role in alcoholism and alcohol related diseases. However, ethanol is an important abiotic factor for many species of Drosophila and ethanol sensitivity and tolerance vary across the genus. In some species, including in *D. melanogaster*, the response to ethanol is also sexually dimorphic. Ethanol sensitivity and tolerance have not been assayed for all the currently sequenced Drosophila species in both males and females, and little is known about how sexual dimorphism in sensitivity or tolerance differs across species. Here we report the results of systematic sedation assays for sensitivity and tolerance in males and females across a diverse group of sequenced species of Drosophila. These experiments place diversity of ethanol sensitivity and tolerance, including sexual dimorphism, in a phylogenetic context. This will allow for a more complete understanding of how phenotypic diversity in the ethanol response is related to differences in the regulatory response to ethanol, in each sex.

P2105C Is genetic architecture predictable? Modeling the roles of mutation, recombination and selective forces in shaping allelic variation. *D. L. Remington*, M. Augustinovic. University of North Carolina at Greensboro, Greensboro, NC.

Research over the last few decades has led to contradictory insights on the genetic architecture and evolution of quantitative traits. Thus, key questions about the relevance of large-effect genes identified in some studies for understanding adaptation and evolution are yet to be resolved. To address these issues, models of quantitative trait variation need to incorporate the contribution of mutations at multiple sites within genes and the potential for recombination between these sites. In addition, predictable patterns of genetic architecture may be specific to particular combinations of evolutionary forces. We are using quantitative genetic simulations to test whether evolutionary genetic models incorporating different modes of selection can explain discordant results from different study systems. In contrast with other modeling efforts, we incorporate both the cumulative effects of multiple mutations in the same gene and realistic rates of intragenic recombination in our simulations. Preliminary results suggest that sharply contrasting genetic architectures may arise in a single population under stabilizing selection versus populations under divergent selection for contrasting phenotypic optima. Unlike the highly polygenic architecture generated

under stabilizing selection, divergent alleles at only a few loci soon come to explain most of the differentiation between populations under scenarios examined so far. However, large allelic effects tend to arise from the cumulative effect of many mutations in multiple potentially-recombining segments of the same locus. These results appear to support previous suggestions that micromutational models and differentiation at large-effect loci are not mutually exclusive. We discuss extension of our modeling to test whether "stepping stone" differentiation along environmental gradients produces similar or different patterns, and address insights into the roles of preexisting variation vs. novel mutations in adaptive divergence.

P2106A Virulence QTLs and Genome-wide Recombination Rates in *Cryptococcus*. *Cullen Roth*[1], Sheng Sun[2], R. Blake Billmyre[2], Joseph Heitman[2], Paul M. Magwene[1,3]. 1) University Program in Genetics and Genomics, Duke University, Durham, NC; 2) Department of Molecular Genetics and Microbiology, Duke University, Durham, NC; 3) Department of Biology, Duke University, Durham, NC.

Cryptococcal disease is estimated to affect 1 million people and kill approximately 600,000 annually. Environmental isolates of *Cryptococcus neoformans*, and its relative *Cryptococcus deneoformans*, vary in their pathogenicity, ranging from benign to hyper-virulent. Key traits that contribute to virulence, such as the ability to grow at human body temperature (37°C), have been identified. However, little is known about the genetic basis of this phenotypic variation. Here we investigate the genetic basis of virulence-related traits using quantitative trait locus (QTL) mapping in *C. deneoformans*. We crossed strains of two different genetic backgrounds (approximately 5 SNPs/kb), generated haploid segregants via bisexual and unisexual mating, and obtained genotypes for 100 segregants using short-read sequencing. We inferred recombination breakpoints using SNP genotype data and calculated a genome wide average recombination frequency of ~7 kb/cM. Five virulence related traits were phenotyped: high temperature growth (at 39°, 40°, 41°, and 42°C), growth at high pH, melanin production, amphotericin B resistance, and fluconazole resistance. We used a marker regression framework to identify QTL underlying variation in these virulence phenotypes. QTLs with major effects were identified for high temperature growth (chromosomes 2 and 12), amphotericin B resistance (chromosome 2), and fluconazole resistance (chromosome 2 and 7). Interestingly, we observed several candidate pleiotropic QTLs, one is located on chromosome 2 and appears to mediate both high temperature growth and amphotericin B resistance, and another is located on chromosome 12 and plays a role in both high temperature growth and melanin production. These results provide novel genome wide estimates of recombination and advance our understanding of the genetic basis underlying virulence in *Cryptococcus*.

P2107B Natural variation in behavior: finding the causal genes in *Drosophila*. *Thomas L. Turner*, Alison Pischedda, Veronica A. Cochrane, Jackson Runte, Wesley G. Cochrane. University of California, Santa Barbara, CA.

We are interested in understanding natural variation in behavior at the genetic and neurological levels. Male courtship behavior in *Drosophila* is a model system for connecting genes, brain, and behavior using molecular genetics, but little is known about how these behaviors vary or evolve. We used a multi-parent panel of recombinant inbred lines to map natural variation in a key parameter of the Drosophila courtship song (inter-pulse interval), and found several loci that explain modest fractions of song variation. The challenge for this and similar studies is then to map these QTL to the gene level for behaviors which don't have obvious candidate genes. We are using a two-step approach. First, we use visible markers to select for recombination in intervals of arbitrarily small size. Benign fluorescent markers can be inserted anywhere in the genome with CRISPR, making this a powerful approach. Second, once we have mapped a QTL to a potentially causal gene, we are using the reciprocal hemizygosity test to validate that gene and quantitatively estimate its effect on our trait. These fine-mapping and validation steps should have broad applicability in other systems and for validating candidate genes from all genome-wide methods.

P2108C Investigating mitochondrial and viral genome contributions to phenotype in *Saccharomyces cerevisiae*. *Sriram Vijayraghavan*[1], Pooja Strope[1], Daniel Skelly[2], Fred Dietrich[1], Paul Magwene[2], John McCusker[1]. 1) Department of Molecular Genetics and Microbiology, Duke University Medical Center, Durham, NC; 2) Department of Biology, Duke University, Durham, NC.

Determining how genotype translates to phenotype is a complex issue. While rapid progress has been made in linking nuclear genome variations to population traits, much less is known about whether and how extra-chromosomal elements shape phenotypic changes. Using the yeast *Saccharomyces cerevisiae* as our model, we analyzed the phenotypic contributions from two classes of non-chromosomal elements—mitochondrial DNA and endogenous double-stranded RNA viruses. *S. cerevisiae* shares highly conserved cellular processes with humans, is ideally suited for Mendelian as well as non-Mendelian genetics, and is markedly similar to clinically relevant pathogenic fungi, making it ideal for our studies.

Through a comprehensive sequence analysis of mitochondrial DNA from 100 geographically diverse strains of *S. cerevisiae*, we firstly identified a wide range of mitochondrial DNA-associated variations including copy number changes, single nucleotide polymorphisms, indels, and presence/absence of introns within select mitochondrial genes. Subsequently, we created a series of iso(genic)-nuclear diploid strains, each carrying a single, unique mitochondrial genotype, and tested these under diverse environmental conditions to systematically assess the contribution of individual mitochondrial genomes to phenotype. Our results indicate that mitochondrial variations significantly influence phenotypic outcome.

Additionally, we genotyped our 100-genome collection for the presence and absence of several naturally occurring viral dsRNA elements and found that up to a third of the population harbors the well-characterized dsRNA virus L-A. We observed pronounced L-A dependent phenotypic effects in our analysis of isogenic +/- L-A strain pairs. Interestingly, both mitochondrial and L-A genotypes were found to significantly influence several phenotypes, further underscoring the contributions of non-chromosomal genetic determinants to quantitative trait variations.

Our studies highlight the complexity of gene-environment interactions that ultimately determine fitness and survival. Future work would be aimed at identification of the precise genetic loci to understand the mechanistic basis of such phenotypic changes.

P2109A Quantitative genetics of skeletal traits in BXD recombinant inbred strain mice. *K. A. Warncke*[1], M. Guo[1], M. Henry[1], D. Alleyne[1,2], J. P. Kenney-Hunt[1]. 1) Westminster College, Fulton, MO; 2) University of Chicago, Chicago, IL.

The BXD recombinant inbred (RI) strain mice are well-characterized with a wide variety of published metabolic and skeletal phenotypes, as well as gene expression data. We perform a quantitative genetic analysis of femur, tibia, humerus, and ulna lengths in a set of 850 BXD mice of both sexes. Quantitative trait loci (QTL) and strain-by-sex interactions are identified for these traits. We also assess association between these identified QTL and published BXD QTL with effects on other skeletal traits. Additionally, we compare the genetic architecture of long bone traits in the BXD RI strains to the genetic architecture of these traits in other murine crosses to investigate intraspecies variation in genetic effects.

P2110B Hybrid male sterility in genetically diverse mice. *S. J. Widmayer*, C. D. McKenney, D. L. Aylor. Program in Genetics, North Carolina State University, Raleigh, NC.

Hybrid male sterility is frequently observed in the wild between two mouse subspecies – *Mus musculus musculus* and *M. musculus domesticus*. This complex trait drives reproductive isolation and ultimately speciation. We have replicated hybrid male sterility in the lab by crossing an inbred mouse strain representing *musculus*, PWK/PhJ, to four strains that are largely descended from *domesticus* (*Dom*). Hybrid males with PWK mothers exhibit a wide spectrum of abnormal reproductive phenotypic variation including reduced testes weights and azoospermia. Importantly, the reciprocal hybrids are reproductively normal and serve as experimental controls in this breeding scheme. We characterized reproductive phenotypes across a panel of 10 genetically distinct hybrid males at 8 weeks of age. PWKx*Dom* hybrid males exhibit significantly lower testis weight and sperm density than reciprocal hybrids. Additionally, we observe significant differences that are driven by the genetic background of each specific hybrid. For example, PWKxA/J F1 hybrid males and PWKxDBA/2J F1 hybrid males differ substantially in sperm count and relative combined testes weight despite sharing known sterility alleles. These findings suggest that unknown hybrid male sterility alleles segregate both between and within mouse subspecies.

P2111C Quantitative studies on gene-environment interaction in hitchhiking behavior of *C. elegans*. *H. Yang*[1], D. Lee[1], H. Kim[2], Y. Paik[2], E. Andersen[3], J. Lee[1]. 1) Seoul National University, Seoul, Korea; 2) Yonsei University, Seoul, Korea; 3) Northwestern University, Evanston, Illinois, United States of America.

Nictation is a dauer-specific hitchhiking behavior of *Caenorhabditis elegans*, which helps dauers to get on to other animals passing by. Nictation is only recently studied and little is known about the genetic and environmental factors related to this behavior. Here we show that several environmental factors including wind and temperature can affect nictation. We investigated how different isotypes respond to these environmental conditions. We are now screening QTL(s) that regulate variation in reaction norm of nictation behavior. We expect our study will help us to understand how gene-environment interactions regulate behavior.

P2112A Spatial and ecological determinants of genotype-by-environment interaction. *Rong-Cai Yang*[1,2], Chen Ding[1]. 1) University of Alberta, Edmonton, Alberta, CA; 2) Alberta Agriculture and Forestry, Edmonton, Alberta, CA.

Genotype-by-environment interaction (GxE) remains to be a major issue in plant and animal breeding as well as in evolutionary biology. Over the past decades, voluminous GxE literature has focused on the development of statistical methods to describe rather than to predict the GxE variability. In this presentation, we will describe a new geostatistical method to predict the GxE variability based on spatial and ecological variables that are easily available or derivable from the geography of environments and/or the origin of genotypes. The method will be illustrated using empirical data from a set of barley breeding trials and a set of pine provenance trials in western Canada.

P2113B Natural variation in sensitivity of rhabditid nematodes to microsporidia. *G. ZHANG*, M.-A. FELIX, C. DUBOIS. ECOLE NORMALE SUPERIEURE DE PARIS, PARIS, FR.

The nematode *Caenorhabditis elegans* is a powerful model for the study of host-pathogen interactions and their co-evolution. The microsporidian *Nematocida parisii* was the first characterized intracellular pathogen of *C. elegans* (Troemel et al. 2008). *N. parisii* proliferates in *C. elegans* intestinal cells and is transmitted horizontally through spores. By sampling rhabditid nematodes worldwide, we found ten new microsporidia species in 9 rhabditid nematode species. We tested the host range of these microsporidia species and measured intraspecific variation in sensitivity of the host. We further plan to detect genetic loci underlying this observed intraspecific variation in host sensitivity, using Quantitative Trait Locus (QTL) mapping.

Specificities of infection of seven nematode-infecting microsporidia were tested on four nematode species (*C. elegans*, *C. briggsae, Oscheius tipulae* and *O*. sp. 3). *N. parisii, N*. sp. 2 only infect *Caenorhabditis,* but not *O. tipulae* or *O*. sp. 3. To the infection of *N.* sp. 1, *Caenorhabditis* are more sensitive than *Oscheius*. *N*. sp. 3 infects both *Caenorhabditis* and *Oscheius* species. Microsporidia JUm408 and JUm1505 infect *Oscheius* spp., but not *Caenorhabditis*. Microsporidia JUm2551 infects both *Oscheius* species, JUm408 only infects *Oscheius* sp. 3, JUm1505 only infects *O. tipulae*.

Variation in sensitivity of ten wild *C. elegans* strains to *N.* sp. 1 infection was revealed by food consumption tests using GFP-labeled *E. coli* in the presence or absence of microsporidia, complemented by progeny production and longevity assays on a subset of these strains. For genetic

studies, we then chose JU2825 as the sensitive strain and JU1249 as the resistant strain. We started to map the genetic loci underlying their difference in sensitivity to *N*. sp. 1. We plan to generate bulk segregating populations after crossing them (Test group); in parallel, we have a Control group where we mixed JU2825 and JU1249 without crossing them (they reproduce by selfing). We will treat both groups with or without *N*. sp. 1. By following allelic proportions in the Control (uncrossed) group using pyro-sequencing of SNPs between the two strains, we can monitor the increase in frequency of JU1249 in the presence of microsporidia and determine when it approaches 100% in the population. Then the infected population in the Test (crossed) group should have recovered large numbers or progeny with beneficial alleles linked to relevant loci. We will pool-sequence each of the test populations and analyze the data for significant shifts in allele proportions along the genome of the infected versus uninfected populations, thus potentially revealing quantitative trait loci affecting sensitivity to *N.* sp. 1.

P2114C Genetic basis of octanoic acid resistance in *Drosophila sechellia*: functional analysis of a fine-mapped region. *J. D. Coolon*[1], J. M. Andrade-Lopez[2], S. M. Lanno[1], S. J. E. Shimshak[1], L. A. Sligar[2], P. J. Wittkopp[2]. 1) Wesleyan University, Middletown, CT; 2) University of Michigan, Ann Arbor, MI.

Drosophila sechellia is a species of fruit fly endemic to the Seychelles islands. Unlike its generalist sister species (*D. simulans*, *D. mauritiana,* and *D. melanogaster*), *D. sechellia* has evolved to specialize on a single host plant, *Morinda citrifolia*. Specialization on *M. citrifolia* is interesting because the fruit of the plant contains secondary defense compounds, primarily octanoic acid (OA), that are lethal to all other *Drosophila* species. Although ecological and behavioral adaptations to this toxic fruit are known, the genetic bases for evolutionary changes in OA resistance are not. Prior work showed that a genomic region on chromosome 3R containing 18 genes has the greatest contribution to differences in OA resistance between *D. sechellia* and *D. simulans*. To determine which gene(s) in this region might be involved in the evolutionary change in OA resistance, we knocked-down expression of each gene in this genomic region in *D. melanogaster* with RNA interference (RNAi) (i) ubiquitously throughout development, (ii) during only the adult stage, and (iii) within specific tissues. We identified three neighboring genes that decreased OA resistance when ubiquitously knocked-down. Tissue specific RNAi, however, showed that decreasing expression of two of these genes specifically in the fat body and salivary glands increases OA resistance demonstrating how specific changes in gene expression can differ from a global change in expression levels. Both genes have derived expression levels in *D. sechellia* and no changes in protein sequence suggesting differences in *cis*-regulation contribute to host specialization in *D. sechellia*.

P2115A A preliminary examination of genetic diversity in mantled howler monkeys (*Alouatta palliata)* in a fragmented forest in Costa Rica. *Marie-dominique Franco*[1], Amy Schreier[1], Matthew Barton[1], Nathaniel Pryor[1], Nancy Barrickman[2]. 1) Regis University, Denver, CO; 2) Salt Lake Community College, Salt Lake City, UT.

In most primates, one sex disperses from their natal group to reduce inbreeding. Habitat fragmentation may limit primates' dispersal opportunities, however, which has implications for species survival. We examined the influence of fragmentation on genetic diversity in wild mantled howler monkeys (*Alouatta palliata*) at La Suerte, Costa Rica. The La Suerte region has seen increased fragmentation over the past decade as forest has been cleared for fruit plantations. We hypothesized that genetic diversity would be lowest in the forest edges compared to the interior because fragment boundaries restrict dispersal opportunities for edge groups. In summer 2015 we collected 96 fecal samples from the howler population and selected 20 samples each from the interior and the edge of the forest, respectively, using GIS locations of sample collection sites. To examine DNA polymorphism, we isolated DNA from these samples and used two primer sets to perform PCR amplifications of selected microsatellite loci (Apm01 and Ab06). Analysis of the amplified fragments was carried out using BigDye Terminator v3.1 sequencing and run on ABI 3730xl instrumentation. We recorded observed (Ho) and expected (He) heterozygosity values under Hardy-Weinberg equilibrium and derived F-statistics indices (F_{IS}, F_{ST} and F_{IT}) to quantify genetic variation in the sub-populations (interior vs. edge). We subsequently assessed the genetic health of the howler monkeys using these indices. Our results show that genetic diversity is highest at the edges of the forest and lowest in the interior. The inbreeding coefficient for the edge population was F_{IS} = 0.45 and for the interior population F_{IS} = 0.58, suggesting inbreeding is occurring in the interior of the forest. In addition, the overall inbreeding coefficient was F_{IT} = 0.52, suggesting that the howler population as a whole is inbred. Overall, our results suggest that howler monkeys may be dispersing across open areas into neighboring fragments. These results may, however, be an artifact of our limited sample size. We therefore intend to analyze all samples collected in summer 2015 and those that will be collected in summer 2016. The results we present here are the initial stage of what we anticipate will become a long-term project examining the influence of habitat fragmentation on dispersal and genetic diversity in wild mantled howler monkeys.

P2116B Population genetics of the monarch butterfly, *Danaus plexippus*, in Mexico. *F. Pérez-Gálvez*[1], C. Chavez Mora[1], M. Ramirez Loustalot Laclette[1], E. Rendón-Salinas[2], E. Pfeiler[3], T. Markow[1,4]. 1) LANGEBIO-CINVESTAV, Irapuato, Mexico; 2) WWF-Mexico, Michoacan, Mexico; 3) CIAD Unidad Guaymas, Mexico; 4) University of California, San Diego, CA.

Population genetic variation and demographic history in migratory monarch butterflies, *Danaus p. plexippus* (L.), from four overwintering sites within the Monarch Butterfly Biosphere Reserve in central Mexico were assessed based on analyses of mitochondrial cytochrome *c* oxidase subunit I (COI) and subunit II (COII) gene segments in a total sample size of just under 100 individuals. Overall, haplotype (h) and nucleotide (π) diversities were relatively low, averaging 0.42 and 0.0006, respectively, in COI, and 0.63 and 0.0024 in COII. Analysis of molecular variance (AMOVA) of the concatenated COI and COII data set (n = 89; 1161 bp) indicated no significant population structure among the four sites. Estimates of demographic history based on the mismatch distribution and Bayesian skyline analyses of the concatenated

Mexican data set showed a population expansion dating to the late Pleistocene (~35,000 to 40,000 years before present), and then a stable and current effective female population size (N_{ef}) of just under 10 million.

P2117C A Second Coming of sechellia: Parallel Adaptation to a Toxic Fruit in *Drosophila yakuba*. *John Pool*[1], Amir Yassin[1], Vincent Debat[2], Héloïse Bastide[1], Nelly Gidaszewski[2], Jean David[2,3]. 1) University of Wisconsin - Madison, Madison, WI; 2) Muséum National d'Histoire Naturelle, Paris, France; 3) Centre National de la Recherche Scientifique (CNRS), Gif-sur-Yvette, France.

Among the *Drosophila* species of the melanogaster subgroup, the island endemic *D. sechellia* is unique for its specialization on noni fruit (*Morinda citrifolia*), which is toxic to related species, making it a renown system for the genetics of detoxification and ecological and diet shift. We recently discovered a second, younger case of *Morinda* specialization in the same clade, involving a unique population of *D. yakuba* from the island of Mayotte. *D. yakuba* was found exclusively amongst *Morinda* on this island, and it shows greatly increased preference and tolerance for the fruit compared with mainland populations. Partial prezygotic isolation is also present, in that island females strongly discriminate against mainland males. Based on a population genomic analysis, these traits have evolved within the past ~30,000 years. Therefore, genetic variation may still hold signals of natural selection at causative genes, providing a major advantage of this system. Using a new F_{ST}-based statistic called *Population Branch Excess* (*PBE*), we identified notable outliers for high genetic divergence in the island population, including several loci with known detoxification genes. We tested for an association between our *D. yakuba* outliers and *D. sechellia* trait mapping intervals, finding a significant enrichment for tolerance loci but not attraction to *Morinda*. Thus, some of the same genes may have contributed to *Morinda* specialization in these two species, reflecting a shared genetic tool kit for detoxification. The existence of a young specialist population of *D. yakuba* will provide noteworthy opportunities to study the genetics of ecological shift, reproductive isolation, and parallel evolution.

P2118A Genetic and environmental components of phenotypic and behavioral trait variation during lake sturgeon (*Acipenser fulvescens*) early ontogeny. *K. T. Scribner*, K. Dammerman, J. P. Steibel. Michigan State University, East Lansing, MI.

Quantifying the relative contributions of genetic and environmental effects and their interaction on phenotypic variation is vital to understand how populations respond to their environment. Adults can plastically respond to environmental conditions by selecting breeding and egg incubation locations that affect offspring traits during embryonic and larval development. Environmental conditions during incubation can also affect traits during later ontogenetic stages (i.e. ontogenetic contingency). Using a population of lake sturgeon (*Acipenser fulvescens*) from Black Lake, Michigan, we conducted field and common garden studies and evaluated whether larval phenotypes and behavior at different ontogenetic stages would vary among families whose eggs were incubated under different thermal and flow regimes in the laboratory, and associated with different micro-habitat conditions in river substrates in the field. A significant family-by-treatment interaction was detected for traits (body length, body area, head area) measured at hatch associated with different flow (high, medium, low) and temperature (10^{o}C, 18^{o}C, variable, ambient) treatments. The greatest range in phenotypic variance was observed among individuals reared in the most environmentally deviant conditions (warm temperature and high flow treatments). Traits measured at hatch from eggs in the stream varied due to the influences of stream micro-habitat variables, while levels of additive genetic variance covaried with age. Results demonstrate that phenotypic variation across sequential ontogenetic stages is dependent on physical stream conditions and additive genetic effects, although the relative contributions of effects differ across ontogenetic stages. Increasingly deviant environmental regimes may reveal cryptic genetic variation, potentially leading to differential survival between genotypes, thereby altering the genetic architecture of populations.

P2119B Quantification of behavioral and heritability correlates in prairie voles, a socially monogamous rodent. *Andrea Vogel*[1,2], Lisa McGraw[1]. 1) North Carolina State University, Raleigh, NC; 2) W.M. Keck Center for Behavioral Biology, Raleigh, NC.

Prairie voles (*Microtus ochrogaster*) are among the rare mammal species that have monogamous relationships and have become a model system for understanding the neurogenetic basis of social behaviors such as biparental care of young and pair bonding. Studying the strength of the pair-bond can inform researchers about complex mental health disorders with social components, such as autism, schizophrenia, depression, and anxiety. Although many prairie voles are monogamous, others will engage in extra-pair copulations, and many never form pair bonds at all. To begin to gain an understanding of the genetic basis for behavioral variation in this species, we examined socially-relevant behaviors including anxiety, alloparental care, and aggression against same-sex intruders. Furthermore, pair-bonding is hypothesized to create behavioral changes in the animals, so we examined these behaviors both before and after mating. We have determined that the related behaviors are not correlated with the amount of time spent with a partner, nor are any of the behaviors highly heritable. This experiment establishes the scope of individual variation of pair-bonding, which will be explored in more depth using neurobiology and genetic techniques.

P2120C Post-mating transcriptome profiles of *Drosophila novamexicana* females after con- and heterospecific copulation. *Y. Ahmed*, A. Clark. Cornell University, Ithaca, NY.

Post-copulatory sexual selection is a potent evolutionary force that can cause rapid divergence of reproductive proteins between closely related species. In many animal taxa, including *Drosophila*, several species are reproductively isolated exclusivley by strong gametic incompatibilities, which result in reduced fertilization in heterospecific copulations. One such species pair are the closely related *D. americana* and *D. novamexicana*, two members of the virilis group that show strong gametic incompatibilitiy when crossed in the lab, especially when *D. americana* males mate with *D. novamexicana* females (~1% fertilization). We are actively expoliting this system to better understand the genetic and molecular basis of post-copulatory sexual selection, in particular the role female proteins play in male-female gametic

interactions. Here we examine mating-induced transcriptome changes in *D. novamexicana* females after mating. In particular, we compare the regulatory response across three tissues (lower reproductive tranct, ovaires, and head) and between conspecific and heterospecific inseminations at several time-points post-insemination. The majority of transcripts that are affected by mating are shared between conspecific and heterospecific matings, but a subset are either uniquely responsive in either the conspecific or the heterospecific cross. We find that several Gene Ontology (GO) terms are enriched among mating-responsive genes, including proteolysis, immune response and proteasome degradation. We also find that several male-specific genes (both from the accessory glands and testes) show increases in abundance in the female reproductive tract after mating. These preliminary results suggest that mating and/or copulation trigger a coordinated regulatory response that can be disrupted when copulation occurs between species, and that the transfer of male RNAs during mating might have a functional consequence.

P2121A Population genetics models with selection for phylogenetic inference. *Jeremy Beaulieu*, Cedric Landerer, Russell Zaretzki, Michael Gilchrist, Brian O'Meara. University of Tennessee, Knoxville, TN.

Models used for phylogenetic inference typically ignore mutation, drift, and selection processes when analyzing protein-coding sequences, and thus try to fit the pattern with parameters that are not entirely based on population genetics. In other words, they do not allow different proteins to have different sensitivities to protein structure, incorporate gene expression levels, and/or strengths of selection. We develop a population genetics based model that uses biological parameters, such as energy cost of protein production, physical properties of amino acids, and levels of gene expression, to create more realistic models for DNA substitution for protein-coding genes. Our new model, which we refer to as SELAC (SELection on Amino acids and/or Codons), specifically infers the strength of selection on codon usage and amino acid sequence, sensitivity of protein function to different amino acid properties such as size and polarity, and mutation rates when inferring phylogenetic relationships among taxa. We use a rigorous simulation approach to show that our model can detect meaningful differences in the model parameters across genes under a variety of many different scenarios, including those that naturally violate the assumptions made by SELAC. We will also present preliminary phylogenetic analyses of several empirical genomic data sets for clades that represent different parts of the tree of life, which all show a dramatic improvement in model fit compared to traditional models. Our model also provides better estimates of the underlying branch lengths in the phylogeny, and can better predict empirical sequences, an indication of its overall adequacy.

P2122B A reverse ecology approach to understand the proximate and ultimate causes of phenotypic divergence during species formation. *C. Eberlein*, L. Nielly-Thibault, J.-B. Leducq, G. Charron, H. Maaroufi, C. R. Landry. Université Laval, Quebec City, Canada.

Research on species formation and adaptive divergence aims at identifying the proximate and ultimate causes of phenotypic differentiation, which involves complex interactions between genes and the environment. We used a reverse ecology approach to investigate the molecular bases of an on-going speciation event in the budding yeast *Saccharomyces paradoxus* in the North American deciduous forests. We applied whole-genome sequencing to identify candidate genes under positive selection and high-throughput phenotyping to determine the conditions into which these genes may play a role. We confirmed the fitness effect of protein divergence at candidate loci through direct allelic competition assays. This comprehensive approach allowed us to gain insights in the complex network of genes and environmental factors that may have shaped the fitness determinants of these two incipient species over the last 100,000 years.

P2123C Genomic analysis of ancestry in hybrid mice. *M. Frayer*[1], L. Turner[1,2], B. Harr[2], D. Tautz[2], B. Payseur[1]. 1) University of Wisconsin-Madison, Madison, WI; 2) Max Planck Institute for Evolutionary Biology, Plön, Germany.

Regions where related species' ranges overlap have the potential to become zones of hybridization and also have the potential to reveal the progression of speciation between those species. The evolutionary history and genetic barriers to reproduction can be revealed by the pattern of ancestry across the genomes of hybrid individuals. Ancestry junctions, historical recombination events between chromosomes of different ancestries, can be used as a measure of ancestry. However, empirical identification of these junctions is rarely performed. Combining whole genome sequencing with probabilistic inference of ancestry, we have identified ancestry junctions across the genome of a single hybrid individual from the well-studied house mouse hybrid zone between *Mus musculus musculus* and *Mus musculus domesticus* in Central Europe. We found that the average block length between junctions was small, but the variance in block length was high. These results show a complex history of hybridization, and may reveal that hybridization has been occurring in the zone longer than previously thought. This analysis demonstrates the power of genomic data in increasing our understanding of speciation.

P2124A Finding Hybrid Sterility Genes Between Two African Malaria Mosquitoes. *R. Green*[1], D. Turissini[1], S. Gamez[1], B. Cassone[2], B. White[1]. 1) University of California Riverside, Riverside, CA; 2) Ohio State University, Columbus, OH.

The Dobzhasnky-Muller model predicts that as species diverge over time they will accumulate genetic differences, which may be incompatible with each other when combined into the same genetic background. Despite the central importance of this process to diversification, identification of genes causing hybrid dysfunction has been primarily limited to model species. *Anopheles gambiae*, the principal mosquito vector of malaria in Africa, belongs to a complex of at least nine isomorphic species. In accordance with Haldane's rule, reciprocal crosses between *An. gambiae* and its sister species *Anopheles merus* produces completely sterile males, but fully fertile females. When we backcrossed F1 hybrid females to their maternal parental males, the resulting male progeny displayed a range of phenotypes from completely sterile to completely fertile. This phenotypic range provides us with the foundation for quantitative trait locus (QTL) mapping. We performed reciprocal backcrosses, phenotyped ~2500 males from those backcrosses, and genotyped each male using a total of ~12,000 markers across the

genome using a reduced representation sequencing approach. Our uniquely large quantitative genomics data set, when combined with testes-specific expression analysis, will allow us to identify a small number of hybrid-sterility candidate genes. Our current findings have shown us an intriguing result that points to a disruption sex chromosome inactivation during spermatogenesis that seems to be the cause sterility in only one of our reciprocal crosses. Not only will identification of hybrid-sterility genes provide insights into how and why postzygotic reproductive isolation barriers evolve, but they could also be important in the development of advanced sterile-insect control strategies aimed at reducing the role of the *Anopheles gambiae* complex in the African malaria transmission cycle.

P2125B Shared and species-specific transcriptional responses of barley (*Hordeum vulgare* L.) to generalist and specialist spider mite herbivores. *Robert Greenhalgh*[1], Huyen Bui[1], Alice Ruckert[2], Ricardo Ramirez[2], Richard Clark[1]. 1) University of Utah, Salt Lake City, UT; 2) Utah State University, Logan, UT.

With rising temperatures and increasing incidences of drought associated with climate change, spider mites, including the two-spotted spider mite (*Tetranychus urticae,* TSSM) and the Banks grass mite (*Oligonychus pratensis,* BGM), are becoming ever more important agricultural pests. An extreme generalist, the TSSM is documented to feed on more than 1,100 plant hosts, while the BGM, a grass specialist, feeds on cereal crops like maize, wheat, sorghum and barley. Historically, studies of plant-herbivore interactions have focused primarily on insects, while far less is known about how plants respond to mite herbivores, especially in grasses. To identify how plant defense pathways respond to both generalist and specialist mites, we compared time course RNA-seq data from barley (*Hordeum vulgare* L.) infested with TSSMs and BGMs. Strikingly, significant changes in the expression of hundreds of genes were detected at only two hours after mite infestation, and by 24 hours this number had increased to several thousand. As assessed by comparisons of TSSM- and BGM-induced responses at both time points, transcriptional reprogramming was strongly correlated for 3963 genes, including the down-regulation of genes involved in photosynthesis and the up-regulation of genes in the hormone signaling and secondary metabolic pathways. In particular, genes in the jasmonic acid biosynthesis and signaling pathway, as well as grass-specific secondary metabolic pathways, were among those with the strongest transcriptional changes. While many shared transcriptional changes were observed, the magnitude of barley responses to the specialist BGM was markedly stronger than that of the generalist TSSM, an observation that was reflected in enzymatic assays of infested leaves (e.g., peroxidase activity). In addition, 3261 genes exhibited BGM-specific changes in expression compared to only 535 genes unique to TSSM-infested plants. A potential explanation for this result is that the broad host range of generalist mite herbivores involves (at least in part) suppression of plant defenses, a finding that has been reported for some other herbivore species. In contrast, host adaptation for the specialist BGM may have involved the evolution of robust detoxification pathways for secondary compounds that typify members of the grass family upon which BGM is restricted.

P2126C Evidence for an epigenetic effect of kinship on fertility of flies (*Drosophila melanogaster)* induced by folic acid with reference to a possible similar mechanism in *Homo sapiens* at clinical dose levels. *M. L. Herbert*. Pinellas Country Dept Public Health , Largo, FL.

It has been shown that kinship determines fertility in humans as well as other mammals, birds, fish and insects. Evidence indicates that once kinship among a couple and their ancestors is taken into account there is no other important factor influencing fertility in a given species. At smaller populations the curve of fertility against kinship rises steeply as kinship rises until inbreeding is reached. At kinship less than an equilibrium point, fertility slowly falls with varying population time courses including: damped oscillation with rapid rise and slow fall seen in the wild, in the lab and by computer model; a two peaked pattern showing slow rise and rapid fall seen in humans, the wild and in computer model; and a single peak showing rapid rise and slow fall in humans, the wild, the lab and computer model, each pattern caused by a post zygotic mechanism or combined pre and post zygotic. Earlier we demonstrated damped oscillation in a population of captive fruit flies.

We hypothesized that the mechanism must be epigenetic and tried giving varying doses of folic acid to our flies looking for an effect.

We were able to demonstrate the two peaked pattern with slow rise and rapid fall characteristic of combined mechanisms.

We were surprised to discover that fertility depression can occur at roughly a dose of folic acid recommended for women. The number of possible confounding factors means that this may coincidental, but considering the importance of the issue this needs more study.

P2127A Robustness versus adaptation? *P. Jiang*[1], V. Sergey[2,3], M. Kreitman[1], J. Reinitz[1]. 1) University of Chicago, Chicago, IL; 2) Institute for Mechanical Engineering Problems, Sankt Petersburg, Russia; 3) ITMO University, Sankt Petersburg, Russia.

For multicellular organisms, a paradox exists between developmental robustness versus evolutionary novelty. On the one hand, in constant environment, robust developmental processes are preferred, in the face of weak or moderate genetic and environmental perturbations. On the other hand, in fluctuating or sudden change of environment, the least robust system will adapt the most quickly. Since environment cannot be in one mode forever, there must exist some balance between the degree of robustness and the ability to evolve. Here we propose a model, taking into consideration genes' combinatorial and pleotropic effects to determine phenotype for multicellular organisms and changing environment, to explore the relationship between robustness and adaptation. We mainly use forward population genetics simulations approach to address the question. We explored different parameter combinations that give rise to systems with different degree of robustness. We also find some connections of the current model to classic population genetics model.

P2128B Fisher's Geometric Model and the Cost of Reality. *K. Karkare*, R. B. R. Azevedo. University of Houston, Houston, TX.

Studies of adaptation strive to understand the relationship between genotype, phenotype, and fitness. Because mutations are the ultimate source of adaptive evolution, the distribution of fitness effects of mutations (DFE) provides critical information about adaptive processes. Fisher's Geometric Model of Adaptation (FGM) is a leading candidate for modeling adaptation because it captures the statistics of complex

gene interactions within a simple framework of mutation and selection. Despite its success fitting experimental data, the model's credibility is weakened because it does not explain all of the available data. FGM suffers an inherent 'cost of reality'. It cannot simultaneously satisfy a realistic DFE and maintain a realistic rate of adaptation. My work addresses if improved biologically plausibility of the underlying mutational and selective regimes can alleviate the cost of reality. I test multiple modifications to FGM and ultimately find that restricted mutational pleiotropy successfully relieves the cost of reality when a small proportion of traits are maladapted. This result harmonizes with previous work that shows restricted pleiotropy to be beneficial when few traits are maladapted because it allows those traits to adapt without disrupting the entire system. My work improves the statistical fit of a popular model of adaptation and finds evidence for an empirically supported mutational regime.

P2129C Identification and characterization of the *Taeniopygia guttata* (Zebra finch) sperm proteome. *T. Karr*[1], M. Rowe[2]. 1) Kyoto Institute of Technology, Kyoto, Kyoto Prefecture, JP; 2) Natural History Museum, University of Oslo, Oslo, Norway.

Spermatozoa exhibit remarkable variability in size, shape and performance, and are a key target of sexual selection due to both sperm competition and sperm-female interactions in sexually reproducing taxa. While knowledge of the evolutionary causes and adaptive significance of sperm morphological and behavioral variation is beginning to accumulate, our understanding of the genetic and molecular basis of sperm form and function remains limited. Here, we describe the first avian sperm proteome using LC-MS based discovery proteomics. The Zebra finch is an important model organism for several fields of study, including sperm competition. Thus, knowledge of the protein constituents of sperm may provide new insights into bird sperm biology and provide an important database for taxon-level comparative studies of sperm function. Sperm were isolated and purified from male seminal glomera (the site of sperm storage in passerine birds) and proteins separated by SDS-PAGE and subjected to trypsin digestion. The resulting peptides were analyzed by nano-electrospray mass spectrometry and resulting peptide spectra queried against the *T. guttata* proteome (uniprot.org) and protein assignments made using Protein Prophet. This approach identified 495 proteins of the zebra finch sperm proteome (ZfSP). Gene Ontology analysis of the major protein classes included numerous categories previously identified in both mammalian and insect sperm proteomes including metabolism/energetics (e.g., oxidoreductases, hydrolases, transferases) and cytoskeletal components of the sperm axoneme and acrosome (e.g., tubulins, dyneins and outer dense fiber proteins). In addition to these known categories, and compared to other defined sperm proteomes, the ZfSP is enriched in actin-related functions and associated processes at, or near, the membrane surface. We view these findings as an important first step in understanding the molecular basis of sperm form and function in a passerine bird, and believe our results will help shed light on the molecular mechanisms underpinning the outcomes of sperm competition and sperm-female interactions.

P2130A Genome-wide RAD genealogical analyses highlight the role of ancient genomic variation during rapid adaptation in threespine stickleback. *T. Nelson*, W. Cresko. Institute of Ecology and Evolution, University of Oregon, Eugene, OR.

Present genetic diversity, from the level of individual genes to genomic regions and entire chromosomes, is the product of the entire evolutionary history of a species. This deep history influences future adaptive potential. Recent advances in sequencing technologies have provided unprecedented views into patterns of genetic variation and spurred the field of population genomics, which aims to understand the distribution of genetic variation throughout genomes. While short sequence reads have greatly facilitated our understanding of genomic patterns of SNP variation, inference of deeper patterns of sequence evolution has been elusive. To facilitate genomic studies of haplotype evolution, we have use restriction site-associated DNA sequencing (RAD-seq) to generate phased sequence of length and quality comparable to Sanger reads — and thus amenable to genealogical analysis — at thousands of genomic loci. By comparing two populations of threespine stickleback (*Gasterosteus aculeatus*) to a sister species, the ninespine stickleback (*Pungitius pungitius*), we show that adaptive divergence in a freshwater pond population occurred primarily from standing genetic variation that originated long before that population was founded. Furthermore, we demonstrate that a chromosomal inversion under divergent selection is harboring a pair of anciently-evolved adaptive haplotypes. These data highlight the ability of RAD-seq to sample haplotypic variation at a genomic scale and help advance the field of populations genomics towards a deeper understanding of the genealogical structure of standing genetic variation and its importance for adaptation in the wild.

P2131B A karyological study of the artificial hybridization between *Clarias gariepinus* (Burchell, 1822) and *Heterobranchus bidorsalis* (Geoffroy, 1809). *G.Chioma. Nzeh*, J. Olaoluwa Ademola. University of Ilorin, Ilorin, Kwara, NG.

This study was carried out to investigate the genetic factors responsible for the differential growth in the artificial hybrid of *C. gariepinus* and *H.bidorsalis*. Five hybrids obtained from the crossing of female *C. gariepinus* and male *H.bidorsalis* were used for the experiment. The live fish was injected intraperitoneally with 0.02% colchicine (1ml/100mg body weight) and left for four hours. Fish sacrificing was done by pitting. The anterior head kidney was used for karyotyping according to the air-drying method. The weights of the stunted growing fish are: 0.2Kg, 0.4Kg and 0.5 Kg, while the fast-growing weighed 0.8Khg and 1.5Kg. *C. gariepinus* has a standard karyotype of 2n = 56, while *H. bidorsalis* has 2n = 52. The hybrids showed differential growth rate. The hybrids were sterile; no gonads were observed within the first year. Karyological observation revealed variation in the hybrid's karyotype. Chromosome clumping was observed in hybrids that showed stunted growth. Further genetic studies should be carried out that will elucidate the genetic mechanism responsible for the differential growth of the hybrid.

P2132C Can Adaptive Evolution Undermine Canalization? The Case of Wing Size Evolution in High Altitude *Drosophila*. *John Pool*, Justin Lack, Matthew Monette, Evan Johanning, Quentin Sprengelmeyer, Amir Yassin. University of Wisconsin - Madison, Madison, WI.

The letter preceding the number is the community. A, B, C after the number is presentation time.
W – *C. elegans*, C – Ciliates, D – Drosophila, M – Mouse, P – PEQG, Y – Yeast, Z – Zebrafish

Many traits show canalization (robustness against genetic or environmental perturbation). But it's unclear how the buffering of a developmental process may be affected if adaptive evolution changes its phenotypic outcome. Highland Ethiopian *D. melanogaster* have evolved the largest thorax and wing length of any natural population. This size evolution is facilitated by an evolutionary tradeoff in which flies lay fewer but larger eggs, and it involves increases in both cell proliferation and somatic ploidy. Motivated by an unexpected frequency of wing vein abnormalities in Ethiopian inbred lines, we hypothesized that wing size evolution was accompanied by decanalized wing development in these flies. We repurposed a classic forward genetic approach (chemical mutagenesis) to test whether Ethiopian strains' wing development was more susceptible to genetic perturbation than a small-winged low altitude population (Zambia). Indeed, the offspring of mutagenized Ethiopian flies showed much higher rates of novel wing abnormalities, demonstrating reduced genetic robustness. Furthermore, wing size and decanalization cosegregated in the advanced generation offspring of a cross between Ethiopia and Zambia strains, implying that wing size variants undermined developmental buffering. Our results constitute the first natural example of a tissue's morphological evolution being associated with decanalized development, suggesting that decanalization might reflect an important cost of adaptation.

P2133A Effects of adaptive Neandertal introgression at the OAS locus on the modern human innate immune response. *A. J. Sams*[1], J. Nédélec[2,3], A. Dumain[2], V. Yotova[2], P. W. Messer[1], L. B. Barreiro[2,3]. 1) Cornell University, Ithaca, NY; 2) CHU Sainte-Justine Research Center, Montreal, QC, Canada; 3) University of Montreal, QC, Canada.

It is now clear the ancestry of all individuals living outside of sub-Saharan Africa is composed of roughly two percent Neandertal ancestry. Yet, it remains largely unclear to what extent this contribution from Neandertals impacts modern human biology, and further, to what extent it may have provided adaptive genetic variation to modern human populations. The immune system is one physiological system that harbors higher than typical amounts of genetic variation in order to provide a flexible set of responses to infection. Here we use coalescent simulation and population genetic approaches to demonstrate a signal of adaptive introgression in the 2'-5' oligoadenylate synthetase (OAS) gene cluster region of chromosome 12. The adaptive region encodes for three active OAS enzymes (OAS1-3) that are involved in the innate immune response to viral infection. In order to evaluate the functional consequences of the adaptive haplotype we infected primary macrophages and peripheral blood mononuclear cells from people with and without the Neandertal haplotype with a panel of bacteria, viruses, and viral-syntetic ligands. Our results show that human cells carrying the Neandertal-like haplotype show marked functional differences in the transcriptional regulation of *OAS3* in response to bacterial and viral agents which activate the type I interferon (IFN) production pathway. Additionally, we find that SNPs associated with the Neandertal haplotype are strongly associated with isoform usage in *OAS1* and *OAS2*. These results illuminate the phenotypic effects of Neandertal haplotypes into the regulation of innate immune responses and a potential functional explanation for adaptive introgression of the OAS locus into modern human populations.

P2134B GC-rich DNA is an inductor of adaptive response in MSCs. *Vasilina Sergeeva*[1], S. V. Kostyuk[1], N. N. Veiko[1], E. S. Ershova[1], L. V. Kameneva[1], E. M. Malinovskaya[1], N. N. Mordkovich[2], V. P. Veiko[2], N. A. Okorokova[2]. 1) Research Centre for Medical Genetics, Moscow, Russia; 2) Bach Institute of Biochemistry, Russian Academy of Sciences, Moscow, Russia.

It has been established that cell-free DNA (cfDNA) circulates throughout the bloodstream, affecting cells. The characteristics of cfDNA depend on the physiological state of the organism. Diseases can cause GC-enrichment of the cfDNA pool (cerebral atherosclerosis, heart attack, rheumatic arthritis, cancer). As was shown previously, cfDNA pool is enriched with ribosomal GC repeat in cases of people working with gamma-radiation (N=230).

GC-rich cfDNA causes adaptive response in human adipose-derived mesenchymal stem cells (MSCs) via DNA damage response. It rapidly induces DNA breaks after 30 minutes of incubation (shown by means of single cell electrophoresis and flow cytometry), leading to increase in DNA reparation gene level *BRCA1* (6,5-fold) and anti-apoptotic genes *BCL2 (4,5 - fold)*, *BCL2A1 (5-fold)*, *BCL2L1 (3-fold)*, *BIRC3 (5-fold)*, *BIRC2(6-fold)* after 3 hours of incubation. Moreover, GC-rich DNA activates NF-kB signaling pathway: NF-kB translocates to the nucleus after 1 h of incubation (fluorescent microscopy) and genes of NF-kB signaling pathway: *MAP3K1, MAP4K4, NFKB1A, REL*, *IKBKB, RelA (p65), NFRKB, NFKB1* and *NFKB2* increase 2 – 5,5-fold (RT-PCR). Expression of NF-kB target proinflammatory cytokines genes *TNFα* (3,9-fold), *IL1B* (2,4-fold), *IL8* (2,8-fold), *IL6* (1,7-fold), *TNFRSF1A* (3,2-fold) increases. In addition, level of apoptosis decreases and proliferation rises, level of Ki-67 and PCNA proteins increases (flow cytometry). Treating MSCs with GC-rich cfDNA prior to exposure to damaging factors such as ionizing radiation positively affects cell survival - radiation induces less DNA breaks and less cell death in cell cultures treated with GC-rich cfDNA.

Conclusion. GC-rich fragments of the ribosomal repeat in the pool of cfDNA can be inductors of adaptive response development in cases of exposure to external damaging factors (ex. ionizing radiation).

P2135C The adaptive significance of natural genetic variation in the DNA damage response of *Drosophila melanogaster*. *Nicolas Svetec*, Julie M. Cridland, Li Zhao, David J. Begun. UCDavis, Davis, CA.

Despite decades of work, our understanding of the distribution of fitness effects of segregating genetic variants in natural populations remains largely incomplete. One form of selection that can maintain genetic variation is spatially varying selection, such as that leading to latitudinal clines. While the introduction of population genomic approaches to understanding spatially varying selection has generated much excitement, little successful effort has been devoted to moving beyond genome scans for selection to experimental analysis of the relevant biology and the development of experimentally motivated hypotheses regarding the agents of selection.

Solar UVB incidence is negatively correlated with latitude and an important agent of DNA damage in nature. Motivated by population genomic results, we investigated whether clinal variation in UVB incidence has led to genetic differences in the DNA damage response of *D.*

melanogaster populations. Using a combination of population genomics, transcriptomics, and organismal phenotypic analysis, we show that genetic variation in the DNA damage response in *D. melanogaster* is maintained by spatially varying selection due to latitudinal variation in solar UVB incidence.

P2136A Can the Y chromosome save males from the mother's curse? *J. Arvid Ågren*, Andrew G. Clark. Cornell University, Ithaca, NY.

Genomic conflicts often arise because not all genes are inherited in the same way. Opportunities for conflict between the biparentally inherited nuclear genome and the maternally inherited mitochondrial genome (mtDNA) seem especially favorable and conflicts between nuclear and mitochondrial genes over sex determination and sex ratio have been well documented. In general, because genes in the mitochondrial genome are strictly maternally inherited, mutations that are beneficial in females can spread in a population even if they are somewhat deleterious in males. This phenomenon has been dubbed the "mother's curse". The accumulation of male-biased mutations in the mitochondrial genome should lead to selection in males for compensatory nuclear modifier loci that alleviate the effect. The Y chromosome, being strictly paternally inherited, has been suggested as a good candidate for such modifiers. Recent work has countered classic predictions by finding that loci in the mitochondrion and the Y chromosome can affect the expression of nuclear autosomal loci. Moreover, several of the autosomal loci shown to be affected by mitochondrial variation overlap with autosomal loci affected by variation on the Y chromosome. The extent to which these loci are subject to mtDNA-Y chromosomal epistatic effects and determine male health and fitness, however, remains unknown. To experimentally examine the extent to which mitochondrial and Y-linked genetic variants interact to determine male fitness, we used *Drosophila melanogaster* strains from the five geographical locations (Ithaca, the Netherlands, Zimbabwe, Beijing, and Tasmania). Through crosses, we generated strains that differed only in the geographical origin of their mitochondrial genome and the Y chromosome. If Y-linked suppressors are important, co-evolved combinations of the mitochondrial genome and the Y chromosome from the same population should outperform novel combinations. We present evidence that the effect of mtDNA-Y interactions depend both the origin of the mtDNA and the Y chromosome, as well as on what aspect of male fitness measured. In light of these results, we outline a simple model for how mtDNA-sex chromosome interactions differ in an XY compared to a ZW sex chromosome system where the female is the heterogametic sex, and the W chromosome is always co-transmitted with the mitochondrion.

P2137B Positive selection and centrality in the yeast and fly protein–protein interaction networks. *D. Alvarez-Ponce*, S. Chakraborty. University of Nevada, Reno, Reno, NV.

Proteins within a molecular network are expected to be subject to different selective pressures depending on their relative hierarchical positions. However, it is not obvious what genes within a network should be more likely to evolve under positive selection. On the one hand, only mutations at genes with a relatively high degree of control over adaptive phenotypes (such as those encoding highly connected proteins) are expected to be "seen" by natural selection. On the other hand, a high degree of pleiotropy at these genes is expected to hinder adaptation. Previous analyses of the human protein–protein interaction network have shown that genes under long-term, recurrent positive selection (as inferred from interspecific comparisons) tend to act at the periphery of the network. It is unknown, however, whether these trends apply to other organisms. Here, we show that long-term positive selection has preferentially targeted the periphery of the yeast interactome. However, the opposite trend is found in flies: genes under positive selection encode significantly more connected and central proteins in the fly interactome. These observations are not due to covariation of genes' adaptability and centrality with protein length, protein abundance, expression level or, in the case of *Drosophila*, expression breadth. These results indicate that the distribution of proteins encoded by genes under recurrent positive selection across protein–protein interaction networks varies from one species to another.

P2138C GC content evolution in the light of nucleic acid molecular dynamics. *G. A. Babbitt*, E. E. Coppola. Rochester Institute of Technology, Rochester, NY.

Molecular evolutionary studies of genomic base composition and GC content have a long unresolved history of frequency-based methods of analysis applied only to DNA sequence data. However, this tradition ignores the physicochemical impacts of mutation that can affect the molecular dynamics of nucleic acid polymers. This is especially problematic during transcription, where mutation can influence the complex interactions at play in chromatin-mediated genomic regulation. Here, we investigate the two primary biophysical constraints required of eukaryotic transcription; a flexible/nuclear-compacted DNA and a stable/non-self-reactive RNA; both features which can be significantly affected by the molecular evolution of GC content in the genome. We utilize a 2x448 core Tesla supercomputer to conduct 2000 nanosecond scale GPU accelerated molecular dynamic simulations of mutation in randomized DNA and RNA sequence backgrounds, where we investigate mutational impacts on molecular dynamics while controlling for varying GC content. Additionally, in *Saccharomyces* yeast alignments, we employ simulations of neutral evolution to locally map natural selection acting on DNA flexibility and RNA stability. We find that different classes of mutation have very different GC-dependent impacts on dynamics, defined via shifts in atomic fluctuation and correlation, and indicating that GC-related molecular dynamics of nucleic acids are correlated and evolvable. In DNA, we report that low GC generally amplifies mutational impacts on molecular dynamics while increasing the impact of transversion over transition, providing a potent functional evolutionary constraint that may form a basis for transition bias observed in most genomes. In RNA, we observe that the molecular dynamic impacts of mutation depend largely upon their impact on uracil, the most interactive of the nucleobases. In *Saccharomyces* yeasts, we find evidence that many yeast genes have effectively decoupled the biophysical relationship between DNA flexibility and RNA stability by elevating GC. We also report a significant genome-wide signature whereby TFBS consensus sequences are partly defined by mutational impacts on DNA flexibility. We conclude that the historical assumption of genetic abstraction in molecular evolution is quite limiting, especially

regarding the role of nucleic acid polymer biophysics in interpreting broad patterns in molecular evolution related to genome packaging and control of transcription.

P2139A A genetic parallel between flightlessness evolution in the Galapagos cormorant (*Phalacrocorax harrisi*) and human skeletal ciliopathies. *A. BURGA*[1,2], W. WANG[3], P. C. WOLF[4], A. M. RAMNEY[5], C. VERDUGO[6], K. LYONS[3], P. C. PARKER[7,8], L. KRUGLYAK[1,2]. 1) Departments of Human Genetics and Biological Chemistry, UCLA, Los Angeles, USA; 2) Howard Hughes Medical Institute (HHMI); 3) Departments of Molecular, Cell and Developmental Biology and Orthopaedic Surgery, UCLA and Orthopaedic Institute for Children, Los Angeles, USA; 4) United States Department of Agriculture/Wildlife Services; 5) U.S. Geological Survey Alaska Science Center, Alaska, USA; 6) Instituto de Patología Animal, Facultad de Ciencias Veterinarias, Universidad Austral de Chile, Valdivia, Chile; 7) Department of Biology and Whitney Harris World Ecology Center, University of Missouri-St. Louis, USA; 8) WildCare Institute, Saint Louis Zoo, Saint Louis, USA.

Changes in the morphology and size of limbs have played a key role in the adaptive evolution of species. Our own ancestors experienced such changes as they transitioned towards a bipedal, manually dexterous primate. However, despite the evolutionary importance of these modifications, we have a very limited idea of how these changes occur on a genetic and molecular level, especially in vertebrates. In order to fill this gap, we studied a recent case of extreme wing size reduction leading to flightlessness in the Galapagos Cormorant (*Phalacrocorax harrisi*). The Galapagos cormorant is unique in that is the only cormorant that lost the ability to fly among approximately 40 extant species. Their entire population is distributed along the coastline of the Isabela and Fernandina Islands in the Galapagos archipelago. *P. harrisi* has a pair of stubby wings, which are smaller than those of any other cormorant in spite of having the largest body mass, resulting in a significant deviation from the allometric relationship between wing length and body mass among flighted birds. We applied a joint predictive and comparative genomics approach to identify deleterious variants that affected the Galapagos Cormorant but were absent in three flighted close relatives. Among these variants, we found a significant enrichment for genes that cause skeletal ciliopathies when mutated in humans. Individuals affected by ciliopathies have small limbs and rib cages, mirroring the phenotype of *P. harrisi*. We show that *CUX1,* a highly conserved transcription factor, has a four amino acid deletion in *P. harrisi* that affects its regulatory domain. Moreover, we demonstrate that CUX1 controls the expression of cilia related genes and can promote the differentiation of chondrocytes. Our results suggest that the combined effect of deleterious variants in genes affecting chondrogenic differentiation led to the highly reduced wings of *P. harrisi.* .

P2140B Comparative Genomic Analysis of Zika Viruses between Southeast Asia and Microcephaly-Related South America Groups. *T. Chookajorn*[1], N. Kotanan[1], K. Kumpornsin[1], D. Loesbanluechai[2], M. Thammasatta[3], P. Auewarakul[1], P. Wilairat[1]. 1) Mahidol Univ., Bangkok, Thailand; 2) Chulalongkorn Univ., Bangkok,Thailand; 3) National Science and Technology Development Agency, Pathum Thani, Thailand.

Zika virus has become a global health crisis, causing devastating effects on lives of almost five thousand pregnant women and their newborns. One of the often overlooked facts is that Zika virus has been in circulation in Southeast Asia for several decades without distinct manifestations of neurological pathologies. An understanding of the cause for discrepancy between potentially mild Southeast Asia and more aggressive Zika viruses in South America could reveal the mechanisms underlying outbreaks and neurological damages of Zika infections in Brazil. We performed a comparative genomic analysis was performed to determine putative causations stemming from the virus. Phylogenetic analyses integrating geographical and time factors showed that Asian Zika virus might not be the direct source of South American outbreaks as previously speculated. The differences in amino acid residues between Southeast Asian and Brazilian Zika viruses are specifically clustered on the outer surfaces of Envelope and NS1 proteins. Comparative genomic analyses also revealed that only a selected few primer/probe sets currently in clinical use are capable of detecting Zika virus strains worldwide. Interestingly, the Envelope proteins of Dengue and Zika viruses show a remarkable degree of similarity especially at the surface residues. This pattern explains the cross-reactivity of Dengue virus antibodies to Zika viruses. It also suggests that therapeutic antibodies and vaccine candidates against Dengue viruses can target the Zika virus, thereby providing a strategy for using already available means to treat and prevent Zika virus infection.

P2141C Three blind mammals: Regressive evolution in the mammalian eye and the identification of new eye-specific *cis*-regulatory elements. *Nathan Clark*[1], Raghav Partha[1], Zelia Ferreira[1], Joseph Robinson[2], Bharesh Chauhan[1], Ken Nischal[1], Maria Chikina[1]. 1) University of Pittsburgh, Pittsburgh, PA; 2) University of California, Berkeley, CA.

After adopting primarily underground lifestyles, 3 independent lineages of subterranean mammals – the naked mole rat, star-nosed mole, and cape golden mole – evolved greatly reduced eyesight in a process known as regressive evolution. The multiple independent cases of regressive evolution allow an investigation of genomic patterns underlying this phenotypic convergence. Using new phylogenomic methods we found that hundreds of genes show increased evolutionary rates specifically in subterranean species, primarily due to a loss of functional constraint. These genes were predominantly involved in eye physiology, such as those encoding lens crystallins, photoreceptors and transduction pathways. Furthermore, bright-light color photoreceptors were clearly more degraded than dim-light receptors indicating they were lost earlier during regression. This finding suggests these species underwent a gradual transition to the subterranean environment, retaining vision in dim light for longer. Regressive evolution proceeded very differently between eye tissues; while lens and retinal genes are highly degraded, corneal genes remain under constraint, perhaps because they continue to provide a protective outer barrier for the vestigial eye. Moreover, genes important for the embryological development of all eye tissues remain highly conserved, potentially because they are expressed during the development of tissues outside the eye. For example, the coding portion of PAX6, a key transcription factor in the development of eye and the central nervous system, showed no signs of regression in subterranean mammals. We also explore an alternative explanation that development of early embryonic eye tissues is important for the canalized development of neighboring tissues such as the

brain. Observed developmental patterns in these species are consistent with this hypothesis. In contrast to its coding sequence, we found that PAX6's eye-specific enhancers were evolving at a much faster rate in subterranean species, likely due to relaxed constraint, relative to aboveground species. PAX6's enhancers active in other tissues did not demonstrate this pattern. This observation led us to perform a genome-wide screen to identify 40 new candidate eye-specific *cis*-regulatory sequences, which clustered near confirmed eye development genes. Thus, the results of convergent, regressive evolution provide a powerful means to assign functions to uncharacterized elements in the genome. We conclude that eye-related genes and regulatory elements show convergent patterns of loss and retention during repeated instances of regressive evolution, and that regression occurs differentially across tissues, physiology and development.

P2142A Plasmodium vivax mdr1 genotypes in isolates from successfully cured patients living in endemic and non-endemic Brazilian areas. *Maria de Fatima Ferreira-Da-Cruz*[1*], L. Gomes[1], Lavigne AR[1], Pina-Costa A.[1], Brasil P.[1], Almeida-De-Oliveira NK[1], Daniel-Ribeiro CT[1], Menard Didier[2]. 1) Fundacao Oswaldo Cruz, Fiocruz, Rio de Janeiro, Brazil; 2) Institut Pasteur , Cambodia.

Plasmodium vivax (Pv) is the most widely distributed species causing the highest number of malaria cases in the world. In Brazil, Pv is responsible for approximately 84 % of reported cases. In the absence of a vaccine, control strategies are based on the management of cases through rapid diagnosis and adequate treatment, in addition to vector control measures. The approaches used to investigate Pv resistance to chloroquine (CQ) were in vivo studies because of the difficulty in keeping parasites in continuous in vitro culture. In view of the limitations related to follow-up of patients and to assessing the plasma dosage of CQ and its metabolites, an alternative approach to monitor chemo-resistance (QR) is to use molecular markers. Single nucleotide polymorphisms (SNPs) in the multidrug resistance gene pvmdr1 are putative determinants of CQ resistance (CQR), but such SNPs in Pv isolates from patients with good response to treatment should be further explored. The aim of this study is to investigate the mutations in the gene, supposedly associated to QR, in Pv isolates from successfully cured patients, living in Brazilian endemic and non-endemic areas. Blood samples were collected from 49 vivax malaria patients from endemic (Amazon Basin: 45) and non-endemic (Atlantic Forest: four) Brazilian regions and analysed for SNPs in the CQR-related Pv gene (pvmdr1). Among the 49 isolates genetically characterized for the gene pvmdr1, 34 (70 %) presented at least one mutation. T958M mutant alleles were the most frequent (73 %) followed Y976F (15 %) and F1076L (12 %). Single mutation was detected in 24 (70.5 %) isolates and double mutations in ten (29.5 %). The most common single mutant genotype was the 958M/Y976/F1076 (79 %), followed by 976F/F1076 (21 %) whereas 958M/Y976/1076L (60 %) and 976F/1076L (40 %) double mutant genotypes were detected. Single mutant profile was observed only in isolates from Amazon Basin, although double mutants were found both in the Amazon and Atlantic Forest regions. Interestingly, the genotype 958M/Y976/1076L was present in all isolates from the Atlantic Forest in the Rio de Janeiro State. Considering that primaquine (PQ) efficacy is highly dependent on concurrent administration of a blood schizontocidal agent and that PQ could not circumvent CQR, together with the fact that no pvmdr1 mutation should be expected in successfully cured patients, these findings seem to indicate that the pvmdr1 gene is not a reliable marker of CQR. Further investigations are needed to define a reliable molecular marker for monitoring Pv CQR.

P2143B Phylogenetic reconstruction using Wright-Fisher models of sequence evolution vastly out perform standard approaches. *M. A. Gilchrist*[1,3], B. C. O'Meara[1,3], R. Zaretzki[2,3], C. L. Landerer[1], J. M. Beaulieu[1,3]. 1) Dept. of Ecology & Evolutionary Biology, University of Tennessee, Knoxville, TN; 2) Dept. of Business Analytics & Statistics, Univerity of Tennessee, Knoxville, TN; 3) National Institute for Mathematical and Biological Synthesis, Knoxville TN.

Most phylogenetic reconstructions using sequence data eitehr ignore natural selection or incorporate it in a heuristic manner such as Yang and Nielsen's ω term for describing either stabilizing or diversifying selection. Here we present an alternative approach in which fixation probabilities are explicitly based on the Wright-Fisher model of population genetics undergoing gene specific, stabilizing selection the amino acid sequence of a given protein. Further, the mechanistic nature of our approach means our model is easier to justify biologically and the parameters estimated describe explicit biological processes such as a gene's average protein production rate or the predicted effect of an amino acid substitution on protein function. Despite being more parameter rich than traditional, heuristic models used in phylogenetics, our model consistently provides astronomically better AIC values when applied to a wide range of test datasets. Finally, because it is mechanistically derived, it is relatively straight forward to expand our model to incorporate additional or alternative biological processes.

P2144C First report of *Rhizoctonia solani* AG-4 on tomato in Pothwar region of Pakistan. *A. S. Gondal*, A. Rauf, G. Irshad, F. Naz. PMAS Arid Agriculture University, Rawalpindi, Punjab, PK.

Rhizoctonia solani Kühn (teleomorph = *Thanatephorus cucumeris* (Frank) Donk) is the most important soil-borne fungal pathogen cause causes significant establishment with typical symptoms of collar rot, seedling death, stunted growth and root rot in tomato. Fungus isolated from diseased plants was identified as *Rhizoctonia solani* by comparing its morphological characters. Isolates were further confirmed as AG-4 by hyphal fusion test with tester isolates and DNA analysis. Present study is the first report of R. solani AG-4 effecting tomato in Pothwar region, Pakistan.

P2145A Comparative genome-wide analysis and evolutionary history of haemoglobin-processing and haem detoxification enzymes in malarial parasites. *T. Kochakarn*[1*], P. Ponsuwanna[1], D. Bunditvorapoom[1], K. Kümpornsin[1], T.D. Otto[2], C. Ridenour[1], K. Chotivanich[1], P. Wilairat[1], N.J. White[1,3], O. Miotto[1,3,4], T. Chookajorn[1]. 1) Mahidol University, Bangkok, Thailand; 2) Wellcome Trust Sanger Institute, Cambridge, UK; 3) University of Oxford, Oxford, UK; 4) Wellcome Trust Sanger Institute, Hinxton, UK.

Intra-erythrocytic parasitism requires malarial parasites to digest haemoglobin and detoxify iron-bound haem. These tasks are executed by

haemoglobin-specific proteases and haem biocrystallization factors that are components of a large multi-subunit complex. Since haemoglobin processing machineries are functionally and genetically linked to the modes of action and resistance mechanisms of several anti-malarial drugs, an understanding of their evolutionary history is important for drug development and drug resistance prevention.

Maximum likelihood trees of genetic repertoires encoding haemoglobin processing machineries within *Plasmodium* species, and with the representatives of Apicomplexan species with various host tropisms, were created. Genetic variants were mapped onto existing three-dimensional structures. Genome-wide single nucleotide polymorphism data were used to analyse the selective pressure and the effect of these mutations at the structural level.

Recent expansions in the falcipain and plasmepsin repertoires are unique to human malaria parasites especially in the *Plasmodium falciparum* and *P. reichenowi* lineage. Expansion of haemoglobin-specific plasmepsins occurred after the separation event of *Plasmodium* species, but the other members of the plasmepsin family were evolutionarily conserved with one copy for each sub-group in every Apicomplexan species. Haemoglobin-specific falcipains are separated from invasion-related falcipain, and their expansions within one specific locus arose independently in both *P. falciparum* and *P. vivax* lineages. Gene conversion between *P. falciparum* falcipain 2A and 2B was observed in artemisinin-resistant strains. Comparison between the numbers of non-synonymous and synonymous mutations suggests a strong selective pressure at falcipain and plasmepsin genes. The locations of amino acid changes from non-synonymous mutations mapped onto protein structures revealed clusters of amino acid residues in close proximity or near the active sites of proteases.

A high degree of polymorphism at the haemoglobin processing genes implicates an imposition of selective pressure. The identification in recent years of functional redundancy of haemoglobin-specific proteases makes them less appealing as potential drug targets, but their expansions, especially in the human malaria parasite lineages, unequivocally point toward their functional significance during the independent and repetitive adaptation events in malaria parasite evolutionary history.

P2146B Is the evolution of innate immunity the next EvoDevo? Changes in molecular function and cellular signaling in an antiviral immune system across the animal phylogeny. *B. Kolaczkowski*, C. Pugh, K. Aadland. University of Florida, Gainesville, FL.

Although it is widely appreciated that a functioning innate immune system is required to support multicellular life, we know surprisingly little about how the immune system of early multicellular animals was put together, how it changed over animal evolutionary history or the consequences of those changes for the organism. Here we combine ancestral sequence reconstruction with *in vitro* molecular-functional analyses and comparative *in vivo* examinations in mammalian and early-animal model systems to characterize the evolution of the RIG-like receptor (RLR) signaling network, an important component of animal innate antiviral immunity. We find that RLRs originated in the earliest animal lineages, probably through fusion of an RNA-binding domain from Dicer with CARD signaling domains, coupled with the origination of a novel structural fold used for viral RNA recognition. RLRs diversified through gene duplication events followed by changes in domain architecture and adaptively-driven protein-coding changes that repeatedly altered RNA preference. We present evidence that RLRs recruited novel signaling partners at least twice in animal evolution, leading to changes in the RLR signaling network and resulting in alteration of cellular immune function. Our work highlights the dynamic nature of immune-system evolution, the roles that protein structural variants, amino-acid variants and genomic clusters can play in evolving novel protein-protein signaling networks and the potential importance of changes in immune-signaling networks for cellular and organismal function. In our view, further understanding how the innate immune system evolved will help us understand how differences in innate immunity may have contributed to animal biodiversity.

P2147C The lower limit of transcription error rate in the bacterium *Escherichia coli*. *Weiyi Li*, Jean-François Gout, Michael Lynch. Indiana University Bloomington, Bloomington, IN, USA.

Errors can occur at any level during replication and expression of genetic information. Genetic mutations are derived mainly from replication errors and have been extensively studied in evolutionary research. However, many details of the transcription error remain largely unknown. Transcription errors can indirectly give rise to misfolded proteins and impose a load on cellular integrity. Same as the rate of genetic mutation, the rate of transcription error is shaped by the directional process of selection and the random process of drift. However, transcription errors are fundamentally different from genetic mutations in many aspects. Firstly, unlike mutations that reside in genomes, transcription errors in RNA transcripts have short life spans and will finally be degraded. Secondly, there are multiple RNA copies of one gene and only a minor portion of them may carry transcription errors. These transient natures would dilute the fitness effect of transcription errors and selection is less sufficient to push down the rate of transcription errors. To investigate the lower limit of transcription error rate in the bacterium *Escherichia coli*, we took a novel rolling-circle sequencing approach and have accurately identified transcriptome-wide transcription errors. Our results indicate that the lower limit of transcription error rate in the bacterium *Escherichia coli* is 10^5 x higher than the corresponding genetic mutation rate.

P2148A A maximum pseudo-likelihood approach for estimating species trees. *L. liu*[1], L. Yu[2], S. Edwards[3]. 1) University of Georgia, Athens, GE; 2) Georgia Southern University, Statesboro, GA; 3) Harvard University, Cambridge, MA.

Several phylogenetic approaches have been developed to estimate species trees from collections of gene trees. We propose to use a pseudo-likelihood function of the species tree to obtain Maximum Pseudo-likelihood Estimates of Species Trees (MP-EST), with branch lengths of the species tree in coalescent units. The MP-EST method estimates species trees from a set of gene trees by maximizing a pseudo-likelihood function. The program can run independent searches (chains) in parallel using the parallel version of the program. Each chain starts with a different seed. The program will find the estimate of the species tree with the largest pseudo-likelihood score across chains.

P2149B Reduction of intergenic non-coding RNAs from the *HBS1L-MYB* locus linked to Thalassemia disease severity. *D. Loesbanluechai*[1], K. Leecharoenkiat[1], S. Fucharoen[2], O. Sripichai[2]. 1) Chulalongkorn University, Bangkok, Bangkok, TH; 2) Thalassemia Research Center, Institute of Molecular Biosciences, Mahidol University, NakornPathom, TH.

Thalassemia is a hematological disease caused by imbalanced globin production. The degree of diseases severity depends on several factors including the expression of fetal globin which can compensate for loss in adult globin. Genome wide association studies were performed to identify loci that are linked to reduction in disease severity. The majority of polymorphic sites are clustered within the globin genes. A subset of key loci is located at or near the genes encoding transcription factors functionally associated with globin gene expression. The polymorphism at the intergenic region between *HBS1L* and *MYB* was shown to one of the top severity modifying factors. A set of short transcripts corresponding to the intergenic *HBS1L-MYB* region was found in RNA-seq analyses of erythroid cell lines and hematologic stem cells, indicating that this intergenic region is actively transcribed. Recently, the enhancer RNA was shown to play roles in transcription control. These small non-coding RNAs might be responsible for change in disease severity. Quantitative RT-PCR was carried out to determine and quantify the non-coding *HBS1L-MYB* transcripts in primary human erythroblasts from normal individuals and Thalassemia patients. Three clusters of transcripts were identified. Interestingly, erythroblasts from beta-thalassemia/HbE patients have significantly lower levels of the non-coding transcripts than those from individuals with normal globin genes, warranting further studies to determine the function of these non-coding *HBS1L-MYB* transcripts.

P2150C Folding and misfolding of evolutionarily young proteins. *Joanna Masel*[1], Scott Foy[1], Ben Wilson[1], Rafik Neme[2], Matt Cordes[1]. 1) University of Arizona, Tucson, AZ, USA; 2) Max Planck Institute for Evolutionary Biology, Ploen, Germany.

Random polypeptides are expected to form amyloids and other toxic aggregates, making de novo gene birth from non-coding sequences a difficult transition. We find that evolutionarily young mouse proteins contain more hydrophilic amino acids than old proteins do, which in turn are more hydrophilic than intergenic sequences would be if they were translated. Low hydrophobicity is presumably a precondition for avoiding harmful aggregation; computationally predicted aggregation propensity tracks amino acid composition. But surprisingly, when amino acid composition is held constant, young proteins (but not old proteins) actually have a higher predicted aggregation propensity than scrambled controls. Preliminary results suggest that this might be explained by the degree of dispersion of hydrophobic amino acids along the primary sequence. Previous work concluded that amino acids with different properties, e.g. polar vs. non-polar or hydrophobic vs. hydrophilic, are overdispersed relative to a random ordering. We find that this conclusion holds only for the very oldest proteins, which are overrepresented in protein structural databases. Young proteins instead show significant underdispersion / clustering. We hypothesize that this clustering to form locally structured regions may be a precondition for a de novo evolved protein to fold, with a greater tendency to misfold/aggregate arising as an inevitable byproduct. Over long evolutionary timescales, more subtle folding strategies allow proteins to become more hydrophobic while still avoiding misfolding, and to have less clustering of their hydrophobicity while still being able to fold.

P2151A Assessing the compatibility of eukaryotic transcript evolution with *de novo* gene birth. *L. Nielly-Thibault*, C. Landry. Laval Univ., Quebec, Canada.

The emergence of new genes is often caused by the duplication or the fusion of ancestral genes. On their own, these mechanisms cannot explain the observation of species-specific genes and seemingly unrelated gene families. Recent studies have revealed cases of gene birth from non-genic ancestral DNA in various Eukaryotes. Such *de novo* gene birth may complement other mechanisms in the explanation of gene content variation between species. However, this phenomenon requires that regions of non-genic DNA acquire transcription and, in the case of protein-coding genes, translation. The roles played by cellular and populational processes in *de novo* gene birth are not yet well understood. We hypothesize that it is mainly driven by selectively neutral mutations generating and disrupting non-functional occurrences of sequence elements involved in transcription and translation. To test this hypothesis, we are using published data from the yeast *Saccharomyces cerevisiae* to assess the impact of mutations on the boundaries of transcribed and translated regions. As a first model, we are examining the evolution of transcriptional initiation and termination following the yeast whole genome duplication. Our results will clarify the impact of neutral evolutionary forces on eukaryotic transcripts, an important component of their potential as a raw material for *de novo* gene birth.

P2152B Improved accuracy of phylogenetic analyses by partitioning schemes that incorporate structural information. *Akanksha Pandey*, Edward Braun. University of Florida, Gainesville, FL.

Phylogenetic analyses of ancient evolutionary relationships, like the earliest divergences among metazoans, have often used protein sequences. Maximum likelihood (ML) analyses of aligned protein sequences typically use “empirical models” of evolution, where the parameters describing the instantaneous rate of change among amino acids is estimated from large-scale “training sets” of proteins. This creates the problem that the analyses essentially assume that all positions in the alignment exhibit similar patterns of evolution (with the exception of the overall rate, which is typically modeled by assuming rates at different sites are drawn from a gamma distribution). Effectively, one assumes that all sites evolve like the average site in the average protein in these analyses. However, it is clear that different sites in proteins exhibit substantial heterogeneity in their patterns of evolution. This variation probably reflects various structural and functional constraints. A number of approaches have been proposed to incorporate this heterogeneity into phylogenetic analyses, but it seems reasonable to postulate that incorporating structural information might provide a means to move toward a more realistic model of protein evolution. Here, we examine two straightforward and computationally efficient partitioning approaches that divide proteins into subset of sites using structural information (i.e. secondary structure and relative solvent accessibility). We then compared the performance of our model on

an alignment of 242 orthologous proteins for 19 metazoan taxa (104,840 sites with 16.9 % missing data). This dataset has been somewhat equivocal regarding the topology it supports but all of our analyses using the new structural partitioning schemes, with parameter estimates for each structural class, place ctenophores sister to all other metazoans. This is the topology found in a number of other analyses using more extensive taxon sampling so it is encouraging for the phylogenetic accuracy of this approach. Our approach is straightforward to implement in existing software and, based on information theoretic criteria, outperform available empirical models. The best-fitting partitioning scheme included both secondary structure and relative solvent accessibility and it used partition boundaries generated by programs in the SCRATCH package on a weighted consensus sequence for each protein. Estimates of parameters for different structural classes show many differences, suggesting that this approach provides a better overall fit to the evolutionary process.

P2153C Here and there, but not everywhere: the repeated loss of uncoupling proteins in reptiles and mammals. *T. S. Schwartz*[1], S. M. McGaugh[2]. 1) Auburn University, Auburn, AL; 2) University of Minnesota, Saint Paul, MN.

Uncoupling proteins in the inner mitochondrial membrane provide a proton "leak", thereby uncoupling the movement of protons down the gradient and the production of ATP. There are six uncoupling proteins (UCP1-6), the largest family of nuclear-encoded mitochondrial transporters. From an evolutionary perspective they provide dramatic steps in evolution including the evolution of endothermy, as well as regulation of ROS that are fundamental to rates of aging and oxidative stress. While the function of UCP1 in nonshivering thermogensis in mammals is well established known, the functions of the other uncoupling protein homologues is less clear. We conducted this study to fill a gap in literature related to the evolution of mitochondrial uncoupling proteins. The purpose of this study was two fold. First, we surveyed the available reptile genomes and transcriptomes for the presence of the different homologues to predicted gene losses in each group. Second, we determined whether there was evidence that positive selection acted on each UCP in the amniotes—mammals and reptiles. Across 66 species, alignments made from transcriptome and genome-derived coding sequence suggest that specific UCPs are missing in several clades, and we confirmed this by examining syntenic regions among different clades and BLAST searches across newly available genomes. The cumulative analysis suggests that all six of the UCP homologues are present in mammals. The *ucp1* gene was lost very early in the reptile lineage and the lost of UCP1 seems to be a repeated occurrence in multiple mammalian lineages despite its role in non-shivering thermogenesis. Further, among reptiles UCP2 was absent in birds, and UCP3 and UCP4 were absent in snakes. Branch-site tests suggest that positive selection acted on UCP2 in the branch leading to mammals and UCP4 on the branch leading to crocodiles. These results in the context of physiological comparisons can bring new insight into the functional roles of these proteins and how they vary across taxa.

P2154A Functional divergence of two young duplicate genes in *Drosophila*. *I. M. Ventura*[1,2], M. Long[1]. 1) Ecology and Evolution, University of Chicago, Chicago, IL; 2) CAPES Foundation, Ministry of Education, Brazil.

New duplicate genes can rapidly diverge from their parental copies in sequence and expression, and acquire novel or specialized functions. Understanding their divergence can shed light on the molecular mechanisms leading to evolutionary innovations. Here, we explore the functional evolution of *Zeus* and *Poseidon* (CG2053), two young genes that duplicated from the same parental gene, *Caf40*, in *Drosophila*. *Caf40* encodes a broadly expressed and highly conserved nucleic acid binding protein in eukaryotes, which is part of a regulatory complex that plays a prominent role in many aspects of transcriptional and translational regulation of many genes. Previous works have shown that *Zeus* affects the expression of a different set of genes from those regulated by *Caf40*, and acquired an important role in male fertility. Curiously, we recently found an older *Caf40* duplicate, which we call *Poseidon*, whose evolutionary trajectory resembles *Zeus*': both originated through retrotransposition of *Caf40*, are only expressed in testis and larval imaginal discs, and rapidly diverged in amino acid sequence, exhibiting signals of positive selection. In addition, both duplicates underwent a burst of amino acid replacements shortly after duplication, whereas more recent branches have rates consistent with purifying selection.

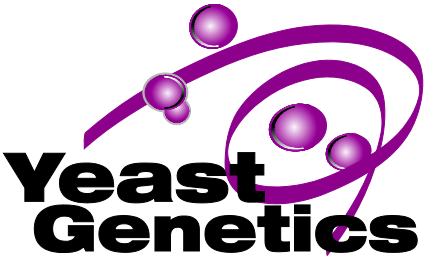
Strikingly, we found that many crucial residues that are invariable among Caf40 proteins from distantly related eukaryotes were substituted in Zeus and Poseidon (for instance, respectively 22% and 51% of the totally conserved sites in the Caf40 alignment were replaced in the duplicates), which suggests that fundamental properties of the original protein may have been altered in the young copies. Using RNAi knockdown in *D. melanogaster*, we also found that silencing *Zeus* results in a 30% decrease in egg to adult survival compared to controls. The impact on both viability and fertility suggests that the young gene was coopted in different tissues and developmental contexts. We will further test the hypothesis that the duplicate paralogs enrolled in new cellular processes by recruiting new protein partners. In addition, the independent evolution of duplicates of the same parental gene suggests that some molecular properties, such as the ability of engaging in protein interactions, may increase the probability of young genes being retained and evolving new functions.

P2155B Function of Ssl2 in RNA Polymerase II Transcription Start Site Scanning. *T. Zhao*, C. Kaplan. Texas A&M University, College Station, TX.

Protein-coding genes are transcribed by RNA polymerase II (Pol II) in three sequential stages: initiation, elongation, and termination. During initiation, Pol II cooperates with general transcription factors (GTFs), including TFIIB, TFIID, TFIIE, TFIIF and TFIIH, for DNA binding, promoter melting, transcription start site (TSS) selection, initial RNA synthesis, and the escape of Pol II from the promoter. TSS selection is the step that determines how many and how efficiently TSSs are used, but the selection mechanism is unclear. In *Saccharomyces cerevisiae*, Pol II finds TSSs through a "scanning" process by which TFIIH's translocase activity melts the promoter, and the Pol II machinery scans downstream for usable TSSs. Our studies support promoter scanning at all yeast promoters by showing that Pol II mutants alter TSS distributions universally in the stereotypical, polar fashion predicted by scanning models. The role of TFIIH in promoter scanning steps downstream of promoter melting is less

well understood. We have proposed a "shooting gallery" model for promoter scanning, where Pol II and TFIIH activities work together to determine the distribution of TSSs and promoter output in yeast. We have identified novel alleles of *SSL2* in genetic screens for *ssl2* mutants with putative initiation defects. Our screens have identified a number of *ssl2* alleles separable into distinct classes based on in vivo growth and transcription phenotypes. We propose that some of these alleles alter promoter scanning in ways that are distinct from how changes to the Pol II active site alter promoter scanning. Our goal is to determine how Pol II and Ssl2/TFIIH work concurrently to promote transcription initiation and influence promoter output.

Yeast Genetics Meeting



Poster Session Abstracts

Y3001A Elimi-NAD-ing fat in old mother yeast cells. *A. O. Beas*, J. C. Berude, J. J. Hsu, K. L. Zhou. Fred Hutchinson Cancer Research Center, Seattle, WA.

In an effort to identify and understand fundamental mechanisms of aging, we screened for changes that occur in the organelles of replicatively aging "mother" cells of the budding yeast, S. cerevisiae. In this screen we identified key changes, including an age-dependent accumulation of lipid droplets (LDs) as shown by staining of LDs and fluorescent tagging of known LD proteins. Classically, LDs are storage sites for energy in the form of neutral lipids (NLs) and therefore play important roles in energy metabolism and lipid-based signaling. To begin to understand the genetic network that underlies LD accumulation during aging, we carried out semi-targeted gene mutation analysis and screened for delays in the age of onset of LD accumulation. Surprisingly, deletion and/or overexpression (OE) of genes known to affect LDs had minor effects on LD accumulation during aging. In fact, deletion of only one of the four acyltransferases that synthesize triacylglycerol, the major NL of LDs, suppressed LD accumulation during aging. These data suggest that a limited number of biosynthetic pathways underlie LD accumulation during aging. Age-associated LD accumulation was also delayed by deletion of Longevity Assurance Gene 1, which encodes the founding eukaryotic ceramide synthase; interestingly, LAG1 was the first gene ever described that when deleted extends the lifespan of an organism (D'mello et. al. JBC 1994). These data suggest a role for sphingolipids in LD accumulation and correlates increased LDs with reduced lifespan. Furthermore, LD accumulation during aging was delayed by OE of the conserved and rate-limiting enzyme of the pathway for nicotinamide adenine dinucleotide (NAD+) biosynthesis. Because NAD+ levels have been shown to decline during aging in eukaryotes, our data suggests that the age-dependent accumulation of lipid droplets is influenced by the age-dependent decline in the levels of NAD+. The levels of NAD+ are regulated in yeast by processes such as biosynthesis, NAD+ dependent histone deacetylases (i.e., sirtuins), the salvage pathway, and the repertoire of NAD+ dependent metabolic reactions occurring at any given time. Lastly, we investigated whether LD accumulation during aging was sensitive to genetic manipulation of the processes that regulate NAD+ levels and to treatment with vitamin precursors of NAD+. We found that perturbations expected to increase NAD+ levels delayed/reversed age-associated LD accumulation, which suggests that the metabolic circuitry of old cells can be manipulated in ways that alleviate LD accumulation. We are now determining which NAD+ dependent metabolic processes influence NL metabolism with age and how those changes affect energy metabolism and lifespan. We speculate that our studies are relevant to the widespread obesity problem and its impact on the aging process and disease.

Y3002B Fin1-PP1 clears the spindle assembly checkpoint protein Bub1 from the kinetochore in anaphase. *M. Bokros*, C. Gravenmier, F. Jin, D. Richmond, Y. Wang. Florida State University, Tallahassee, FL.

The spindle assembly checkpoint (SAC) ensures faithful chromosome segregation during mitosis by preventing the onset of anaphase when the kinetochore is not attached. The mechanism for activation of the SAC has been well studied yet it remains ambiguous how the SAC is silenced after chromosome bipolar attachment. Recently we identified Bmh1, one of the two 14-3-3 proteins in S. cerevisiae, as a regulator of the SAC silencing. Data from our lab and others indicates that Bmh1 sequesters Fin1 and PP1, a key SAC silencing phosphatase, until early anaphase. We find this prevents premature SAC silencing. In addition, immediately following anaphase entry, the Cdc14 early anaphase release (FEAR) pathway promotes the release of Fin1-PP1 from Bmh1 allowing Fin1-PP1 to localize on the kinetochore. Importantly we find that kinetochore recruitment of Fin1-PP1 promotes the removal of the SAC protein Bub1 from the kinetochore during anaphase, thereby revealing a mechanism for SAC disassembly in anaphase. We are continuing to investigate the molecular mechanism for Fin1-PP1 mediated SAC disassembly and its physiological function during the cell cycle.

Y3003C How TORC controls growth through metabolism. *J. Chen*. UT Southwestern Medical Center at Dallas, Dallas, TX.

Nitrogen permease regulator 2 (Npr2) is a conserved negative regulator of target of rapamycin complex 1 (TORC1), which promotes cell growth and proliferation in nutrient-sufficient conditions. Npr2 forms a complex with Npr3 and Iml1, and can function as a GTPase activating protein (GAP) complex for the small GTPases important for TORC1 function. Npr2 is frequently deleted or mutated in cancers, suggesting it plays a critical role in cell growth control. Interestingly, yeast cells lacking Npr2 (*npr2Δ*) can grow faster or slower than wild type in a manner dependent on the growth medium. We dissected the metabolic changes that occur in *npr2Δ* cells under these different nutrient environments, which has revealed the consequences of deregulated TORC1 signaling in different contexts. These findings have started to help us understand what TORC1 is really doing to cellular metabolism to reciprocally regulate cell growth and autophagy.

Y3004A Cell-Cycle Control of a Pulse-Generating Network Restricts Frequency of Periodic Transcription. *C. Cho*, S. Haase. Duke University, Durham, NC.

Periodic transcription plays an essential role in eukaryotic cell cycle. We have proposed that a transcription factor (TF) network could function autonomously to drive genome-wide periodic transcription during the cell cycle in budding yeast *Saccharomyces cerevisiae*. In support of this model, multiple pulses of cell-cycle transcription persist even when budding yeast cells are arrested by perturbing the oscillation of S-phase and mitotic cyclin-dependent kinase (CDK) activity. However, how the dynamics of the TF network are coupled with the normal cell cycle remains unclear. Here we show that G1 cyclin-CDKs and Cdc14 phosphatase oppositely regulate the pulse-generating and pulse-transmitting capability of the TF network during cell cycle commitment and mitotic exit, respectively. Using an integrated genetic-genomic approach, we established that G1 cyclin-CDKs relieve the inhibition of the TF network by inhibiting transcriptional corepressors Whi5/Stb1 and E3 ubiquitin ligase complex APC-Cdh1. Importantly, genetic perturbation of Whi5/Stb1 and APC-Cdh1 in cells lacking G1 cyclin-CDK activity is necessary and sufficient for the TF network to drive a robust pulse of cell-cycle transcription. On the other hand, timely activation of Cdc14 in late mitosis is necessary for preventing ectopic pulses of cell-cycle transcription, potentially through reactivating Whi5/Stb1 and APC-Cdh1 to restore the

inhibition of the TF network. In conclusion, we propose that frequency control of periodic transcription in budding yeast is an emergent property of the global network with coupled CDKs and the pulse-generating network.

Y3005B The Yeast Genome Project: Exploring APD1. *C. A. Douds*, J. Keeney. Juniata College, Huntingdon, PA.

Yeast is considered to be "man's oldest industrial microorganism" and has been used by humans for over 5,000 years. Today, its use has expanded and *Saccharomyces cerevisiae* has become an ideal eukaryotic model due to its quick growth and easily manipulated genome. After its genome was sequenced in 1996, scientists came together to create a full encyclopedia of systemized gene functions characterized according to the Gene Ontology Consortium (GO). However, nearly twenty years later, the functions of more than 10% of these genes still remain unknown. The ORFan gene project aims to aid the characterization of the *S. cerevisiae* genome by exploring the function of specific open reading frames (ORFs). In order to classify these unknown ORFs, a putative pipeline has been constructed beginning with the identification of an ORFan of interest through the Saccharomyces Genome Database (SGD). This project focuses on YBR151W or *APD1*. The selected ORF is fluorescently tagged at the C and N terminals by PCR and visualized with fluorescent microscopy to verify cellular localization. Then a deletion strain is constructed and SGD reported phenotypes are verified. Verified phenotypes for *Δapd1* cells include increased H_2O_2 sensitivity and abnormal actin patch localization. Next, a comparison between the wild type and target gene knockout strains is analyzed through RNAseq. However, in this study RNAseq data has yet to be obtained. Instead, microarray analysis using SGD's SPELL was conducted to explore hypotheses. Further exploration into the putative function of *APD1* has led to studies involving actin patch localization, as well as the protein's potential role in oxidative stress mechanisms. We have observed the effects of actin patch localization under various forms of oxidative stress such as HU and H_2O_2 between wildtype and *Δapd1* strains.

Y3006C Mmf1p protects Hem1p from damage caused by the ubiquitous metabolic stressor, 2-aminoacrylate. *Dustin C. Ernst*, Diana M. Downs. University of Georgia, Athens, GA.

Members of the RidA/YER057c/UK114 protein family are observed throughout each kingdom of life. Despite being widespread, a biochemical role for these proteins *in vivo* remained elusive until work in *Salmonella enterica* showed RidA prevents free 2-aminoacrylate (2AA) accumulation. Strains lacking RidA experienced 2AA stress, revealed as damage to a variety of metabolic enzymes and decreased fitness. The generation of 2AA in *S. enterica* was dependent on the activity of pyridoxal 5'-phosphate (PLP)-dependent serine/threonine dehydratases (IlvA/TdcB; EC 4.3.1.19). Previous studies of *Saccharomyces cerevisiae* RidA homologs, Mmf1p (mitochondrial) and Hmf1p (cytosolic), showed the lack of Mmf1p resulted in a *petite* growth phenotype. Given the paradigm described for *S. enterica*, we hypothesized that 2AA accumulation, and the resulting damage to a PLP-dependent enzyme, was responsible for the growth phenotypes observed for *S. cerevisiae* Δmmf1 strains. The nuclear encoded serine/threonine dehydratases, Ilv1p (anabolic) and Cha1p (catabolic), are both localized to the mitochondrial matrix. When Ilv1p and Cha1p are simultaneously disrupted, respiratory activity is maintained in a Δmmf1 background. These results showed that diminished respiratory activity in the absence of Mmf1p is a consequence of 2AA formation. The paradigm in *S.* enterica suggested that the target for 2AA stress would be a PLP enzyme. Our data show that the first step in heme production, catalyzed by PLP-dependent aminolevulinic acid (ALA) synthase (Hem1p; EC 2.3.1.37), is inhibited in the absence of Mmf1p under conditions where 2AA is predicted to accumulate. Consistent with previous reports, diminished ALA production in *S. cerevisiae* adversely impacted respiration, perhaps highlighting a role for Mmf1p in maintaining Hem1 activity.

Y3007A Global Analysis of Molecular Fluctuations Associated with Cell Cycle Progression in *Saccharomyces cerevisiae*. *Ben Grys*[1], Helena Friesen[2], Oren Kraus[3], Adrian Verster[2], Brendan J. Frey[2,3], Charles Boone[1,2,4], Brenda J. Andrews[1,2,4]. 1) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 2) The Donnelly Centre for Cellular and Biomolecular Research, University of Toronto, Toronto, Ontario, Canada; 3) Electrical and Computer Engineering, University of Toronto, Toronto, Ontario, Canada; 4) Banting and Best Department of Medical Research, University of Toronto, Toronto, Ontario, Canada.

The regulation of protein expression, turnover, and localization has been recognized as imperative for eukaryotic cell cycle progression. However, there has been no systematic study of proteomic fluctuations throughout the cell cycle in eukaryotes. By combining Synthetic Genetic Array (SGA) technology with high-throughput fluorescence microscopy of the ORF-GFP fusion collection, we have generated image-based data for ~75% of the yeast proteome. Our strategy involves scoring diagnostic fluorescent markers that indicate cell cycle position, which permits the computational classification of yeast cells into one of six predetermined cell cycle stages, and subsequently quantifying protein abundance and localization for each member of the GFP collection, We automated cell cycle classification using a supervised neural network-based approach that functions with ~97% accuracy. With mean GFP-pixel intensity as a metric for protein abundance, we determined how the entire visible budding yeast proteome fluctuates over the course of the cell cycle. We have also adapted our neural network classification method for the automated assignment of GFP-fusion proteins to 21 different subcellular compartments. After applying statistical analyses, we have resolved those GFP-fusion proteins that change in abundance and/or localization in a cell cycle-dependent manner. When combined with cell cycle transcriptional information, and ribosome profiling, this unique platform will provide a resource that can be mined to better characterize existing pathways of cell cycle control, while also identifying novel players in the regulation of cell growth and division. On a broader scale, our dataset will allow us to study pre- and post-translational gene regulation in an ordered and highly conserved biological process, providing a unique opportunity that is not possible with existing eukaryotic data.

Y3008B Interplay between Rfa2 N-terminal phosphorylation and Rad53 dephosphorylation in regulating exit from a checkpoint in the presence of persistent DNA damage. *Stuart Haring*[1], Timothy Wilson[1], Jessica Kesson[1], Nolan Miles[1], Trevor Baumgartner[1], Sarah Klein[2],

Sakina Khaku[2], Andre Walther[2]. 1) North Dakota State University, Fargo, ND; 2) Cedar Crest College, Allentown, PA.

Replication Protein A (RPA) is a heterotrimeric, single-stranded DNA binding complex with critical roles in DNA metabolism and cell cycle progression. While human RPA is observed to be hyper-phosphorylated in response to genotoxic stress, primarily on the N-terminus (NT) of the 32 kDa subunit (Rpa2), the Rfa2 NT of yeast Replication Factor A (RFA) had not been identified as a major site of phosphorylation upon DNA damage induction. Despite this, examination of Rfa2 NT phospho-mutants strongly suggested that the phospho-state of the Rfa2 NT plays a key role in cell cycle progression, especially when DNA damage persists. This phenomenon is termed checkpoint adaptation, and although it provides the cell the chance to survive and grow, it comes with the negative consequence of increased genomic instability that can ultimately lead to cellular disease.

Using *Saccharomyces cerevisiae*, it was demonstrated that in the presence of persistent DNA damage, Rfa2 NT hyper-phosphorylation is readily detected, and that the Rfa2 NT is required for checkpoint adaptation to occur. Phosphorylation of the Rfa2 NT is also observed upon prolonged exposure to an array of genotoxic agents. Using checkpoint kinase deletion strains, some kinases responsible for phosphorylation of the Rfa2 NT during genotoxic stress have been identified.

Additionally, a chimeric yeast Rfa2 containing the human Rpa2 NT was examined. This chimeric protein was previously demonstrated to be hyper-phosphorylated in response to an array of DNA damaging agents. The yeast Rfa2 containing the human Rpa2 NT displayed earlier and more robust phosphorylation after stress than cells containing wild-type (WT) Rfa2. Furthermore, this robust phosphorylation of the chimeric Rfa2 promoted dephosphorylation of Rad53 and even earlier and more efficient checkpoint adaptation than in WT Rfa2-containing yeast cells.

Taken together, the data suggest a model where Rad53 deactivation (necessary for checkpoint bypass) and Rfa2 NT phosphorylation are linked to coordinate checkpoint adaptation in yeast. Specifically, Rfa2 NT phosphorylation drives Rad53 dephosphorylation to promote bypass of the checkpoint despite the continued presence of DNA lesions. Understanding how the Rfa2 phospho-state influences cell cycle progression in the presence of genotoxic stress will assist in deciphering the molecular signaling mechanisms cells employ to maintain the integrity of their genomes.

Y3009C The function of Sgo1-centromere recruitment pathway and spindle assembly checkpoint silencing. *F. Jin*, Y. Wang. Florida State University, Tallahassee, FL.

Accurate chromosome segregation during cell division is critical to maintain genomic stability. Kinetochore-microtubule bipolar attachment, in which sister chromatids attach to microtubules emanating from opposite spindle poles, ensures chromosome segregation fidelity. Improper kinetochore microtubule attachments activate the spindle assembly checkpoint (SAC) to prevent anaphase onset. Following kinetochore bi-orientation, the SAC is silenced allowing for anaphase onset. The aurora kinase Ipl1, and a centromere-associated protein Sgo1, sense bi-orientation defects and delay anaphase entry. Previous works from our lab and others have found that Ipl1 and Sgo1 in *Saccharomyces cerevisiae* prevent SAC silencing in the presence of tension defects. How Sgo1 prevents SAC silencing is still unknown. Bub1 kinase facilitates Sgo1-centromere recruitment through phosphorylates H2A and Sgo1 further recruits Rts1. In this study, we find *bub1* kinase dead (*bub1-KD*), phosphodeficient H2A (*H2A-121A*), and *RTS1* deletion mutants all exhibit premature SAC silencing. In the presence of syntelic chromosome attachments, these mutants enter anaphase prematurely and result in high levels of chromosome missegregation. Moreover, these mutants suppress the anaphase entry delay of *dam1* phospho-mimicking mutant. Therefore, the centromere recruitment of Sgo1 plays a major role in preventing SAC silencing.

Y3010A Regulation of lifespan by vitamin B_6 metabolism-related genes in yeast. *Y. Kamei*, Y. Mukai. Nagahama Institute of Bio-Science and Technology, Nagahama, Shiga, JP.

Lifespan is thought to be largely determined by the combined effects of genetics and environmental factors including stress and nutrients. The effects on individual lifespan by a large amount of nutrients, such as carbohydrates and amino acids, and a limited amount of nutrients, such as vitamins, are well-studied. However, molecular mechanism of cellular lifespan determination by vitamins is not elucidated. Here, we show that pyridoxal 5'-phosphate (PLP), a biologically active form of vitamin B_6 (VB6) consisting of pyridoxine, pyridoxal, and pyridoxamine, is a key factor to regulate cellular lifespan of budding yeast. Through microarray analysis of yeast aging cells, we found that the expression of *SNZ1* gene encoding PLP synthase was increased in senescent cells. Yeast cells synthesize PLP via the salvage pathway as well as *de novo*, and import extracellular VB6 by a plasma membrane VB6 transporter Tpn1p. Deletion of *SNZ1* and *TPN1* shortened yeast replicative lifespan, which is defined by the number of daughter cells that a mother cell can generate before dying. Simultaneous deletion of *SNZ1* and *TPN1* severely shortened the lifespan. Excess supplementation of pyridoxine to medium restored the lifespan of the Δ*snz1* and Δ*tpn1* mutants to wild-type level. *SNZ1* overexpression in the Δ*tpn1* cells and *TPN1* overexpression in the Δ*snz1* cells prolonged the lifespan to normal. These data strongly suggested that VB6 regulates yeast replicative lifespan. To confirm this, we measured the intracellular content of VB6 by a microbiological assay and that of PLP by an enzymatic assay in the wild-type and mutant strains. The contents of VB6 and PLP in Δ*tpn1* mutant were decreased. Pyridoxine supplementation to Δ*tpn1* mutant culture recovered the VB6 and PLP contents to wild-type level. Overexpression of *SNZ1* in the Δ*tpn1* cells did not change the VB6 content but elevated the PLP content. These results reveal that the short lifespan of Δ*tpn1* cells is caused by reducing the PLP content. Unexpectedly, the VB6 and PLP contents of Δ*snz1* mutant were comparable to that of wild-type strain. We found that the VB6 and PLP contents were increased in senescent cells of both wild-type and Δ*snz1* mutant strains, suggesting that the elevated PLP level in old cells is due to increasing VB6 uptake by Tpn1p but not due to increasing de novo PLP synthesis by Snz1p. We propose that PLP is required for maintenance of cellular lifespan against aging.

Y3011B The role of protein acetylation in stress defense. *Jeffrey Lewis*[1], Rebecca Sides[1], Aaron Storey[2], Alan Tackett[2]. 1) University of Arkansas, Fayetteville, AR; 2) University of Arkansas for Medical Sciences, Little Rock, AR.

Cells face a staggering array of environmental challenges during their lifetimes. Not surprisingly, cells have evolved sophisticated rapid-response mechanisms to deal with acute environmental changes. Our focus has been on post-translational lysine acetylation, which was originally discovered as a histone modification over fifty years ago. Recent proteomic studies have identified thousands of acetylated proteins in diverse organisms, rivaling phosphorylation in terms of number of targets. While the sheer size of the "acetylome" points to its importance, we have little idea how acetylation affects protein function for the vast majority of targets. The striking enrichment of stress defense proteins as acetylation targets suggested an underappreciated role for protein acetylation in stress defense. We now provide evidence that protein acetylation plays a key role in stress defense. First, we have identified a post-translational mechanism for thermotolerance that requires properly coordinated protein acetylation. Second, through quantitative proteomics we observe extensive acetylome remodeling during acute heat stress. Intriguingly, we find increased acetylation of choline kinase (Cki1p) during heat shock, which in turn regulates Cki1p activity. Because Cki1p plays a known role in cell membrane turnover, this provides an exciting new link between protein acetylation and cell membrane metabolism during heat stress.

Y3012C A genome-wide screening identifies novel filament-forming metabolic enzymes in *Saccharomyces cerevisiae*. *J. L. Liu*[1], Q. J. Shen[1], H. Kassim[1], Y. Huang[1,2], H. Li[1,3]. 1) Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford OX1 3PT, United Kingdom; 2) Southwest University, Chongqing 400715, China; 3) Institute of Physics, Chinese Academy of Sciences, Beijing 100190, China.

Compartmentation via filamentation has recently emerged as a novel mechanism for the regulation of metabolism. In order to identify filament-forming metabolic enzymes systematically, we performed a genome-wide screening of all strains available from an open reading frame-GFP collection in *Saccharomyces cerevisiae*. We discovered 9 novel filament-forming proteins and also confirmed those identified previously. Out of the 4,159 strains, we found 23 proteins, mostly metabolic enzymes, that are capable of forming filaments in vivo. In silico protein-protein interaction analysis suggests that these filament-forming proteins can be clustered into several groups, including translational initiation machinery, glucose and nitrogen metabolic pathways. Using glutamine-utilising enzymes as examples, we found that the culture conditions affect the occurrence and length of the metabolic filaments. Furthermore, we found that two CTP synthases (Ura7p and Ura8p) and two asparagine synthetases (Asn1p and Asn2p) form filaments both in the cytoplasm and in the nucleus. Live imaging analyses suggest that metabolic filaments undergo sub-diffusion. Taken together, our results identify novel filament-forming proteins in *Saccharomyces cerevisiae* and suggest that filamentation of metabolic enzymes is more general than currently appreciated.

Y3013A TOR pathway mediates cytoophidium assembly in *Schizsaccharomyces pombe*. *J. L. Liu*, L. Hulme, K. Wesley. Department of Physiology, Anatomy and Genetics, University of Oxford, Oxford OX1 3PT, United Kingdom.

The essential metabolic enzyme CTP synthase catalyses CTP formation and has been demonstrated to form large, evolutionarily conserved intracellular filaments, termed cytoophidia (meaning cellular serpents in Greek). The exact functional role of cytoophidia, or how formation and maintenance is regulated remains unanswered. By monitoring cytoophidium formation in a GFP tagged CTP synthase background in *Schizsaccharomyces pombe,* we have discovered that the TOR (target of rapamycin) kinase pathway regulates cytoophidium formation. The TOR pathway is highly conserved and is essential for regulation of cell growth and response to nutrient deprivation. We show that the TOR signalling cascade is involved in cytoophidium assembly. Moreover, this relationship is specific to the TORC2 complex. This study connects cytoophidium assembly and the TORC2 complex which is potentially relevant considering the increasing evidence implicating these two major pathways in cancer development.

Y3014B Candida albicans Pho84 is required for anabolic TOR signaling, stress responses and virulence determinants. *Ning-Ning Liu*[1*], Priya Uppuluri[2], Kicki Ryman[3], Ylva Engström[3], Per Olof Ljungdahl[3], Julia R. Köhler[1]. 1) Boston Children's Hospital/Harvard Medical School, Boston, MA; 2) UCLA David Geffen School of Medicine, Torrance, CA; 3) The Wenner-Gren Institute, Stockholm University, Stockholm, Sweden.

Systems of phosphate homeostasis are required for virulence of bacterial pathogens. In a transposon mutant screen for new elements of *Candida albicans* Target of Rapamycin (TOR) signaling, we found a homolog of the major phosphate plasma membrane transporter in *S. cerevisiae*, Pho84, to be required for normal TOR activity. The link between Pho84 and TOR signaling in *C. albicans* does not seem to consist in pH homeostatic mechanisms, but appears to go through the EGO complex component Gtr1. Mutants in *PHO84* are hypersemsitive to cell wall stress and oxidative stress, and fail to eliminate reactive oxygen species. Their hyphal morphogenesis is misregulated, and they are defective in biofilm formation. They are unable to damage host cells in ex vivo models, and are killed more efficiently by neutrophils. In a wild type Drosophila model, they are nearly avirulent. The macronutrient phosphate is required for DNA replication, ribosome biogenesis, expansion of membranes and key metabolic processes like glycolysis and oxidative phosphorylation. We found its acquisition to be connected to critical functions in *C. albicans* pathogenesis.

Y3015C Response of quiescent cells to exogenous DNA damage. *L. J. Long*[1], J. S. Welty[1,2], M. A. Osley[1]. 1) University of New Mexico School of Medicine, Albuquerque, NM; 2) University of Pittsburgh, Pittsburgh, PA.

Under certain conditions, such as nutrient deprivation, cells exit the cell cycle and enter G0, a state of quiescence. Quiescent cells are viable but non-growing and can re-enter the cell cycle when appropriate stimuli are provided. Quiescence is an important feature of adult stem cells, where it provides a pool of cells for self-renewal or differentiation into appropriate cell lineages. Quiescent cells must respond to exogenous stresses such as DNA damage so that deleterious mutations are not transmitted to progeny upon differentiation. Our data show that quiescent

cells are more sensitive to UV irradiation when compared to growing cells. We find that the majority of UV lesions are removed from quiescent cells before these cells re-enter the cell cycle. Moreover, we observe that the frequency of UV-induced mutations is significantly higher in quiescent cells than in G1 arrested cells. We are currently using genetic, molecular, and genomic approaches to investigate the hypothesis that UV induced lesions are directly repaired in G0 cells through the gap-filling activity of mutagenic translesion DNA polymerases.

Y3016A Regulation of lifespan by phosphate starvation response factors in budding yeast. *Y. Mukai*, T. Maruhashi, S. Jiang, Y. Kamei. Nagahama Institute of Bio-Science and Technology, Nagahama, Shiga, JP.

Lifespan of organisms is determined by genetic factors and environmental factors, such as stress and nutrients. Calorie restriction is well studied to extend organismal and cellular lifespan in a variety of eukaryotes from yeast to mammals. Phosphate, an essential nutrient for all organisms, has been reported to be involved in lifespan regulation: the mutant mice lacking *klotho* exhibits hyperphosphatemia to shorten lifespan. However, molecular mechanism of lifespan regulation by phosphate is not known. Here, we show that phosphate starvation response factors regulate replicative lifespan in budding yeast. Yeast replicative lifespan, the number of daughter cells produced by a mother cell, is usually measured on YPD medium, which contains high amounts of phosphate. To know the effect of extracellular phosphate on yeast lifespan, we measured replicative lifespan on synthetic high- and low-phosphate medium. Phosphate restriction did not extend the lifespan of wild-type strain. Deletion of *PHO80* and *PHO85*, which encode cyclin and cyclin-dependent kinase in phosphate starvation response pathway, respectively, shortened the lifespan under both high and low phosphate conditions. Pho80p-Pho85p phosphorylates and exports transcription factor Pho4p from the nucleus under high phosphate condition, resulting in no expression of phosphate starvation response genes. Simultaneous deletion of *PHO80* and *PHO4* restored the lifespan to wild-type level, indicating highly expression of the Pho4p target genes by deletion of *PHO80* causes short lifespan. We screened for Pho4p target gene mutations that recovered the lifespan of the Δ*pho80* cells, and found such mutations in *VTC1*, *VTC2*, and *VTC4* genes. The *VTC* genes are transcriptionally regulated by Pho4p and are required for vacuolar polyphosphate accumulation. Deletion of *PPN1*, which encodes vacuolar polyphosphate phosphatase, also shortened the lifespan as did that of *PHO80*. *In vivo* ^{31}P-nuclear magnetic resonance analysis showed that polyphosphate was accumulated in Δ*pho80* and Δ*ppn1* mutants compared with the wild type, but not in Δ*pho80* Δ*pho4* mutant, indicating that accumulation of polyphosphate shortens yeast replicative lifespan.

Y3017B Natural variation in the cell adhesin, FLO11, and its effects on biofilm formation. *H. A. Murphy*, B. A. Lenhart, B. K. Meeks. William and Mary, Williamsburg, VA.

A biofilm is a type of cooperative microbial community that is found wherever microorganisms are found— in aquatic and terrestrial systems, in living and dead tissues, on medical devices and dental surfaces. These communities are anchored to a surface and enmeshed in a protective extracellular matrix, properties which lead to increased resistance to antimicrobials and environmental stresses. Recent work has demonstrated that some natural isolates of *Saccharomyces cerevisiae* are capable of forming complex, structured biofilm-like colonies, a phenotype known as complex colony morphology (CCM). The flocculin, Flo11p, is required for CCM and is involved in cell-cell and cell-surface adhesion. In order to investigate the role of FLO11 in natural cellular interactions, the gene and its 2kb regulatory region were sequenced in 55 isolates from various geographic and ecological niches using PacBio technology. These data exhibited a large amount of genetic variation, suggesting that numerous alleles are segregating in the global population and that they may affect inter-cellular interactions. Allele swaps were performed among a subset of the strains to determine the effect of the alleles on biofilm formation and showed a detectable effect of allele status. Finally, mixed-strain colonies were assayed to determine whether the different FLO11 alleles changed the interactions between the individual cells in the biofilm.

Y3018C *GPH1* over-expression rescues glycogen and calcium accumulation defects in a *pgm2Δ* mutant strain of *Saccharomyces cerevisiae*. *K. Ngo*, A. Charales, R. McDonald, V. Bahram, A. Selvamani, D. Aiello. Austin College, Sherman, TX.

Phosphoglucomutase (PGM) plays an important role in yeast carbohydrate metabolism. It is responsible for interconverting glucose-1-phosphate (G1P) and glucose-6-phosphate (G6P). Pgm2 is the major isoform of PGM in *Saccharomyces cerevisiae.* Yeast that lack *PGM2* exhibit slow growth, sensitivity to cyclosporine A, high glycogen accumulation, and calcium homeostasis defects when metabolizing galactose. The purpose of this investigation is to determine whether or not hyperaccumulation of glycogen contributes to other phenotypes observed in the *pgm2Δ* mutants. The high glycogen accumulation can be rescued using two different approaches: decreasing glycogen synthesis or increasing glycogen breakdown. To decrease glycogen synthesis, knockouts of the two known glycogen synthase enzymes, *gsy1Δ* and *gsy2Δ*, were constructed in both wt and *pgm2Δ* strains, alone and in combination. *GPH1*, encoding glycogen phosphorylase, was over-expressed to enhance glycogen breakdown in the context of the wt and *pgm2Δ* strains alone, and in combination with the *gsy1Δ* and *gsy2Δ* mutants. Gph1 is responsible for catalyzing the breakdown of glycogen to G1P. The growth, glycogen accumulation, and calcium accumulation phenotypes of each strain were analyzed. Glycogen accumulation was monitored by both iodine vapor staining and by quantitative enzymatic assay. Loss of either isoform of glycogen synthase (*gsy1Δ* or *gsy2Δ*) failed to rescue *pgm2Δ* defects. However, we report here that *GPH1* over-expression partially rescues the *pgm2Δ* cyclosporine A growth defect when metabolizing galactose as a carbon source. Additionally, *GPH1* over-expression rescues the high calcium and glycogen accumulation defects observed in *pgm2Δ* mutants.

Y3019A Strategies for metabolic engineering and optimization of *S. cerevisiae* into microbiofactories for the production of terpenes. *P. Prochasson*, T. Johnson, B. Wenndt, A. Kirkland, J. Whitaker, K. Thomas, D. Saran, S. Park, B. Julien. Evolva, Lexington, KY.

S. cerevisiae has been used for millenniums to make wine, beers and bread. The rise and development of Synthetic Biology has turned many micro-organisms, especially *S. cerevisiae*, into microbiofactories allowing the production of a wide range of molecules from other organisms in

a sustainable way using fermentation.

Evolva produces many important high value molecules from the terpene family (valencene, nootkatone, and rebD and rebM [components of the artificial sweetener Stevia]) which all use the same metabolic pathway to produce the isoprene precursor farnesyl pyrophosphate (FPP) used by terpene synthases.

We present an approach of combinatorial genome integrations of the mevalonate pathway genes into *S. cerevisiae* to maximize carbon flux towards terpene production. The levels of key metabolites are monitored during fermentation as an indicator of desired changes in the metabolic flux towards FPP. Flux imbalance can negatively affect terpene production, particularly when scaled-up. Hence, we applied a stepwise engineering method and took advantage of the push and pull strategy to minimize the accumulation of inhibitory concentrations of metabolites and maximize carbon flux to product formation.

We will also discuss strategies for biological formation of nootkatone from valencene. Nootkatone is not only important as a flavor and fragrance molecule but it also has potential applications in insect control. The CDC has shown that nootkatone both repels and kills ticks and mosquitos, making it a promising agent to control the spread of Lyme disease carried by the black-legged tick, *Ixodes scapularis*, and of the Zika virus carried mainly by the yellow fever mosquito, *Aedes aegypti*.

Y3020B NASA's BioSentinel mission: using the power of yeast genetics in deep space. *S. R. Santa Maria*, D. Marina, S. Bhattacharya. NASA Ames Research Center, Moffett Field, CA.

Ionizing radiation presents a major challenge to human exploration and long-term residence in space. The deep-space radiation spectrum includes energetic particles that can generate a series of DNA lesions, including DNA double strand breaks (DSBs). DSBs represent a major disruption in the integrity of the genome, which can lead to cell death or the onset of carcinogenesis. DSBs can be repaired without errors via homologous recombination (HR), a conserved pathway in all eukaryotes from yeast to humans. While progress identifying and characterizing biological radiation effects using Earth-based facilities has been significant, no source duplicates the unique space radiation environment.

We are currently developing a biosensor-based nanosatellite to fly aboard NASA's Exploration Mission 1 (EM-1) in 2018. Our biosensor uses *S. cerevisiae* to measure DSBs in response to ambient space radiation. The BioSentinel payload will contain a series of yeast strains, including: (1) a wild type strain as a control for yeast health and unrepairable DNA damage, (2) DNA repair defective strains that cannot repair DSBs and serve as radiation sensitive controls, and (3) a DSB BioSensor strain that can only grow in the presence of DSBs via heteroallelic HR repair. The BioSensor strain contains genetic defects that prevent growth until and unless a radiation-induced DSB near a reporter gene activates the yeast's HR repair mechanisms. Thus, cell growth indicates a successful DSB-and-repair event. In BioSentinel, desiccated cells will be carried within microfluidic cards, and each card will be activated by medium addition at different time points over 18 months. Cell growth and metabolic activity will be tracked continuously via optical density. One reserve set will be activated only if a solar particle event (SPE) occurs during the mission. Biological measurements will be compared to data provided by onboard dosimeters and to Earth-based experiments.

BioSentinel will conduct the first study of biological response to space radiation outside Low Earth Orbit in over 40 years. BioSentinel will thus address strategic knowledge gaps related to the biological effects of space radiation and will provide an adaptable platform to perform human-relevant measurements in multiple space environments, including the International Space Station (ISS), on and around other planetary bodies, and other exploration platforms.

Y3021C Dissecting the role of the transcription factor Hap1 in *Saccharomyces cerevisiae* respiration and fitness. *K. C. Serdynski*, D. Boulton, C. Ramirez, S. Renna, M. J. Hickman. Rowan University, Glassboro, NJ.

Oxygen is crucial for the survival of many organisms, as it functions as the final electron acceptor in aerobic respiration and as a substrate in essential biosynthetic reactions. Several cell types experience hypoxia, or reduced oxygen levels, including human cells within tumors and tissues during cardiovascular disease. Cells of the yeast *Saccharomyces cerevisiae* are similar to human cells in that they adapt to hypoxia by mounting a large gene expression response. One of the mediators of this response is the heme-dependent transcription factor Hap1, functionally analogous to human Rev-Erb. Hap1 activity is regulated directly by binding the biomolecule heme, which converts Hap1 from a repressor to an activator of genes involved in aerobic respiration and other cellular processes. Heme biosynthesis requires oxygen, so the level of cellular heme is dependent upon oxygen level. Despite Hap1 playing a critical role in regulating cellular respiration, *hap1Δ* cells do not have an obvious phenotype during aerobic or hypoxic conditions. Thus, we took several approaches to test how Hap1 contributes to cellular function and fitness. First, we found that deleting the *HAP1* gene had no effect on replicative lifespan, showing that dysregulation of respiration does not affect aging. Second, we found through competitive growth assays that a strain without *HAP1* exhibited a lower fitness per generation compared to a wild type strain. This lower fitness was observed on both fermentable and non-fermentable carbon sources, demonstrating that Hap1 is required for optimal cellular fitness by promoting aerobic respiration. Third, we wanted to test whether Hap1 is important in fermentation as well, so we constructed a strain unable to undergo aerobic respiration. In this strain, deleting *HAP1* does not affect growth on glucose, indicating that Hap1 does not play a role in fermentative respiration. Together, our results suggest that while Hap1 is not absolutely required for respiration, Hap1 provides a fitness advantage by fine-tuning aerobic respiration.

Y3022A Nutrient starvation induces upregulation of α-mannosidase Ams1 in *Saccharomyces cerevisiae*. *M. Umekawa*[1], M. Ujihara[1], K. Makishima[1], S. Yamamoto[1], H. Takematsu[2], M. Wakayama[1]. 1) Ritsumeikan University, Kusatsu, JP; 2) Kyoto University, Kyoto, JP.

Cells have evolved the mechanisms to survive nutritional shortages in the environment. In *Saccharomyces cerevisiae*, α-mannosidase Ams1 is known to play a role in catabolism of *N*-linked free oligosaccharides in the cytosol. Although, this enzyme is also known to be transported selectively from the cytosol to the vacuoles by autophagy, the physiological significance of this transport has not been clarified.

To elucidate the regulatory mechanism of the activity of Ams1, we assessed the enzymatic activity of the cell free extract of the wild-type and various gene disruptants under different nutritional conditions. In addition, the regulation of Ams1 at both transcription and post-translation was examined. The activity of Ams1 was significantly increased upon the depletion of glucose in the medium. Interestingly, the activity of the enzyme was also stimulated by nitrogen starvation. Our data showed that the activity of Ams1 is regulated by the stress responsive transcriptional factors Msn2/4 through the protein kinase A and the target of rapamycin complex 1 pathways. In addition, Ams1 is post-translationally activated by Pep4-dependent processing in the vacuoles.

Y3023B Differential Acetylation of Protein N-Termini in Response to Nutrient Starvation. *S. Varland*[1], P. Van Damme[2,3], J. Hollebeke[2,3], F. Kryuchkov[1], H. Aksnes[1], K. Gevaert[2,3], T. Arnesen[1,4]. 1) Department of Molecular Biology, University of Bergen, Bergen, Norway; 2) Department of Medical Protein Research, Vlaams Instituut voor Biotechnologie, Ghent, Belgium; 3) Department of Biochemistry, Ghent University, Ghent, Belgium; 4) Department of Surgery, Haukeland University Hospital, Bergen, Norway.

N-terminal acetylation (Nt-acetylation) is a ubiquitous protein modification involving the transfer of an acetyl moiety from acetyl-CoA to the α-amino group of a nascent polypeptide. The modification is presumed irreversible and is catalyzed by a group of enzymes called N-terminal acetyltransferases (NATs). The NATs have defined substrate specificities, which are largely determined by the N-terminal sequence identity. The acetylation event can be partial or complete and occurs primarily cotranslational. The biological role of Nt-acetylation remains an enigma. Increasing evidence suggest that Nt-acetylation has diverse molecular functions depending upon the protein being targeted, such as protein degradation, protein folding, protein-protein interaction, and membrane targeting.

Another major type of protein acetylation is the more commonly known lysine acetylation. Unlike Nt-acetylation, lysine acetylation is a reversible process, due to the action of lysine deacetylases. An additional level of regulation is provided by the sensitivity towards the availability of acetyl-CoA. This is particularly the case for histone lysine acetylation where energy availability, and thus acetyl-CoA levels, is linked to altered expression of genes involved in metabolism.

Although the intricate linkage between lysine acetylation and metabolism has been highlighted by several studies, the effect of cellular energy status on Nt-acetylation remains unclear. To address this, we have used COFRADIC proteomics to perform a global analysis of Nt-acetylation in response to nutrient starvation. Our study shows that Nt-acetylation is largely unaffected by alterations in cellular metabolism. However, a minor group of cytosolic proteins are differentially acetylated at their N-termini. The majority of affected neo-N-termini presented the same acetylation trend as histones, becoming less acetylated at stationary phase. To our surprise, a group of affected mature N-termini were more acetylated in stationary phase as compared to active phase. Our results indicate that specific Nt-acetylation events are subjected to metabolic-dependent regulation. This is the first study concerning regulation of Nt-acetylation from a nutrient perspective, and thus provides an important insight to metabolic regulation of protein acetylation as an entirety.

Y3024C Identification of Unforeseen Functions of Ataxin-2, a Conserved Protein Linked to Neurodegenerative Disease. *Y. S. Yang*, X. Wu, B. P. Tu. UT Southwestern Medical Center, Dallas, TX.

Poly-glutamine expansions in ataxin-2 have been linked to neurodegenerative diseases, but the disease-driving mechanism remains elusive. Unexpectedly, we identified the yeast ortholog of ataxin-2, Pbp1p, in a screen for novel regulators of autophagy. Autophagy is a process that degrades cytoplasmic contents and damaged organelles to maintain cell viability during nutrient starvation, and is thought to be an effective mechanism for degrading aggregation-prone proteins linked to neurodegenerative diseases. Our work aims to understand how Pbp1p functions to induce autophagy in response to the metabolic status of cells. In efforts to understand the regulation mechanism, we have focused on its localization properties under different nutrient conditions and its effects on cellular metabolism. The potential function of ataxin-2/Pbp1p in autophagy hints that alterations in this function could play a key role in neurological pathogenesis.

Y3025A Phospholipid methylation regulates sulfur homeostasis in coordination with maintenance of the epigenome. *C. Ye*, B. M. Sutter, Z. Kuang, B. P. Tu. The University of Texas Southwestern Medical Center, Dallas, TX.

Phospholipids are the major component of cell membranes that compartmentalize metabolism and a variety of other processes. Not surprisingly, the regulation of the synthesis of phospholipids necessitates coordination with metabolic status. However, how cells might utilize membrane lipids in cellular and metabolic homeostasis is poorly understood. Among thousands of metabolic reactions, the transmethylation reaction is one of the most important and universal. The reaction transfers a methyl group from the donor S-adenosylmethionine (SAM) to a variety of cellular substrates, including proteins, lipids, nucleic acids, and cellular metabolites. These SAM-dependent methyltransferases engage in nearly every aspect of biology, thereby underscoring the importance of SAM homeostasis. I recently found in the yeast *Saccharomyces cerevisiae* that the methylation of particular phospholipid species is the major cellular consumer of SAM, and dysregulation of phospholipid methylation has remarkable consequences on other methylation events ongoing in the nucleus. Using a combination of approaches in genetics, metabolomics, and biochemistry, I addressed an underappreciated link between phospholipid metabolism and the maintenance of the epigenome. I propose a cellular strategy through which cells integrate epigenetic regulation with metabolic information from membrane lipids.

Y3026B Production of volatile aroma compounds by yeast during fermentation of Chinese Baijiu. *C. Zhang*[1,3], W. Li[2,3], J. Wang[2,3], Y. Chen[1,3], D. Xiao[1,3]. 1) Key Laboratory of Industrial Fermentation Microbiology, Ministry of Education, Tianjin University of Science and Technology, Tianjin, CN; 2) Tianjin Industrial Microbiology Key Laboratory, Tianjin University of Science and Technology, Tianjin, CN; 3) College of Biotechnology, Tianjin University of Science and Technology, Tianjin, CN.

Appropriate levels of volatile aroma compounds are the most important factors influencing the quality of Chinese Baijiu, an alcoholic beverage from China, and the perception of Chinese Baijiu flavor and aroma is the result of a large amount of interactions between a great deal of volatile aroma compounds and sensory receptors. During fermentation of Chinese Baijiu, most of the volatile aroma compounds are owing to the metabolic activity of microbial community. Yeast, one of the most important microorganisms, plays an important role in formation of higher alcohols, esters and many other aroma compounds. Meanwhile, many environmental factors greatly affect the production of volatile aroma compounds, of which yeast-derived aroma compounds are affected by factors acting on the expression of relevant yeast genes. The known function and regulation of several individual genes are involved in volatile aroma metabolism of *Saccharomyces cerevisiae*. *ATF1* and *ATF2* genes code for alcohol O-acetyltransferases, key enzymes for the synthesis of acetate esters from higher alcohols. *EHT1*- and *EEB1*-encoded esterases are required for synthesis of the medium-chain volatile flavor esters. Isoamyl acetate is degraded into a higher alcohol by the catalysis of *IAH1*-encoded esterase. *BAT2* gene codes for a cytosolic branched-chain amino acid aminotransferase which plays an important role in the synthesis of branched-chain alcohols. *LEU1*-, *LEU2*-, and *ILV1*-encoded enzymes affect the production of higher alcohols in Harris pathway. Different environmental factors effect on the expression of these gene to have a large impact of volatile aroma production. Furthermore, in fermentation process of Chinese Baijiu, material, composition of distillers' grains, temperature and oxygen have great influences on the quality of base liquor.

Y3027C Newly made prion particles must overcome actin-based spatial quality control mechanisms. *A. L. Manogaran*, D. Lyke, J. Dorweiler, E. Legan, B. Wisniewski. Marquette University, Milwaukee, WI.

Prions are self-perpetuating misfolded proteins that can be passed during cell division. *De novo* formation of yeast prions naturally occurs at an extremely low frequency. Yet, increasing the level of the prion protein can induce higher prion frequencies, presumably because the abundance of protein molecules makes it more likely that a small percentage of proteins misfold and form prions. Using the prion [*PSI*$^{+}$], which is the misfolded version of the Sup35p translation termination protein, prion formation can be monitored by transiently over expressing the prion domain of Sup35p fused to GFP. A notable early hallmark of prion induction is the formation of cytoplasmic fluorescent rings. These ring-like structures are retained in the mother cell, and prion induction is dependent upon inheritance of prion particles by the daughter cells. Our previous work identified several genes that reduced prion induction. These genes fell into two groups: the first affects ring formation, and the second appears to be involved in later events after the ring has formed. Since most of the genes identified encoded proteins associated with the actin cytoskeleton, we further investigated the role of actin in prion formation. We found that low levels of the actin cable-disrupting drug, Latrunculin A, had no effect on ring formation, but increased prion induction frequency. Similar effects were identified in an actin mutant with documented cable defects, *act1-101*, suggesting that actin cables are important for later stages of prion formation. It was previously shown that altered actin networks in strains lacking *SIR2* reduce the asymmetrical retention of damaged proteins to the mother cell. To explore whether the actin effects on prion induction are due to spatial quality control, we induced prion formation in *sir2D* strains. We found that ring formation was again unaffected in *sir2D* strains, but prion induction frequency was significantly increased. Taken together, our data suggests that later prion events are dependent upon the ability to overcome spatial quality control mechanisms.

Y3028A Duplication of the budding yeast spindle pole body. *D. Rüthnick*, A. Neuner, E. Schiebel. Zentrum für Molekulare Biologie Heidelberg (ZMBH), DKFZ-ZMBH Allianz, Heidelberg, DE.

The functional equivalent of the centrosome in budding yeast is the spindle pole body (SPB). It is the principle microtubule-organizing center. For centrosomes and SPBs it is crucial that they, just like DNA, duplicate exactly once per cell cycle. During this process the parental structure serves as a nucleation platform for the assembly of the new complex. A major difference in duplication of SPBs and centrosomes arises from the fact that budding yeast undergoes a closed mitosis without nuclear envelope (NE) breakdown. Therefore the new SPB has to be embedded into the NE to fulfill its microtubule organizing functions. The process of SPB duplication starts in anaphase with the elongation of the half bridge into a full bridge. In a next step, the satellite, a miniature version of the SPB, develops at the distal end of this bridge structure on the cytoplasmic side of the NE. After the Start point of the cell cycle the satellite grows into the duplication plaque, which simultaneously becomes inserted into the NE. In the a final step, after the assembly of the nuclear side of the SPB components, the bridge is severed in its center and the two SPBs become the poles of the mitotic spindle.

Our lab is particularly interested in the two major characteristics of the SPB cycle: restricting SPB duplication to one event per cell cycle and insertion of the duplication plaque into the NE. In order to get new insights into these topics we uncoupled duplication plaque formation from NE insertion. We then ask whether the overly large duplication plaque subsequently can be inserted into the NE. For this, we applied standard fluorescence microscopy, super-resolution microscopy (PALM, dSTORM, SIM) and electron microscopy next to a variety of molecular techniques. Our analysis identified novel properties of SPB components and showed that structures as big as 1 µm can be inserted into the NE post-assembly.

Y3029B A new experimental system to study meiotic non-allelic homologous recombination in yeast. *H. N. Conover*, J. L. Argueso. Colorado State University, Fort Collins, CO.

Nearly half of the genetic differences between individuals are rooted not in their nucleotide DNA sequences, but instead come from changes in chromosome structure known as copy number variations (CNVs). Such structural variation causes genes within certain genomic regions to deviate from the “normal” two copies found in a standard diploid cell. *De novo* gene copy number variations (CNV) are now recognized as a significant source for a wide range of human diseases, including autism spectrum disorder. However, the cellular mechanisms and

environmental factors that contribute to copy number mutagenesis still are poorly understood. In the human germline, meiotic recurrent CNVs form through non-allelic homologous recombination (NAHR) between low copy repeat elements (LCRs). Such large repeated sequences are found at CNV hotspot regions of our genome, but are absent in *Saccharomyces cerevisiae*. To study LCR-mediated CNV pathways in this tractable model system, we modified a yeast chromosome through the introduction of engineered LCRs: 10 to 40 Kb segments of yeast DNA that we duplicated to simulate the NAHR substrates that exist in humans. The engineered LCRs flank allelic insertions of genes encoding resistance to geneticin and hygromycin (KanMX and HphMX, respectively) and the *SFA1-CUP1* cassette that confers dose dependent resistance to copper and formaldehyde (CuFA). The segregation of these markers in the haploid cell progeny within tetrads is used to identity and classify CNV events. Normal allelic recombination produces cells that express one of each drug resistance marker (never both together), and intermediate resistance to CuFA. In contrast, interhomolog NAHR between the LCRs produces tetrads with a pair of haploid cells expressing (i) double drug resistance and hyper-resistance to CuFA, and (ii) double drug sensitivity and hypersensitivity to CuFA. These spores carry, respectively, recombinant chromosomes with reciprocal segmental duplication and deletion. Tetrads that contain an intersister NAHR event have a pair of spores with (iii) single drug resistance and hyper-resistance to CuFA, and another (iv) sensitive to both drugs and hypersensitive to CuFA. Finally, intrachromatid NAHR between the LCRs produces tetrads in which only one spore has a deletion of the markers, without an associated duplication. This system allows us to not only measure the overall frequency of *de novo* meiotic CNV, but also to determine the relative occurrence of each of the NAHR classes. We are using this approach to investigate meiotic CNV mechanisms and to interrogate the CNV stimulation activity of a diverse panel of candidate meiotic genes and environmental copy number mutagens. The experimental system will be described in the poster, with our initial analyses of the role of LCR size and distance from each other on the formation of CNVs.

Y3030C Program number not assigned

Y3031A Coordination of meiotic cytokinesis by the GCKIII kinase, Sps1. *L. S. Huang*[1], S. M. Paulissen[1], C. J. Slubwoski[1,2], J. M. Roesner[1,3], B. C. Seitz[1]. 1) Univ Massachusetts, Boston, Boston, MA; 2) Beth Israel Deconess Medical Center, Boston, MA; 3) Merck, Boston, MA.

During sporulation, an atypical cytokinesis event occurs in which prospore membranes grow from the spindle pole bodies to engulf the meiotic nuclei. As the prospore membranes grow, they assume varying morphologies, first appearing as small cups, then forming elongated structures around the nucleus, before rounding up and closing. The leading edge of the growing prospore membrane is marked by a complex of proteins, which include Ssp1; these proteins are removed from the leading edge when the prospore membrane closes. We find that the GCKIII kinase encoded by *SPS1* is required for this process, with *SPS1* acting together with the sporulation-induced *SPO77* to promote prospore membrane closure. Cells lacking either *SPS1* or *SPO77* make hyper-elongated prospore membranes that sometimes do not close. Previous studies show that cells lacking *AMA1*, which encodes an activator of the meiotic anaphase promoting complex, also have partially penetrant prospore membrane closure defects. Our genetic analyses demonstrate that *SPS1* and *SPO77* act in parallel to *AMA1*, as double mutants of either *sps1* or *spo77* and *ama1* exhibit completely penetrant prospore membrane closure defects. We also find that *SPS1* acts through *SSP1*. We see that Ssp1 is stabilized and not properly removed from the leading edge at the time of prospore membrane closure in *sps1* mutants. Sps1 and Ssp1 are found in a complex, suggesting that the action of Sps1 on Ssp1 may be direct. Taken together, our results suggest that Sps1 regulates meiotic cytokinesis by promoting the proper degradation and/or removal of Ssp1. To determine how this cytokinetic event is coordinated with meiosis, we have examined how meiotic regulators interact with *SPS1*.

Y3032B The synaptonemal complex is dispensable for MutSγ-mediated crossover recombination during meiosis in budding yeast. *A. J. MacQueen*, K. Voelkel-Meiman, S. Morehouse, M. Parziale, Michelle Cheng. Wesleyan University, Middletown, CT, USA.

Meiosis is a specialized cell division that enables sexually reproducing organisms to generate reproductive cells with reduced chromosome ploidy. Crossover recombination is normally essential for successful ploidy reduction during meiosis, as crossovers create attachments that orient homologous chromosomes and facilitate their subsequent segregation apart from one another on the spindle. Thus, the meiotic cell must ensure a sufficient number of recombination events repair as interhomolog crossovers (instead of non-crossovers). Many of the events that process meiotic DNA repair intermediates into interhomolog crossovers occur within the context of a meiosis-specific tripartite structure called the synaptonemal complex (SC), which assembles along lengthwise-aligned homologous chromosomes. Mutants missing building block components or regulators of SC assembly typically exhibit reduced or absent crossover recombination. In several organisms including budding yeast, crossovers specifically associated with SC are mediated by MutSg, a set of proteins related to the prokaryotic MutS family of mismatch repair enzymes. Despite the correlation between SC and crossover formation, the functional relationship between the SC structure, SC components, and MutSg crossover recombination has remained obscure. Our analysis of several budding yeast mutants demonstrates unequivocally that the SC structure is dispensable for MutSg crossover formation. First, through an interspecies complementation experiment we found that the crossover promoting activity of budding yeast SC component, Zip1, can be replaced by *Kluyveromyces lactis* Zip1, yet *K. l.* Zip1 does not assemble SC in *S. cerevisiae* cells. Second, we found that mutants missing either of the SC central element proteins - Ecm11 or Gmc2 - exhibit no deficit in, but rather an increase in, MutSg crossovers. We furthermore identified a non-null *zip1* mutant that phenocopis *ecm11* and *gmc2* mutants: *zip1-N1* mutant meiotic cells fail to assemble SC and exhibit an elevation in MutSg crossovers. Our studies reveal that the SC structure is built of two classes of components: Zip1 represents an SC component with genetically separable activities that promote crossover recombination and SC assembly, while the central element proteins Ecm11 and Gmc2 solely function in SC assembly. Interestingly, we discovered that *ecm11* and *gmc2* mutants exhibit a mismatch repair defect during meiosis. The mismatch repair activity associated with SC central element proteins does not require Ecm11 SUMOylation, suggesting that it is independent of the SC structure *per se*. Thus both SC

transverse filaments and central element components collaborate in building SC structure that attenuates crossover recombination, while these proteins act independently of the SC structure to positively influence recombination in distinct ways.

Y3033C Coupling activation of the Smk1 MAPK to the completion of meiosis. *G. Omerza*, CW. Tio, T. Phillips, E. Winter. Thomas Jefferson University, Philadelphia, PA.

Smk1 is a meiosis-specific MAPK that controls spore morphogenesis in *S. cerevisiae*. While Smk1 is activated by phosphorylation of its T-X-Y activation loop similar to other MAPKs, this pathway does not require a MAPK kinase family member. Instead, the CDK activating kinase, Cak1, phosphorylates Smk1 on the T, producing a low activity form of the enzyme that is uniformly distributed throughout the cell early in meiosis. Smk1 autophosphorylates the Y in-cis at prospore membranes (PSMs) at anaphase II. This spatiotemporally-regulated autophosphorylation reaction is triggered by Ssp2, a PSM-localized protein whose translation is induced specifically at anaphase II. To interrogate the mechanism of this developmentally-regulated autophosphorylation reaction, Smk1 activation has been reconstituted in bacterial cells and with purified proteins. Our data indicate that Ssp2 binding to Smk1 is sufficient to trigger Smk1 autophosphorylation. We previously reported that the meiosis-specific bridging protein for the anaphase promoting complex (Cdc20 homolog), Ama1, regulates Smk1 activation. We find that Ama1 controls Smk1 autophosphorylation by influencing the interaction of Smk1 and Ssp2 at the PSM. Thus, despite the timely production and localization of Smk1 and Ssp2 to PSMs in the *ama1Δ* background, they fail to form a complex. We will present a model in which Ama1 triggers the productive interaction of Ssp2 and Smk1, thereby coupling the completion of the meiotic chromosome cycle to spore wall differentiation.

Y3034A Kel1p mediates yeast cell fusion through a Fus2p and Cdc42p-dependent mechanism. *Jean Smith*, Mark Rose. Princeton University, Princeton, NJ.

Cell fusion is ubiquitous among eukaryotes. However, little is known about the molecular mechanism. In yeast, as cells polarize growth toward the mating partner, the tip of the shmoo comes into contact with its partner, forming a zone of cell fusion. As such, the shmoo tip comprises a hub for proteins necessary for cell fusion. Fus2p, a key regulator of cell wall removal during fusion, forms a heterodimer with Rvs161p, an amphiphysin, and the complex localizes to the shmoo tip. We have shown that Rvs161p facilitates the membrane interaction required for cortical localization. However, domain mapping of Fus2p revealed that the last eight amino acids form a novel signal also required for localization, independent of Rvs161p. Point mutations and truncations in this region cause severe mating defects. Analysis of successive C-terminal Fus2p truncations suggested a model in which an auto-inhibitory mechanism interferes with localization via an upstream region. Previous evidence showed that Fus2p is retained at the shmoo tip by both Fus1p and actin-dependent pathways. Fus1p is a pheromone-induced transmembrane protein broadly localized to the shmoo tip. We find that the actin-dependent pathway requires the C-terminus, whereas the Fus1p pathway depends on more internal sequences. Thus, the C-terminal mutations affect both pathways through auto-inhibition. To identify additional proteins interacting with Fus2p, we performed a high copy suppressor screen of the C-terminal mutations, and identified Kel1p. *KEL1*, encoding a kelch-domain protein, was previously implicated in cell fusion, but its function in fusion is unknown. Localization suppression by Kel1p is dependent upon Fus1p, showing that it does not bypass the normal pathway. Kel1p and its homologue, Kel2p, are required for normal levels of Fus2p localization, and act through the actin-dependent pathway. Kel1p also plays a role in mating independent of Fus2p localization; a *kel1* deletion reduces cell fusion despite proper Fus2p localization. Moreover, overexpression of Kel1p can weakly suppress the fusion defect of *fus2*Δ, arguing that Kel1p has a Fus2p-independent function. Fus2p interacts with Cdc42p, a Rho-like GTPase that plays numerous roles in growth and morphogenesis, and the interaction is required for fusion. Overexpression of Kel1p suppresses the mating defect of a Cdc42p mutant that cannot bind to Fus2p, but suppression is dependent upon Fus2p. We hypothesize that Fus2p, Cdc42p and Kel1p form a complex during fusion. In support, Kel1p interacts with two different domains of Fus2p, dependent on Cdc42p. We propose that Fus2p localization is dependent on actin, Kel1p and Fus1p and that Kel1p enhances the activity of Fus2p/Cdc42p in cell fusion.

Y3035B *NDT80* dependent internal transcriptional initiation sites during budding yeast sporulation. *S. Zhou*, R. Sternglanz, A. Neiman. Stony Brook University, Stony Brook, NY.

Budding yeast sporulation is a developmental process that generates stress-resistant progeny under nutritient limitation. Sporulation is regulated by a cascade of transcriptional signals. The transcription factor *NDT80* is induced during sporulation, and drives the meiotic divisions and spore formation by inducing the transcription of hundreds of genes. The *NDT80* regulon consists of both sporulation-specific genes and constitutively expressed genes that are upregulated during sporulation. For these constitutively expressed genes, tiling array and RNA-seq studies indicate that alternative transcription start sites (TSS) are sometimes seen in sporulating cells as compared to vegetative growth.

Here we investigate a subset of the sporulation specific TSSs that initiate within ORFs and generate a shorter transcript and protein that could serve specific functions during sporulation. One such TSS initiates within an intron of the *MRK1* gene, encoding one of the four homologs of GSK-3 kinases in budding yeast. We find that an *NDT80* binding site within the intron is required for the induction of this shorter transcript and that the shorter transcript results in the expression of an N-terminally truncated form of Mrk1 that nonetheless contains the entire kinase domain. A survey of published datasets identified additional genes with internally initiated transcripts induced in mid-sporulation that have nearby *NDT80* consensus sites. We show using qPCR that four other genes have *NDT80*-dependent internal transcription initiation. We are currently investigating the regulation of these genes as well as the possible function of the truncated proteins during sporulation.

Y3036C *S. cerevisiae RTT105* mediates Ty1 Gag localization under stress. *J. Keeney*, J. Scales. Juniata College, Huntingdon, PA.

The mRNA of LTR-retrotransposons encodes the replication proteins (*gag* and *pol*) and serves as the genomic material for virus-like particles (VLPs), a cytosolic structure in which the element's genome is reverse transcribed. In the genome of Baker's yeast (*Saccharomyces cerevisiae*),

there are several families of such retrotransposons, including the abundant Ty1 element. In *S. cerevisiae*, genome-wide screens have identified numerous candidate genes that mediate Ty1 transposition activity. One of these candidates, *RTT105*, has previously been identified as a negative regulator of native Ty1 mobility in a genetic screen. Here, we show *RTT105* as a positive regulator of galactose-induced Ty1 mobility. *RTT105* is uncharacterized and contains no conserved domains of known function, thus the nature of the role of *RTT105* in Ty1 transposition activity remains unknown. We identified that the *rtt105* mutation does not interrupt Ty1 Gag protein processing nor cDNA synthesis within mature VLPs. In permissive conditions, Rtt105p localizes at discrete cytoplasmic Ty1 Gag foci, indicating a role in VLP assembly and maturation. Ty1 RNA has been shown to localize to the ER membrane in association with the signal recognition particle (SRP), facilitating virus-like particle assembly. In RNA-Seq analysis with isogenic *rtt105* deletion and wild type strains, we found a slight down-regulation of several subunits of the signal recognition particle (SRP) complex and a significant downregulation of the RNA subunit, scR1. Further, growth in stressful environmental conditions, such as the presence of galactose or glucose deprivation, triggers Ty1 Gag protein localization to the vacuole. Interestingly, an *rtt105* mutation inhibits movement of cytoplasmic Ty1 Gag protein to the vacuole in the presence of these stressors. Gag localization to the cytoplasm is reduced in an *rtt105* mutant as assayed by growth of strains containing a Gag::URA3 fusion construct on 5-FOA. These results illuminate an important step in the processing and regulation of retrotransposons and suggest an additional route by which the host cell actively maintains Ty1 mobility in variable environmental conditions.

Y3037A Early stage prion formation and the insoluble protein deposit (IPOD). *D. Lyke*, AL Manogaran. Marquette University, Milwaukee, WI.

The yeast prion [*PSI*$^{+}$] is the misfolded version of the translation termination protein Sup35p. The study of [*PSI*$^{+}$] has greatly enhanced our understanding of how prions propagate; yet the cellular mechanisms underlying how prions form are not well understood. It has been proposed that the initial misfolding and assembly of Sup35p aggregates accumulate at a site called IPOD, Insoluble Protein Deposit, which is tethered to the vacuole. To uncover other cellular pathways that may be involved in prion formation, we previously performed a small scale screen of deletion mutants. We identified several gene deletions that impaired early stages of prion formation and others that that affected later stages. Since most of the deletions possessed fragmented vacuoles, we originally hypothesized that vacuole integrity and the maintenance of its tethered component IPOD is essential for prion formation. Our current data indicate that vacuole fragmentation and prion formation are independent of each other. In fact, introduction of a centromeric plasmid alone was sufficient to cause fragmentation but not impact prion formation. However, it appears that gene deletions that impair early stages of prion formation did have altered localization of IPOD. This alteration in IPOD is not seen in wild type strains or gene deletions that affect later stages. Together our data suggest that although vacuole fragmentation does not affect prion formation, its tethered component IPOD likely plays an important role in the early stages of prion formation. Efforts to further characterize IPOD as it relates to prion formation will be presented. .

Y3038B Mechanisms of suppression of Cox1p degradation by Oma1p. *Gavin McStay*. New York Institute of Technology, Old Westbury, NY.

Cytochrome *c* oxidase is the terminal electron acceptor in the electron transport chain in many aerobic organisms. This multi-protein complex can be composed of a varying number of subunits depending on species. In the budding yeast, *Saccharomyces cerevisiae*, cytochrome *c* oxidase is made up of 11 subunits, 8 are derived from the nuclear genome and 3 are derived from the mitochondrial genome. To ensure these subunits associate at the correct time and place a family of assembly factors is required. In the case of the mitochondrial DNA encoded subunit 1 there is a linear pathway of biosynthesis where these assembly factors and other structural subunits associate at specific times to regulate specific maturation events. In the absence of some assembly factors, subunit 1 is subject to degradation by the protease Oma1p. In yeast, this results in a deficiency in cytochrome *c* oxidase activity and the inability to grow on substrates requiring intact oxidative phosphorylation. We have performed a mutagenic screen of mitochondrial DNA to identify mutations that can suppress the oxidative phosphorylation deficient phenotype caused by the absence of the assembly factors, COA2 and SHY1. The information gathered from this research will guide us in identifying putative regions required for cytochrome *c* oxidase subunit 1 degradation and also provide more information regarding the proteolytic requirements of the Oma1p protease.

Y3039C *MTG3*, a putative GTPase that regulates mitochondrial ribosome function in *Saccharomyces cerevisiae* . *U. Mehra*, Y. Verma, S. Jakar, K. Datta. University of Delhi, South Campus, New Delhi, INDIA.

Mitochondria are made up of proteins encoded by the nuclear genome as well as its own genome, thus requiring both cytosolic as well as its own translation apparatus for its biogenesis. The proper biogeneis of mitochodria is critical as 1 in 5,000 humans suffers from a mitochondrial disease and a number of these diseases are due to defects in the mitochondrial translation apparatus. Importance of mitochondrial translation apparatus can be estimated with the fact that approximately 25% of the mitochondrial proteome is involved in the establishment and the maintenance of the mitochondrial protein synthesis apparatus and mitochondrial DNA. Mitochondria utilize dedicated ribosome molecules that are encoded by a set of nuclear genes distinct from those coding for its cytosolic counterpart. Mitochondrial ribosomes have reduced RNA content and a higher protein content giving rise to numerous mitochondrial specific proteins conserved from lower eukaryotes to humans. Ribosome biogenesis is a multi-step process aided by assembly factors including GTPases which are thought to utilize energy released upon GTP hydrolysis to promote its biogenesis activity. Mtg3p, is a nuclear encoded mitochondrial protein that is conserved from yeast to humans and is a member of YawG/YlqF family of circularly permuted GTPases. Deletion of *MTG3* leads to defects in utilization of glycerol as the sole carbon source and accumulate 15S rRNA precursors. We have shown Mtg3p associates with the 37S small subunit of the mitochondrial ribosome in a salt dependent manner. Cells harboring *mtg3ts* mutants have aberrant large to small ribosomal subunit ratio consistent with a role in mitochondrial ribosome biogenesis. Our studies also indicate that Mtg3p requires guanine nucleotide binding as well as hydrolysis to carry out

its *in vivo* function at a late step during mitochondrial ribosome biogenesis perhaps just prior to association with mRNA to form 74S monosome. In addition, we have isolated spontaneous suppressors for *Δmtg3ρ*$^{+}$ and have determined them to be due to second-site mutations in the mitochondrial genome. We will be presenting our studies aimed at identifying the molecular complexes that Mtg3p is associated with, domains of Mtg3p that are essential for its *in vivo* function and the downstream partners/processes that it likely controls.

Y3040A Mitochondrial genome large scale deletions in Saccharomyces cerevisiae natural population. *T. Nguyen*, J. DeJesus, H. Fiumera. Binghamton University, Binghamton, NY.

Mitochondrial DNA (mtDNA) large-scaled deletions have been reported in a broad spectrum of human health conditions. Petite-postive yeast species, *Saccharomyces cerevisiae*, offers a powerful model to study mtDNA loss, which can be monitored by quantifying the frequency of spontaneously-formed respiratory-deficient (i.e "petite") colonies in a population. The natural genetic variants contributing to mtDNA loss in yeast presently remain in unmapped territory. By investigating the petite frequency of a subset of haploid derivatives of *S. cerevisiae* natural isolates, we learned that petite frequency is a variable and heritable trait. We also employed a novel collection of yeast strains harboring unique mito-nuclear genome combinations to determine that petite frequency is influenced by both nuclear and mitochondrial genetic variants, and by mt-n epistatic interactions to a lesser extent. In pursuit of unravelling the mechanism of mtDNA loss in yeast, we also looked into the rate of homologous recombination, which has been proposed to be the predominant mechanism for generating mtDNA deletions in yeast. Our preliminary data suggested that petite frequency positively correlated with growth rate, which leads us to hypothesize that fast growing yeast strains require higher mtDNA replication, hence higher rate of homologous recombination in mtDNA. We sought to investigate if high petite frequency can be explained by high rate of mtDNA recombination. Using yeast strains with diverged nuclear genomes paired with a mitochondrial background containing an *ARG8*^{m} auxotrophic reporter gene, we found that the rate of homologous recombination, specifically the rate of mtDNA deletion mediated via direct repeats at the *COX2* locus, is not correlated with the petite frequency in these yeast strains. Simultaneously, we are developing strategies to map the genetic basis underpinning petite frequency, in hopes of better understanding the mechanism behind spontaneous mtDNA loss in *S. cerevisiae*.

Y3041B The Influence of Mitochondrial Morphology on Mitochondrial DNA Stability. *Rey Sia*[1], Christopher Prevost[1,2], Nicole Ashman[1], Christina Seger[1], Kathryn Wershing[1], Elaine Sia[2]. 1) The College at Brockport, State Univ New York, Brockport, NY; 2) University of Rochester, Rochester, NY.

Mitochondria are dynamic organelles that fuse and divide. These changes alter the number and distribution of mitochondrial structures throughout the cell in response to developmental and metabolic cues. Copies of the mitochondrial DNA (mtDNA) and associated proteins are packaged into structures called nucleoids. The replication and distribution of nucleoids is coordinately regulated with mitochondrial division, and alterations to proteins involved in mitochondrial fission and fusion affect the maintenance of functional mtDNA. The proteins that drive the mechanics of mitochondrial fission and fusion have been studied, however, knowledge of the connection to mtDNA integrity is limited. We observed that growth of yeast in different carbon sources affects the frequency of spontaneous petites, independent of whether the sugar is fermentable or non-fermentable. In the cells in which the mitochondrial function is lost, analysis of mtDNA in these yeast reveals that they have undergone large-scale deletions of the mtDNA. When the wild-type yeast strain is grown in dextrose or fructose, the frequency of spontaneous petites is significantly higher than when the same cells are grown in raffinose or galactose. This increase in genome stability is dependent on proteins involved in mitochondrial fission, and components of the ERMES complex, which forms junctions between the ER and mitochondria. This observation provides us with a simple experimental system in which to interrogate the connections between metabolic signals, mitochondrial dynamics, and genome maintenance.

Y3042C Nuclear to mitochondrial translocation of cyclin C promotes stress-induced fission and programmed cell death. *Daniel Smethurst*, Katrina Cooper, Randy Strich. Rowan School of Osteopathic Medicine, Stratford, NJ.

The decision to undergo programmed cell death (PCD) is controlled by a complex interaction between nuclear and mitochondrial signals. The mitochondria are highly dynamic organelles that constantly undergo fission and fusion. However, one of the earliest PCD events is a dramatic shift in mitochondrial morphology toward fission. We have identified the transcription factor cyclin C as the biochemical trigger for stress-induced mitochondrial hyper-fragmentation in yeast (Cooper et al., 2014 Dev. Cell) and mammalian (Wang et al., 2015, MCB) cells. In response to PCD stimuli such as oxidative stress, cyclin C, but not its cognate kinase Cdk8, is released from the nucleus then associates with the fission machinery. Loss of cyclin C prevents mitochondrial fission while its ectopic introduction into the cytoplasm induces complete fragmentation in the absence of stress. The Cdk8 module subunit Med13 anchors cyclin C in the nucleus, and is degraded in response to oxidative stress. Deletion of *MED13* results in mitochondrial hyperfragmentation in unstressed cells. Recent studies have found that mitochondrial fission occurs at junctions between the mitochondria and the endoplasmic reticulum (ER). We have found that the number of these junctions increases upon stress in a cyclin C-dependent manner. The results suggest that cyclin C plays a role in establishing and/or maintaining these stress-enhanced mitochondrial-ER junctions. In yeast, continuous cytoplasmic cyclin C causes constitutive mitochondrial fragmentation, stress hypersensitivity and loss of mtDNA integrity. Conversely, loss of cyclin C function protects cells from oxidative stress. The dual role for cyclin C couples the derepression of stress response genes with a mitochondrial fission program that can lead to cell death. In addition, these roles for cyclin C have been conserved from yeast to mammals.

Y3044B Mitochondria as signaling organelles in aging. *V. Titorenko*, A. Leonov, A. Arlia-Ciommo, Y. Medkour. Concordia Univ, Montreal, PQ, CA.

We employ the yeast *Saccharomyces cerevisiae* as a model to study mechanisms of cellular aging in multicellular eukaryotes. Our high-throughput chemical genetic screen identified lithocholic bile acid (LCA) as a geroprotector which significantly slows yeast chronological aging. Using a combination of subcellular fractionation and mass spectrometry-based quantitative analyses, we revealed that exogenously added LCA enters yeast cells, is sorted to mitochondria, resides mainly in the inner mitochondrial membrane, and also associates with the outer mitochondrial membrane. We found that LCA elicits an age-related remodeling of phospholipid synthesis and movement within both mitochondrial membranes, thereby causing substantial changes in mitochondrial membrane lipidome and triggering major changes in mitochondrial size, number, and morphology. In synergy, these changes in the membrane lipidome and morphology of mitochondria alter the age-related chronology of mitochondrial respiration, membrane potential, ATP synthesis, and reactive oxygen species homeostasis. Our data revealed that the LCA-driven alterations in the age-related dynamics of these mitochondrial processes extend yeast longevity. Thus, mitochondrial membrane lipidome plays an essential role in defining yeast longevity. Using quantitative mass spectrometry, we demonstrated that LCA also alters the age-related dynamics of changes in levels of many mitochondrial proteins, as well as numerous proteins in cellular locations outside of mitochondria. These proteins belong to two regulons, each modulated by a different mitochondrial dysfunction. Proteins constituting these regulons 1) can be divided into several "clusters";, each of which denotes a distinct type of partial mitochondrial dysfunction that elicits a different signaling pathway mediated by a discrete set of transcription factors; 2) exhibit three different patterns of the age-related dynamics of changes in their cellular levels; and 3) are encoded by genes whose expression is regulated by the transcription factors Rtg1p/Rtg2p/Rtg3p, Sfp1p, Aft1p, Yap1p, Msn2p/Msn4p, Skn7p and Hog1p, each of which is essential for longevity extension by LCA. Our findings suggest that LCA-driven changes in mitochondrial lipidome alter mitochondrial proteome and functionality, thereby enabling mitochondria to operate as signaling organelles that orchestrate an establishment of an anti-aging transcriptional program for many longevity-defining nuclear genes. We propose a model for how such LCA-driven changes early and late in life of chronologically aging yeast cause a stepwise development of an anti-aging cellular pattern and its maintenance throughout lifespan.

Y3045C [*PSI*$^+$] formation: Differentiating the role of the retromer complex from vacuole fusion. *B. Wisniewski*, A. Manogaran. Marquette University, Milwaukee, WI.

Prions are misfolded proteins that can aggregate into infectious amyloid fibrils. In yeast, misfolding of the translation termination protein, Sup35p, leads to the formation of a prion called [*PSI*$^+$]. Fusion of Sup35p to GFP (Sup35p-GFP) leads to the appearance of fluorescent intracellular rings: a hallmark of [*PSI*$^+$]. Our lab previously found that strains lacking the open reading frame YOR069W have both reduced ring and [*PSI*$^+$] formation frequencies compared to wild type. Deletion of YOR069W leads to the removal of two genes: *VPS5* and *VAM10* (YOR068C). *VPS5* encodes the retromer complex involved in the recycling of endosome vesicles to the late Golgi and *VAM10* encodes a protein involved in vacuolar fusion. We set out to identify whether *VPS5* or *VAM10* is responsible for the reduced prion formation seen in YOR069W deletion strains. A plasmid containing YOR069W and surrounding regulatory sequences was subjected to site-directed mutagenesis. The start codon of *VPS5* was mutated to arginine or the start codon of *VAM10* was mutated to isoleucine without disrupting the amino acid sequence of the opposite open reading frame. Mutated plasmids were introduced into the YOR069W deletion background and tested for the ability to form Sup35p-GFP rings. Wild type control plasmids rescued the low ring formation phenotype. However, each individual gene disruption plasmid showed the same low ring formation frequency as the double deletion. These data suggest a synergistic effect of the seemingly unrelated *VPS5* and *VAM10* genes in prion formation, and furthermore imply that the endosome recycling pathway and vacuolar fusion pathway both contribute to prion formation.

Y3046A Arl1 and Ypt6 are involved in autophagy in *Saccharomyces cerevisiae*. *Shu Yang*, Anne Rosenwald. Georgetown University, Washington, DC.

Autophagy is a cellular degradation process that sequesters organelles or proteins into a double-membrane structure called the autophagosome, which then fuses with the lysosome or vacuole for hydrolysis. Factors that control membrane traffic are also essential for each step of autophagy. Here we demonstrate that two small GTP-binding proteins in *Saccharomyces cerevisiae,* Arl1 and Ypt6, which belong to the Arf/Arl/Sar protein family and the Rab family, respectively, and control endosome – *trans*-Golgi traffic, are also necessary for starvation-induced autophagy under high temperature stress. Using established autophagy-specific assays we found cells lacking either *ARL1* or *YPT6,* which exhibit synthetic lethality with one another, were unable to undergo autophagy at an elevated temperature, although autophagy proceeds normally at normal growth temperature; specifically strains lacking one or the other of these genes are unable to construct the autophagosome because these two proteins are required for proper traffic of Atg9 to the phagophore assembly site at the restrictive temperature. Using degron technology to construct an inducible *arl1Δ ypt6Δ* double mutant, we demonstrated that cells lacking both genes show defects in starvation-inducted autophagy at the permissive temperature. Our data show that these two membrane traffic regulators have novel roles in autophagy.

Y3047B Cohesin Binding and Function at a Model Euchromatic Gene. *M. Borrie*, H. Joshi, J. Campor, M. Gartenberg. Rutgers University, Piscataway, NJ.

Cohesin is a toroidal-shaped protein complex that binds chromatin by encircling either one or two DNA duplexes. The complex joins distant DNA sites together to mediate sister chromatid cohesion, double-strand break repair and the regulation of gene expression. In yeast, cohesin often associates with the bodies of inactive genes. However, transcriptional activation mobilizes the complex, causing loss from gene bodies and a corresponding increase in binding at intergenic regions between convergently oriented genes. It is not clear whether cohesin mobilization occurs by sliding complexes along DNA or by displacing complexes from DNA entirely. Here, *URA3* was used as a model system to study how

cohesin arrives at a eukaryotic gene and what happens to the complex when transcription ensues. Site-specific recombination was used to excise a pair of DNA circles from sister chromatids that cohesed when *URA3* was present on the circles. Deletion analysis identified a region of the *URA3* promoter that included a poly(dA-dT) segment that was required for cohesion. The cohesin loading complex Scc2/4 is known to bind poly(dA-dT) regions, suggesting that this *URA3* promoter element may be a loading site for cohesin that accumulates on the gene. The DNA circle assay was also used to study how cohesive complexes are mobilized by transcription. Induction of transcription after circularization did not diminish cohesion. However, induction of transcription before circularization (when the template was effectively linear) caused loss of cohesion. Insertion of a convergent gene downstream of *URA3* prevented transcription-driven loss of cohesion. Collectively, these data are consistent with transcription mobilizing cohesin complexes by sliding along DNA.

Y3048C Ubiquilin/Dsk2 promotes inclusion body formation and lysosome-mediated disposal of mutated Huntingtin. *K. Chuang*[1], F. Liang[2], R. Higgins[1], Y. Wang[1]. 1) Florida State University, Tallahassee, FL; 2) Yale University, New Haven, CT.

Ubiquilin proteins contain an ubiquitin-like domain (UBL) and ubiquitin-associated (UBA) domain that interact with the proteasome and ubiquitinated substrates, respectively. Previous works have established the link of ubiquilin proteins to several neurodegenerative diseases, but their molecular function remains elusive. Here, we used misfolded Huntingtin exon I containing 103 polyglutamine expansion (Htt103QP) as a misfolded protein substrate to investigate the function of ubiquilin proteins. We found that yeast ubiquilin mutant (*dsk2*Δ) is sensitive to Htt103QP overexpression and shows defects in formation of Htt103QP inclusion body, a structure containing protein aggregates. Surprisingly, proteasome-dependent Htt103QP degradation is normal in *dsk2*Δ mutant, but *dsk2*Δ mutant showed a defect in the delivery of Htt103QP into vacuoles (lysosomes) in yeast, indicating that ubiquilin proteins facilitate lysosome-dependent clearance of misfolded proteins by promoting inclusion body formation. Our further evidence indicates that the UBL domain of Dsk2 contributes to its functional specificity of ubiquilin/Dsk2. Importantly, the defect of inclusion body formation in in *dsk2* mutants is rescued by human ubiquilin 1 or 2, suggesting functional conservation of ubiquilin proteins.

Y3049A Genetic selection coupled to next-generation sequencing reveals structural requirements for tail-anchor targeting to mitochondria. *Cory D. Dunn*, Abdurrahman Keskin, Emel Akdoğan. Department of Molecular Biology and Genetics, Koç University, Sariyer, Istanbul, TR.

Proteins localized to mitochondria by a carboxyl-terminal tail anchor (TA) play important roles in apoptosis, mitochondrial dynamics, and mitochondrial protein import. In order to reveal structural characteristics of TAs that may be important for mitochondrial targeting, we focused our attention upon the TA of the *Saccharomyces cerevisiae* Fis1 protein. We generated a library of Fis1p TA variants fused to the transcription factor Gal4p. By selecting for mutations within the TA permitting Gal4p to translocate to the nucleus and activate transcription, we were able to enrich for TA variants within our mutant pool which led to decreased membrane insertion. Next-generation sequencing allowed quantification of each TA variant in our mutant library both before and after selection, and high-throughput results were confirmed by microscopy-based and functional analysis of individual, reconstructed Fis1 TA mutants. Consistent with the prediction that the Fis1 TA is alpha-helical, prolines within the TA generally prevented membrane insertion. Charged residues within the hydrophobic core of the Fis1 TA were also able to perturb membrane insertion. Surprisingly, positively charged residues were much more acceptable at several positions within the Fis1 TA than negatively charged residues, providing strong, *in vivo* evidence that lysine and arginine can "snorkel," or partition the nonpolar portion of their side chains into the hydrophobic region of the lipid bilayer while placing the terminal charge near the polar interface of the membrane. In further experiments, we found that lengthening or shortening the Fis1 TA by up to three amino acids did not alter its behavior or localization, arguing against a model in which TA length directs insertion into specific organelles. Finally, our data affirm previous results indicating that the charged carboxyl-terminus of Fis1p is important for localization and insertion at the mitochondrial outer membrane. Our work provides the first high-resolution analysis of an organelle targeting sequence to be generated by deep mutational scanning.

Y3050B Membrane trafficking underlies aging and rejuvenation. *Kiersten A. Henderson*[1], Jason V. Rogers[2], Patricia Gordon[1], Netty Lim[1], Daniel E. Gottschling[1,2]. 1) Fred Hutchinson Cancer Research Center, Seattle, WA; 2) Calico Life Sciences, LLC, South San Francisco, CA.

Replicative aging is asymmetric – mother cells age but produce daughter cells with full lifespans. We recently identified that mother-daughter asymmetry of the plasma membrane H+-ATPase, Pma1, underlies age asymmetry (Henderson et al., eLife, 2014). We found that Pma1 accumulates at the plasma membrane of mother cells during aging, but that daughter cells have very low levels of Pma1.

Pma1 is the major regulator of cytosolic pH (Serrano et al., MCB, 1986). By accumulating at the plasma membrane of mother cells during aging, Pma1 causes an increase in cytosolic pH that limits lifespan by antagonizing vacuolar function. However, nascent daughter cells (buds) and newborn daughters have very low levels of Pma1. Thus, the asymmetric distribution of Pma1 allows daughter cells to achieve normal cytosolic pH and vacuole function, and they are born young.

Because mother-daughter asymmetry of Pma1 underlies aging and rejuvenation, we sought to identify how the spatial distribution of Pma1 is achieved. We performed high-throughput microscopy screens and identified mutants that disrupted Pma1 asymmetry (i.e. increased levels of Pma1 at the bud plasma membrane). We found that disrupting endocytosis, endocytic trafficking, and sorting at the late golgi increases the level of Pma1 in nascent daughter cells.

Because these processes contribute to Pma1 asymmetry, this suggests that they are spatially regulated to occur differently between mother cells and buds and/or cell cycle regulated. We are currently dissecting how these processes are regulated to establish Pma1 asymmetry and we will determine how each process influences asymmetry of cytosolic pH, vacuole function, and lifespan.

Y3051C Clearance of mutated huntingtin protein via K63-linked ubiquitination in yeast cells. *R. Higgins*[1], F. Liang[2], K. Chuang[1], Y. Wang[1]. 1) Florida State University, Tallahassee, FL; 2) Yale University, New Haven, CT.

Misfolded proteins that evade chaperone-mediated refolding and proteasome-dependent degradation can form aggregates in cells. These protein aggregates are cytotoxic and are linked to several neurodegenerative diseases, including Alzheimer's and Huntington's diseases. However, the aggregates can further form a cytoprotective structure termed an aggresome (inclusion body), and studies in higher eukaryotes indicate that K63-linked ubiquitination promotes aggresome formation for some substrates. Polyglutamine (polyQ) expansion within Huntingtin protein contributes to the development of Huntington's disease and expression of mutated Huntingtin with 103 polyQ (Htt103QP) leads to aggresome formation in both mammalian and yeast cells. Using yeast as a model organism, we demonstrate that Htt103QP is degraded primarily through the proteasome prior to aggresome formation, while vacuole (lysosome)-dependent autophagy pathway is responsible for Htt103QP clearance once an aggresome is formed. We further show that K63-linked ubiquitination promotes aggresome formation of Htt103QP, as abolishment of K63 ubiquitination in yeast cells compromises aggresome formation. The observation that mutation of the three lysine (K) residues in the N-terminus of Htt103QP resulted in aggresome formation defect indicates that ubiquitination of Htt103QP itself contributes to aggresome formation. In addition, we found that the E3 ubiquitin ligase Rsp5 (Nedd4) promotes K63-linked ubiquitination of Htt103QP and is required for aggresome formation. Therefore, we can use yeast as a model organism to study the clearance process for misfolded proteins linked to neurodegenerative diseases.

Y3052A A SUMO-targeted ubiquitin ligase reduces the toxicity and transcriptional activity of a poly-Q expanded protein. *O. Kerscher*[1], G. Dreissnack-Sclar[3], R. Levy-Myers[1], N. Pasupala[2]. 1) The College of William & Mary, Williamsburg, VA; 2) The Johns Hopkins School of Medicine, Baltimore, MD; 3) Emory University, Atlanta, GA.

SUMO-targeted ubiquitin ligases (STUbLs) play an important role in the homeostasis of SUMO-modified proteins and SUMO-dependent signaling. Eukaryotic cells that lack STUbLs are hypersensitive to DNA damage, and accumulate gross chromosomal rearrangements and high-molecular weight adducts of SUMO-modified proteins. In this study we show that budding yeast STUbLs (Slx5 and Slx8) also modulate the aggregation, toxicity, and transcriptional properties of poly-glutamine (poly-Q) expanded huntingtin (Htt), the causative agent of Huntington's Disease (HD). We demonstrate that expression of an aggregation-prone Htt construct with 103 glutamine residues (103Q), but not the non-expanded form (25Q), results in severe growth defects in slx5Δ and slx8Δ cells. Concomitantly, an extra copy of SLX5 reduces the accumulation of 103Q aggregates in the cytosol of wild type cells while overexpression of SUMO led to diffuse nuclear staining of Htt. This nuclear enrichment of Htt prompted us to assess the effect of STUbLs on the transcriptional properties of 25Q, 55Q and 97Q. Expression of 25Q, 55Q and 97Q fused to the Gal4 activation domain (AD) resulted in reporter gene auto-activation. Remarkably, the auto-activation of Htt constructs was abolished by expression of Slx5 fused to the Gal4 DNA-binding domain (Slx5-BD) but not an Slx5 SIM mutant (BD-Slx5sim) that fails to interact non-covalently with SUMO. These data suggest a novel role for STUbLs in the recently described proteolysis-independent stripping of transcription factors that also involves Cdc48 and its co-factors.

Y3053B Mechanism of protein quality control at the inner nuclear membrane in budding yeast. *B. Koch*, R. Abblett, H. G. Yu. Florida State University, Tallahassee, FL.

The nucleus of a eukaryotic cell is enclosed by a double-membrane structure, termed the nuclear envelope, which separates the nucleoplasm from the cytoplasm. The outer and inner membranes of the nuclear envelope have individualized functions within the cell. The outer nuclear membrane is continuous with the endoplasmic reticulum membrane, whereas the inner nuclear membrane acts as the intermediate connecting the outer nuclear membrane to the nucleoplasm. Proteins within the inner nuclear membrane (INM) interact with the telomeres, the nuclear lamina and the nuclear pore complex, and play important roles in chromosome movement and nuclear migration. Defective INM proteins can lead to genetic diseases, such as Emory driefuss muscular dystrophy. In order to maintain protein homeostasis at the INM, a specific protein quality control mechanism must be present to remove dysfunctional proteins from the nuclear envelope. Recent work has shown that some INM proteins are degraded through the Asi-E3 ubiquitin ligase pathway in budding yeast. However other INM proteins, including the SUN-domain protein Mps3, are independent of the Asi pathway for degradation. We report here a novel protein quality control mechanism at the INM that is dependent on protein cleavage. Using the expression levels of Mps3 as a genetic tool, we found that noncleavable Mps3 forms aggregates at the nuclear periphery and is lethal in vegetative cells. Genetic analysis demonstrates there is an interaction between the INM proteins and vacuole components, which leads us to propose that certain INM proteins are targeted by the autophagy pathway. Because the SUN-domain and other INM proteins are conserved from yeast to higher eukaryotes, a similar autophagic regulation of INM proteins may take place in mammalian cells.

Y3054C Dissecting pathways underlying asymmetric plasma membrane protein retention. *J. V. Rogers*[1], K. A. Henderson[2], D. E. Gottschling[1,2]. 1) Calico Labs, San Francisco, CA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

Saccharomyces cerevisiae divides asymmetrically to generate a rejuvenated daughter cell and an aged mother. Identifying the underlying asymmetric cellular components could uncover new aging factors and will inform general models for how cellular asymmetries are generated. A recent biochemical screen in our laboratory identified three proteins that are long-lived and asymmetrically retained for ~18 cell divisions in the plasma membrane of mother cells: Pma1, Mrh1, and Sur7. To uncover the mechanism underlying these proteins' asymmetric localization, we have performed a high-throughput microscopy screen to discover genes that, when deleted, cause these asymmetric plasma membrane proteins to appear symmetric during budding.

We found that Pma1 asymmetry requires endocytic, vacuolar, and golgi-to-endosome trafficking whereas Mrh1 and Sur7 do not. Sur7

asymmetry is uniquely lost in a subset of cell wall and vesicular trafficking mutants (*e.g., gas1*Δ, *ecm33*Δ, and *pho88*Δ). A third set of mutants broadly affecting vesicle trafficking pathways (*e.g., cdc50*Δ, *drs2*Δ, *rcy1*Δ, and *swa2*Δ) accumulated cytoplasmic puncta containing Sur7, Mrh1, and Pma1 during budding, but only led to increased plasma membrane symmetry for Pma1. In contrast to Pma1 and Sur7, no mutants were identified that resulted in a strongly symmetric plasma membrane localization of Mrh1. Pulse-chase and photoconversion experiments have demonstrated that all identified mutants affect asymmetry at the step of new synthesis; that is, these mutants aberrantly express and localize new protein to the early bud at a time when, in wild-type, protein localization is repressed. A mechanistic analysis of these mutants and their role in plasma membrane protein asymmetry is ongoing and will be presented.

Y3055A Protein quality control that regulates unassembled ribosomal proteins. *M. Sung*, R. Deshaies. California Institute of Technology, Pasadena, CA.

Assembly of ribosomes accounts for a large fraction of total RNA and protein synthesis in yeast. All ribosomal subunits are present in assembled ribosomes at 1:1 stoichiometry, but it is anticipated that in synthesizing the ~80 proteins that form a ribosome, modest variations in expression must inevitably occur with some subunits expressed in modest excess over others. Ribosomal proteins produced in slight excess will not be able to assemble and are presumably degraded by a quality-control pathway(s) that senses unusable proteins. Given the major contribution of ribosome assembly to total cellular biosynthesis, such a quality-control pathway is likely to play a significant role in protein homeostasis. However, the responsible quality-control mechanisms remain poorly characterized. Here, we demonstrate that overexpression of multiple proteins of the small and large yeast ribosomal subunits is suppressed. Our studies reveal that ribosomal proteins that fail to assemble into ribosomes are rapidly distinguished from their assembled counterparts and are ubiquitinated and degraded by proteasome within the nuclear compartment.

Y3056B Multiple signaling pathways control the *S. cerevisiae* gene expression response to hypoxia. *Erica Avery*, Samuel Macleon, Gurmannat Kalra, Nawshad Hossian, Olivia Wojtowicz, Stephen Willis, Nasrine Bendjilali, Mark Hickman. Rowan University, Glassboro, NJ.

Many organisms, including humans and the yeast *S. cerevisiae*, experience hypoxia, or low oxygen. To adapt to this new environment, cells employ signaling pathways to mount a global change in gene expression. In *S. cerevisiae*, previous studies have focused on the mechanisms of individual pathways but how multiple pathways together mount a large hypoxic response is not well understood. Here, we attempt to identify and characterize all signaling pathways that contribute to the hypoxic response. We propose at least seven signaling pathways composed of 19 genes that mediate the response, with many genes conserved in humans. To study the role of each signaling gene, we have created single deletion strains. To study each pathway, we have created "pathway" mutant strains that contain deletions of all the genes in a pathway. Studying these strains will help delineate the contribution of each pathway and also reveal redundancy in the signaling network. Surprisingly, all of the strains can grow during hypoxia, suggesting that the signaling genes may be important for long-term survival or fitness in hypoxia. To test the role of the signaling genes and pathways in the gene expression response, each strain was subjected to an anaerobic environment for 5, 10, 30, 60, 120, 180, and 240 minutes. RNA was extracted from the cells and mRNA level was determined by RNA-Seq and RT-qPCR analyses. First, we described the wildtype hypoxic response by employing three statistical tests to identify the genes that exhibited a robust time-dependent response. The first test employs DESeq to identify the genes that fit a quadratic when comparing expression to time. The second uses autocorrelation as a measure of the smoothness of a gene's response, and the third compares the means of early vs. late time points to isolate large expression changes over time. A total of 715 genes were identified including almost all of the expected oxygen-regulated genes as well as previously undiscovered genes. Additionally, we found that the hypoxic response is distinct from the environmental stress response and appears to represent a transition to a new growth state. By observing the gene expression response in some of the mutants, we have found that multiple signaling pathways are indeed responsible and that there is redundancy in the response network. This work contributes to our understanding of a large cellular response that involves the coordination of several signaling pathways.

Y3057C Exploring the role of tyrosine phosphorylation in regulating Yck1/2 activity in the glucose sensing pathway. *T. Biswas*, M. Johnston. University of Colorado Denver, Aurora, CO.

Glucose triggers the SRR (Snf3-Rgt2/Rgt1, or Sensor-Receptor/Repressor) glucose sensing pathway, which induces expression of hexose transporters (*HXT*). Extracellular glucose binds to the Snf3 and Rgt2 glucose sensors, leading to Yck1/2-mediated phosphorylation of the Mth1 and Std1 corepressors, resulting in their degradation, which relieves repression of the *HXT* genes. Most signaling pathways are modulated by an interplay of protein kinases and phosphatases. To identify protein phosphatases involved in glucose sensing we tested catalytic and regulatory subunits of protein phosphatases for their ability to induce *HXT1* expression when overexpressed. Over-expression of PTP1 (phosphotyrosine phosphatase) and PPS1 (protein phosphatase S phase; dual-specificity phosphatase) increased *HXT1* expression in cells growing on glucose. A plausible target for a phosphatase in the glucose signaling pathway is Yck1/2, whose Casein kinase 1 orthlogs in mammals and *S. pombe* are inhibited by autophosphorylation and activated by protein phosphatases. Since our results suggest a role for Tyr dephosphorylation, we tested if Yck2 activity is regulated by phosphorylation/dephosphorylation at Tyrosine residues. Conserved Tyr resudues were mutated to Phe (dephosphorylated form) or Glu (phosphomimetic). Interestingly, Tyr76>Glu showed a significant decrease in activity. Our study suggests a role for Ptp1 in regulation of glucose sensing pathway.

Y3058A Multiple targets on the Gln3 transcription activator are cumulatively required for control of its cytoplasmic sequestration. *T. G. Cooper*[1], R. Rai[2], J. J. Tate[3]. 1) University of Tennessee Health Science Center, Memphis, TN; 2) University of Tennessee Health Science Center, Memphis, TN; 3) University of Tennessee Health Science Center, Memphis, TN.

A remarkable characteristic of nutritional homeostatic mechanisms is the breadth of metabolite concentrations to which they respond and resolution of those responses; adequate but rarely excessive. Two general ways of achieving such exquisite control are known: stoichiometric mechanisms where increasing metabolite concentrations elicit proportionally increasing responses, and the actions of multiple independent metabolic signals that cumulatively generate appropriately measured responses. Intracellular localization of the nitrogen-responsive transcription activator, Gln3 responds to four distinct nitrogen environments: nitrogen limitation or short-term starvation, i.e. nitrogen catabolite repression (NCR), long-term starvation, glutamine starvation and rapamycin inhibition of mTorC1. We have previously identified unique sites in Gln3 required for rapamycin-responsiveness and Gln3-mTor1 interaction. Alteration of the latter results in loss of about 50% of cytoplasmic Gln3 sequestration. However, except for the Ure2-binding domain, no evidence exists for a Gln3 site responsible for the remaining cytoplasmic Gln3-Myc^{13} sequestration in nitrogen excess. Here we identify a serine/threonine-rich (Gln3$_{477\text{-}493}$) region required for effective cytoplasmic Gln3-Myc^{13} sequestration in excess nitrogen. Substitutions of alanine but not aspartate for serines in this peptide partially abolish cytoplasmic Gln3 sequestration. Importantly, these alterations have no effect on Gln3-Myc^{13}'s responses to rapamycin, methionine sulfoximine or limiting nitrogen. However, cytoplasmic Gln3-Myc^{13} sequestration is additively and almost completely abolished when mutations in the Gln3-Tor1 interaction site are combined with those in Gln3$_{477\text{-}493}$ cytoplasmic sequestration site. These findings clearly demonstrate that multiple individual regulatory pathways cumulatively control cytoplasmic Gln3 sequestration. Supported by NIH grant GM-35642-26.

Y3059B The ergosterol biosynthesis pathway is required for optimal induction of the unfolded protein response after phenol stress. *G. Edwalds-Gilbert*, A. Baris, O. Smith, A. Hilborn, A. Marks, K. Tanguay, V. Yu. Claremont McKenna, Pitzer, and Scripps Colleges, Claremont, CA.

Phenolic compounds exist in abundance in the environment as the product of natural and synthetic processes and can be harmful, stress-inducing exotoxins. Bisphenol-A (BPA), butylated hydroxyanisole (BHA), and butylated hydroxytoluene (BHT) are phenol-based compounds found in polycarbonate plastics and food preservatives and therefore have a particularly high degree of human exposure. Exposure to these compounds has been associated with numerous diseases, yet their mechanisms of action are not well understood. A quantitative evaluation of growth of wild type and haploid deletion strains was used to identify the genes that modulate response to phenol stress induced by BPA, BHA, and BHT in Saccharomyces cerevisiae. Exposure to phenol stress in wild type yeast induces the unfolded protein response (UPR). The UPR is a conserved cellular process that responds to stressors that cause unfolded proteins to accumulate in the endoplasmic reticulum, eventually inducing cell death. In yeast, one portion of the UPR is activated when unfolded proteins bind to inositol-requiring enzyme 1 protein (Ire1p). Ire1p then oligomerizes, activating HAC1 pre-mRNA splicing; Hac1 is a transcription factor that promotes expression of chaperone proteins that refold or degrade unfolded proteins. Ire1-GFP showed clustering after treatment with BHT for 2 hours. Ergosterol is similar to cholesterol in humans and maintains membrane fluidity; mutants with deleted ergosterol genes do not produce ergosterol and were identified in the deletion mutant screen as possible modulators of phenol stress response. This suggests that like the UPR, ergosterol biosynthesis is affected by phenols and reduced membrane fluidity may potentially inhibit Ire1p movement and oligomerization. To test this hypothesis, we treated ergosterol pathway deletion mutants *Δerg 2*, *Δerg6* and *Δerg24* with BPA, BHA, and BHT during 12 hour time courses. We measured HAC1 pre-mRNA splicing using RT-PCR. Strains deleted for genes encoding proteins in the ergosterol biosynthesis pathway had growth rates that were below wild type growth rates when exposed to BPA, BHA, and BHT and showed lower levels of UPR induction after phenol stress. These data demonstrate an important pathway through which common phenols act in yeast, which may inform research on human exposure to these chemicals.

Y3060C The scaffold protein Bem1 connects active Cdc42$_{GTP}$ to different effector proteins in a cell cycle specific manner. *S. Grinhagens*, L. Rieger, N. Johnsson. Ulm University, Ulm, Baden-Württemberg, DE.

Saccharomyces cerevisiae is a generally accepted model organism to study the establishment and maintenance of cell polarity. In order to polarize, the yeast cells have to accumulate the GTPase Cdc42 in its active GTP bound form at the growth tip of the cell. The scaffold protein Bem1p performs an important function in this process by simultaneously binding to Cdc42$_{GTP}$, its GEF Cdc24, and certain effector proteins of Cdc42$_{GTP}$. We show that Bem1p can channel the flow of Cdc42$_{GTP}$ from Cdc24 to its effectors through a SH3 domain-based interaction network. Channelling becomes essential once the concentration of Cdc42$_{GTP}$ is artificially reduced. We further show that the composition of this network changes during the cell cycle. During bud growth Bem1p links Cdc42 and Cdc24 to PAK kinases and effectors of exocytosis and the actin cytoskeleton. Upon entry into mitosis and during cytokinesis Bem1 becomes actively isolated from these effectors. This behaviour of Bem1 reflects its changing localization during different stages of the cell cycle. Using isolated domains and mutants thereof we try to understand the localization of Bem1 to these different compartments.

Y3061A Altered expression levels of *HKR1*, which encodes a transmembrane signaling mucin, confer resistance to HM-1 killer toxin on *Saccharomyces cerevisiae*. *S. Kasahara*, U. Suzuki. Miyagi Univ, Sendai, Miyagi, JP.

The yeast *Williopsis saturnus* var. *mrakii* (syn. *Hansenula mrakii*) produces a proteinous killer toxin called HM-1, which has a strong cytocidal effect on sensitive yeasts such as *Saccharomyces cerevisiae*. *HKR1* (*Hansenula mrakii* killer toxin resistant gene 1) was originally identified in the genome of *S. cerevisiae* as a gene whose overexpression overcame the effect of HM-1. The gene product Hkr1p is a large cell surface protein composed of 1,802 amino acids. It contains a signal peptide sequence at the N-terminus, Ser/Thr-rich mucin-like repetitive sequences and a putative transmembrane domain. Also the calcium binding EF hand motif and the leucine zipper are found in its cytoplasmic tail and the extracellular domain is presumed to be highly glycosylated. It is hence categorized as a transmembrane signaling mucin. Recently it has been reported that Hkr1p and another transmembrane signaling mucin Msb2p act as putative osmosensors in the high osmolarity glycerol (HOG) signaling pathway.

We here report that only short portions of *HKR1* endow HM-1 resistance to *S. cerevisiae* cells. Moreover, even when the reverse strand of *HKR1* was transcribed (presumably the expression of the gene was suppressed by the antisense RNA), *S. cerevisiae* cells acquired resistance to HM-1. Since mutations at the positions of internal ATGs which could act as translation initiation codons in *HKR1* did not affect the resistance to HM-1, we speculated that the acquisition of HM-1 resistance by partial *HKR1* expression was independent from the translation event, that is, overexpression of Hkr1p was not the case. Also we speculate that the expression of *HKR1* was downregulated rather than overexpressed due to transgenic cosuppression when the gene was driven by the *GAL1* promoter, then the accumulation of the gene product Hkr1p declined finally. From these observations, we postulate that when the expression level of *HKR1* was altered, especially downregulated, the cells acquired resistance to HM-1. Quantifying studies for Hkr1p accumulation using antibodies are anticipated. We also observed budding patterns of those transformants expressing partial *HKR1*. The cells of the haploid *S. cerevisiae* A451 strain typically select budding sites axially in a unipolar pattern, but bipolar and randomized budding patterns were observed more frequently under the existence of HM-1. We then found that expression levels of *HKR1* affected bud site selection of *S. cerevisiae* as well.

These observations will provide critical information to understand the mechanism of the cytocidal effect of HM-1 and the function of Hkr1p in the cellular signaling of *S. cerevisiae* in the context of HM-1 resistance.

Y3062B Multiple MAPK cascades regulate the transcription of *IME1*, the master transcriptional activator of meiosis in *Saccharomyces cerevisiae*. *Y. Kassir*, S. Kahana-Edwin, M. Stark. Technion Inst, Haifa, IL.

Entry into meiosis in *S. cerevisiae* depends on the expression and activity of a master regulator, Ime1. The transcription of *IME1* is regulated by all the meiotic signals through an atypical large and complex 5' region. In this report we focus on a distinct *cis*-acting regulatory element UASru, whose activity is regulated by multiple signals. A glucose signal inhibits UASru activity through the cAMP/protein kinase A pathway and the transcription factors (TF), Com2 and Sko1. A nitrogen source represses UASru activity through the TF Sum1. Our results demonstrate that all the known MAPK cascades that operate in vegetative cultures directly affects UASru function: The Hog1 MAPK transmits a high osmolarity signal to UASru through the Sko1 TF; The Mpk1 MAPK transmits an elevated temperature signal through the TFs Swi4/Mpk1 and Swi4/Mlp1; Fus3 and Kss1 MAPKs transmit novel nutrient signal to UASru through the Ste12/Ste12 and Ste12/Tec1 TFs, respectively. This signal is specific to UASru and does not affect the mating and filamentation response elements that are regulated by these MAPK and TFs. Moreover, UASru does not respond to the mating and filamentation signals. Thus, the three optional developmental pathways available to yeast, namely, meiosis, filamentation and mating are regulated by the same MAPKs in a specific manner. A hypothesis aimed to explain how specificity is achieved will be discussed.

Y3063C The Transmission Interface in Yeast Pleiotropic Drug Resistance (PDR) Pumps Controls Substrate Specificity by Linking ATP Hydrolysis to Drug Extrusion. *Karl Kuchler*[1], Narakorn Khunweeraphong[1], Thomas Stockner[2], Cornelia Klein[1]. 1) Medical University Vienna, Vienna, AT; 2) Medical University of Vienna, Institute of Pharmacology, Vienna, AT.

ABC transporters constitute a ubiquitous superfamily of membrane pumps containing an evolutionary conserved ATP-binding cassette domain. They mediate energy-driven efflux of a great variety of substrates, including amino acids, ions, sugars, as well as synthetic and naturally occurring xenobiotics or toxins. A subset of yeast pumps plays a major role in the so-called pleiotropic drug resistance (PDR) phenomenon, where overexpressed ABC transporters such as *S. cerevisiae* Pdr5 or Snq2 confer resistance to a vast variety of drugs. This phenomenon resembles anti-tumor resistance in cancer cells, which is mediated by proteins such as P-glycoprotein, BCRP or MRP. However, very little is known about the molecular mechanism of function of yeast PDR transporters, mainly due to a lack of structural information. To gain insight into the principles underlying transport through yeast ABC proteins, we have initiated a structural modelling approach yielding improved homology models of yeast PDR transporters. The models enabled the prediction of the structural organization of putative transmembrane regions and their connection to the dimeric nucleotide binding domains (NBDs). Remarkably, we have identified residues in the transmission interface, which are critical for both function and formation of the NBD dimer, which is essential for ATP hydrolysis and substrate translocation. A mutational analysis of the Pdr5 and Snq2 transporters identifies further residues critical for ATP-binding, hydrolysis as well as drug substrate specificity, and defines the molecular basis of substrate specificity in the context the interplay of NBD dimerization and ATP consumption. We will present modeling data along with mutational validation, and discuss how homology modeling can facilitate genetic structure-function analysis to reveal possible mechanisms of yeast PDR transporters.

This work was supported through the SFB035-P20 project from the Austrian Science Foundation to KK.

Y3064A Boi1 and Boi2 contribute to Secretory Pathway Polarization. *J. Kustermann*, Y. Wu, N. Johnsson. Ulm University, Ulm, Baden-Württemberg, DE.

Asymmetric cell division is essential for the generation of cell diversity and forms the basis for rejunvenation during cellular aging. For decades, the model organism *Saccharomyces cerevisiae* (*S. c.*) has been studied to elucidate the protein networks that enable asymmetric cell division and connect cell polarity establishment to intracellular transport processes. In our work we decipher a new pathway in which the annilin-related yeast proteins Boi1 and Boi2 link Cdc42, the master regulator of cell polarity establishment in *S. c.* to exocytosis. Boi1 and Boi2 are scaffold proteins of similar structure and partially redundant functions that both bind Cdc42. *BOI1* and *BOI2* exhibit synthetic lethality and a knock-down of *BOI1* in a *BOI2* deletion strain causes a severe accumulation of post-golgi vesicles in the daughter cell. In accordance with this observation, I found physical and genetic interactions between Boi1/2 and members of the vesicle fusion machinery. Furthermore, I provide evidence that Boi1 and Boi2 are on top of an interaction cascade to polarize the fusion of post-golgi vesicles to the tip of the cell.

Accordingly, I propose a model in which Boi1 and Boi2 serve as direct adapters between essential core components of the cell polarity and the vesicle fusion machinery and thereby contribute to the polarization of the secretory pathway.

Y3065B The NaCl-activated signaling network responsible for protein phosphorylation in yeast reveals potential decision points in the growth-versus-stress decision. *M. MacGilvray*[1], E. Shishkova[2], D. Chasman[3], J. Coon[2], A. Gasch[1]. 1) Laboratory of Genetics, University of Wisconsin - Madison; 2) Department of Chemistry, University of Wisconsin - Madison; 3) Wisconsin Institute for Discovery, University of Wisconsin - Madison.

Cells respond to stressful conditions using a complex, multi-faceted approach that includes changes in gene expression, protein abundance, and post-translational modification. Coupled to these changes is arrest of growth, suggesting that these are competing cellular processes. Although the affects of transcript changes in response to stress are well characterized in *Saccharomyces cerevisiae*, we have only a rudimentary understanding of the upstream regulatory network and post-translational protein modifications that regulate stress response. To gain a better understanding of the regulatory network that controls stress response, including how stress and growth response pathways are connected, we developed an experimental and computational workflow to infer stress-activated signaling networks using protein-protein interactions and phosphorylation changes. Using a integer linear programming approach, we combined high throughput protein interaction datasets with quantitative mass spectrometry performed on the lab strain, BY4741, and derivative mutants of the cell cycle protein Cdc14, the MAPK Hog1, and the phosphodiesterase Pde2, before and five minutes after NaCl exposure. The resulting network implicated new regulators in the yeast stress response, revealed a complex, hierarchical organization of kinases and phosphatases, and identified potential decision points in the growth-versus-stress decision. Interestingly, our network is enriched for yeast genes whose human orthologs are linked to diseases, such as cancer, that can be caused by defects in kinase regulation. Through identification of novel pathway and regulator connections, including those involved in stress response and growth, we will improve our understanding of both yeast physiology and human disease causing mechanisms.

Y3066C Identification of Interacting Partners of the Yeast Trans-Membrane Stress Sensor Protein Mtl1p as a Model for Drug Discovery in Fungi. *N. Martínez-Matías*[1], E. Santiago-Cartagena[1], I. Stagljar[2], J. Rodríguez-Medina[1]. 1) University of Puerto Rico, Medical Sciences Campus, San Juan, PR; 2) 1. Donnelly Centre, Department of Biochemistry, and Department of Molecular Genetics, University of Toronto, Ontario M5S 3E1 Canada.

Statement of the purpose – Cell wall and membrane–embedded proteins comprise a very special class of molecular components. They are usually involved in processes such as adhesion, signal transduction, and metabolism. Moreover, some of them have even been associated to disease. It is for this reason that these proteins, and also their cytosolic interacting partners, constitute major targets in drug discovery for pharmacotherapy. Despite being often difficult to study because of their hydrophobicity, methods have been developed to study membrane proteins and their interactions *in vivo*. In *Saccharomyces cerevisiae,* the membrane sensor Mtl1p has been shown to have a role in the cellular response to oxidative stress induced by exposure to H_2O_2, and to glucose starvation. The purpose of our research is the identification of protein partners whose interactions with the cytosolic domain of Mtl1p are relevant to its function in order to test them as targets for therapeutic drug discovery in pathogenic fungi. **Methods** – Our method is based in the *integrated Membrane Yeast Two Hybrid* (iMYTH) system for the detection of interactions between two proteins of interest. The membrane protein Mtl1p was employed as the *bait*, while all cytosolic and some membrane protein partners of Mtl1p that were captured by this assay (referred to as the *prey*) were subjected to a confirmatory test. **Summary of results** – We have preliminarily identified 25 novel prey proteins that interacted with the cytosolic domain of the Mtl1p bait and were classified as potentially relevant to its function. **Conclusions** – Our results demonstrate that novel interactions with cytosolic partners of trans-membrane proteins can be identified using this experimental approach. **Acknowledgments** - This research is supported by the University of Puerto Rico, Medical Sciences Campus, and NIH awards RCMI G12MD007600, RISE R25GM061838, and INBRE P20GM103475.

Y3067A Exploration of stress-induced genetic interactions in *Saccharomyces cerevisiae*. *V. Messier*[1], E. Koch[2], M. Costanzo[1], C. Myers[2], C. Boone[1], B. Andrews[1]. 1) Donelly Center, Toronto, Ontario, CA; 2) University of Minnesota, USA.

Our group has developed and exhaustively screened genetic interactions (GIs) at a genome-wide scale under standard growth conditions [1]. The Synthetic Genetic Array (SGA) methodology has also been used to explore how genetic interactions change in response to DNA damage and other stress conditions (e.g. [2, 3]), but a systematic exploration of the condition-sensitivity of genetic interactions has not been undertaken. We are building a conditional GI reference dataset, using high density single and double mutant arrays grown on agar plate. We aim at probing cellular responses to a panel of chemical-induced stress targeted at essential functions such as DNA and membrane integrity, transcription, translation and protein turnover, nutrient quality and sensing. As a proof of principle, we crossed ~200 condition-sensitive mutant query strains with a mini-array of 1200 highly informative mutant bait strains and performed a SGA analysis in six different growth conditions. Surprisingly, we observed genes that previously failed to be characterized by SGA under standard growth conditions displaying conditional GIs for specific functions, revealing their purpose in stress-induced cells. For example, the gene URM1 encoding an ubiquitin-like protein shared GIs with genes annotated for chromatin remodeling and signal transduction, both functions being suggested for urmylation in cells [4, 5]. Moreover, genes implicated in condition stress-response demonstrate GIs enrich for expected and unexpected functions, the latest represent new functions or functional switch under specific stress conditions. For instance, the target of rapamycin (TOR) kinase (TOR1, TOR2) and regulators shared GIs enrich for ribosome biogenesis (10^{-8}), chromatin remodeling (10^{-6}), chromosome segregation (10^{-5}) and DNA replication (10^{-5}). Chromosome missegregation and chromatin remodeling were described as a target in rapamycin treated yeast cells [6, 7]. The regulation of DNA replication by rapamycin-induced stress is novel and requires further validation. We, therefore, assemble data supporting a role of TOR activity in DNA replication under rapamycin growth.

Y3068B The Yeast Kinase Ksp1 Regulates Cellular Stress Response and mRNP Dynamics. *Nebibe Mutlu*, Daniel T. Sheidy, Philip C. Andrews, Anuj Kumar. University of Michigan, Ann Arbor, MI.

The cellular stress response in yeast and metazoans is complex, encompassing precisely regulated signaling pathways that coordinate processes such as nutrient sensing and transcriptional/translational regulation. The *S. cerevisiae* kinase Ksp1 plays a central role in this process. *KSP1* was first identified in a screen for high-copy suppressors of a mutation in the nucleotide exchange factor *SRM1*. More recently, we and others have identified *KSP1* as a gene required for wild-type yeast pseudohyphal growth, likely through its association with the Target of Rapamycin Complex (TORC1). Ksp1 negatively regulates autophagy via TORC1, and its localization changes during pseudohyphal growth. In particular, we have found that Ksp1 kinase activity is required for the transition to a pseudohyphal growth form in competent strains of *S. cerevisiae*. The signaling network of Ksp1, however, has not been studied directly on a proteome-wide scale in a filamentous background. To address this, we undertook an analysis of Ksp1 signaling through quantitative phosphoproteomics, identifying proteins differentially phosphorylated in a catalytically inactive kinase-dead Ksp1 mutant under conditions of nitrogen and glucose stress. Gene Ontology term enrichment analysis of the set of proteins differentially phosphorylated upon loss of Ksp1 kinase activity identifies a statistically significant set of proteins associated with mRNA-protein (mRNP) granule formation. mRNPs, encompassing P-bodies and stress granules, present an additional form of stress response thought to regulate mRNA translation. We find that Ksp1 localizes to mRNP granules in a filamentous background, in agreement with recent studies of mRNPs in a non-filamentous yeast strain. Moreover, the kinase activity of Ksp1 is required for wild-type localization of several mRNP component proteins/regulators upon growth to a high cell density, including Pbp1 and the P21-activated kinase ortholog Ste20. We further find that Ksp1 kinase activity regulates the localization of Kog1, a subunit of TORC1. Collectively, these results suggest a function for Ksp1 in coordinating TORC1-signaling and the regulation of mRNP dynamics, likely through phosphorylation of key effectors. Ongoing studies are aimed at identifying the mechanism through which this signaling is coordinated.

Y3069C Investigation of the nuclear translocation and degradation of Mth1. *J. Pierce*, M. Johnston. University of Colorado, Aurora, CO.

The rapid response of *Saccharomyces cerevisiae* to glucose is regulated by several pathways. The Snf3/Rgt2-Rgt1 (SRR) pathway detects extracellular glucose and regulates induction of *HXT* gene expression, allowing the cells quickly to import glucose. In the absence of glucose, Mth1 acts as a co-repressor with the Rgt1 DNA-binding protein to repress *HXT* gene expression. Upon addition of glucose, Mth1 exits the nucleus, interacts with the glucose sensors, where it is phosphorylated by the casein kinases Yck1/2. Mth1 is consequently ubiquitinated and then degraded, relieving repression of *HXT* gene expression. We determined by a heterokaryon assay that shuttling of Mth1 between the nucleus and the cytoplasm is not regulated by glucose. Inhibiting shuttling by adding an NLS to Mth1 prevented derepression of *HXT1* expression. Adding an NES to Mth1 prevents its degradation but does not interfere with the induction of *HXT1* expression. These results suggest that Mth1 is degraded in the nucleus and must be exported from the nucleus for *HXT* expression to be induced. Intrinsic NLS and NES sequences must be present in Mth1 to permit its shuttling between the nucleus and the cytoplasm. We located one NLS through truncation and internal deletion experiments. Previous studies identified eight serine residues in conserved Yck1/2 consensus phosphorylation sequences in Mth1 required for its degradation. We found that phosphorylation of only four of these eight serine residues, most importantly Ser133, are necessary for degradation of Mth1. Therefore, nuclear translocation and phosphorylation of Mth1 are required for its degradation and the ability of *Saccharomyces cerevisiae* to rapidly respond to glucose.

Y3070A Novel interacting protein partners of Wsc1p and Mid2p identified by iMYTH and TAP-MS. *E. Santiago-Cartagena*[1], M. Babu[2], I. Staglar[3], J. R. Rodriguez-Medina[1]. 1) University of Puerto Rico-Medical Sciences Campus, San Juan, PR; 2) Research and Innovation Center, University of Regina, Saskatchewan, Canada; 3) Donnelly Centre for Cellular and Biomolecular Research, University of Toronto, Toronto, Canada.

The PKC1-Cell Wall Integrity Pathway (PKC1-CWIP) is essential for survival and maintenance of cell wall integrity in pathogen and model yeast cells. In *S. cerevisiae*, the main protein sensors of the PKC1-CWIP, Wsc1 and Mid2, are responsible for the activation of the pathway in the presence of cell wall stress. Therefore, Wsc1p and Mid2p are an attractive target for antifungal drugs because they contribute to cell viability. The purpose of this research is to validate the sensor-interacting proteins previously identified by integrated Membrane Yeast Two-Hybrid (iMYTH) using Tandem Affinity Purification coupled to Mass Spectrometry (TAP-MS). To validate the iMYTH interactions, Wsc1-TAP and Mid2-TAP bait strains were co-precipitated by affinity to calmodulin sepharose beads and compared with a wild-type BY4741 strain under normal growth conditions. Results showed that Wsc1p and Mid2p baits were recovered. One protein, encoded by RPL40A gene was confirmed as a Mid2p interactor. Twenty new interactors were identified for Wsc1p and 23 new interactors for Mid2p in the TAP-MS. Ndr1p was the only interactor found to be previously annotated in the BioGRID. In conclusion, the Mid2-Rpl40a interaction was validated by both iMYTH and TAP-MS. The novel Wsc1p and Mid2p-interacting proteins identified come from a range of different biological processes, including stress response, protein synthesis and cell wall organization.This research was supported by University of Puerto Rico-Medical Sciences Campus, University of Toronto, University of Regina and NIH grants G12MD007600, U54MD007587, P20GM103475 and R25GM061838.

Y3071B Spatial control of translation repression and polarized growth by conserved NDR kinase Orb6 and RNA-binding protein Sts5. *Illyce Suarez*[1], David J. Wiley[1], Maitreyi Das[1,3], Marbelys Rodriguez Pino[1], Chuan Chen[1], Tetsuya Goshima[6], Kazunori Kume[5], Dai Hirata[5], Takashi

Toda[4,5], Fulvia Verde[1,2]. 1) University of Miami Miller School of Medicine, Miami, FL, FL; 2) Marine Biological Laboratory, Woods Hole, MA, USA; 3) Department of Biochemistry and Cellular and Molecular Biology. The University of Tennessee, Knoxville, TN, USA; 4) The Francis Crick Institute, Lincoln's Inn Fields Laboratory, 44 Lincoln's Inn Fields, London WC2A 3LY, United Kingdom; 5) Department of Molecular Biotechnology, Graduate School of Advanced Sciences of Matter, Hiroshima University, Higashi-Hiroshima 739-8530, Japan; 6) National Research Institute of Brewing, 3-7-1 Kagamiyama, Higashi-Hiroshima 739-0046, Japan.

Recent work has highlighted the role of RNA-binding proteins in the formation of ribonucleoprotein (RNP) granules by phase transition, but the mechanisms and regulation of this process are not fully understood. Here, we describe a novel function of the conserved NDR kinase Orb6 in inhibiting the localization of mRNA-binding protein Sts5 into RNPs. In fission yeast, Orb6 kinase has an established function in cell morphogenesis through the spatial control of Cdc42 GTPase. In this work, we show that regulation of Sts5 represents a genetically separable mechanism by which Orb6 kinase promotes polarized cell growth.

We find that Orb6 kinase inhibits the formation of Sts5 puncta that often colocalizate with processing (P) bodies by promoting Sts5 interaction with 14-3-3 protein Rad24. In addition, Orb6 kinase prevents degradation of Sts5-bound mRNAs, many of which encode proteins that have been shown to be essential for polarized cell growth. The condensation of Sts5 into cytoplasmic puncta is spatially and temporally controlled by Orb6 kinase, and interfering with this regulatory mechanism disrupts the pattern of polarized cell growth. Our work thus uncovers a role for Orb6 kinase in the spatial control of translational repression during normal cell morphogenesis.

Y3072C Ty1 integrase interacts with RNA polymerase III-specific subunits to promote insertion of Ty1 elements into the *Saccharomyces cerevisiae* genome. *S. T. Cheung*[1,2], L. Ma[2], P. H. W. Chan[3], H. Hu[4], T. Mayor[1,3], H. Chen[4], V. Measday[1,2]. 1) 1Department of Biochemistry and Molecular Biology, University of British Columbia, Vancouver, BC, Canada; 2) Wine Research Centre, University of British Columbia, Vancouver, BC, Canada; 3) Centre for High-Throughput Biology, University of British Columbia, Vancouver, BC, Canada; 4) Institute of Molecular Biology, Academia Sinica, Taipei, Taiwan 115.

The Ty1 retrotransposon belongs to a family of long terminal repeat elements in the *Saccharomyces cerevisiae* genome that replicates through an mRNA intermediate and is subsequently reverse transcribed into cDNA for genome insertion mediated by Ty1-encoded integrase (IN). Like many eukaryotic retroviruses, Ty1 insertions avoid the coding regions of the genome in order to prevent lethality of the host and propagate. Ty1 elements insert within a 1-2 kb region upstream of actively transcribed RNA Polymerase (Pol) III genes but the host factors that mediate Ty1 element insertion remained elusive for decades. We purified Ty1IN from yeast cell lysates using anti Ty1IN antibody-coupled magnetic beads followed by mass spectrometry analysis. The Ty1IN co-purified proteins were enriched with peptides corresponding to multiple RNA Pol III subunits. To further investigate the interaction between Ty1IN and Pol III subunits, we purified Pol III using GFP-Trap Immunoprecipitation (IP). Co-IP experiments with multiple GFP-tagged Pol III subunits and Ty1IN showed that Ty1IN interacts with most Pol III-specific subunits, but not with shared Pol subunits. However, since RNA Pol III is a stable complex and salt washes after GFP-Trap purification may not eliminate indirect protein interactions, we conducted an *in vitro* binding assay with purified Pol III-specific subunits and Ty1IN produced in *E. coli.* We demonstrated that the Pol III complex purified from yeast and Rpc31, Rpc34 and Rpc53 purified from *E. coli* interact with Ty1IN *in vitro*. To further characterize the Pol III IN-binding domain we used a strain carrying an N-terminal truncation mutant of Rpc53, *rpc53Δ2-280* and found that Ty1 element insertion upstream of an integration hotpot, *SUF16*, a glycine tRNA gene, was ablated. Yet, the overall transposition frequency of the *rpc53Δ2-280* mutant strain was reduced by only ~25%, suggesting possible retargeting of Ty1 element insertions in the genome. Furthermore, we found that the interaction between Ty1IN and Rpc37, but not other Pol III subunits, is disrupted in the *rpc53Δ2-280* strain. This data suggests that Ty1IN may bind to multiple subunits of Pol III to mediate Ty1 integration independently. Together, we reported that Ty1IN interacts with RNA Pol III through the Rpc53/Rpc37 subcomplex, and plausibly via the Rpc82/Rpc34/Rpc31 subcomplex, to mediate insertion of Ty1 elements upstream of Pol III-transcribed genes. Since the structure of Ty1IN and the mechanism of genome integration are highly conserved among retrotransposons and eukaryotic retroviruses such as HIV-1, our study provides important insights into how INs seize host proteins for targeted genome insertion.

Y3073A The Shu complex promotes error-free tolerance of alkylation-induced base-excision repair products. *B. W. Herken*[1], S. K. Godin[1], Z. Zhang[1,2], J. W. Westmoreland[3], A. G. Lee[1], M. J. Mihalevic[1], Z. Yu[1,2], R. W. Sobol[1,4], M. A. Resnick[3], K. A. Bernstein[1]. 1) University of Pittsburgh School of Medicine, Pittsburgh, PA; 2) Tsinghua University School of Medicine, Beijing, China; 3) National Institute of Environmental Health Sciences, Research Triangle Park, NC; 4) University of South Alabama Mitchell Cancer Institute, Mobile, AL.

The budding yeast Shu complex is an obligate heterotetramer that promotes error-free homologous recombination by facilitating the assembly of Rad51 filaments on single-stranded DNA after the resection of a double-strand break. The Shu complex is composed of two Rad51 paralogs, Psy3 and Csm2, a third protein Shu1, and a SWIM domain containing protein called Shu2. Orthologs of the Shu complex are conserved among eukaryotes, and mutations in human Rad51 paralogs are associated with cancer predisposition and Fanconi anemia. We have been characterizing a novel function for the Shu complex in the repair of DNA alkylation damage during post-replicative repair (PRR). Here we uncover the interplay between the Shu complex members and base excision repair (BER) machinery upon MMS-induced alkylation damage, providing evidence for the Shu complex's role in bypassing certain BER intermediates. Specifically, cells that lack the BER glycosylase *MAG1*, or the apurinic/apyrimidinic (AP) endonucleases *APN1* and *APN2,* preferentially utilize HR to repair MMS damage. The increased HR observed in *mag1Δ* and *apn1Δ apn2Δ* cells is Shu complex dependent. Furthermore, mutation of the translesion polymerase *REV3*, which is involved in error-prone PRR, further sensitizes these cells to MMS in a *shuΔ* background. Our work illustrates a role for the Shu complex in the promotion of error-free DNA damage resolution in a replicative context and provides further evidence for its importance in maintaining genomic stability.

Y3074B The role of the MRX complex in chromosome mobility and homology search. *F. Joseph*, R. Rothstein. Columbia University Medical Center, New York, NY.

Homologous recombination (HR) is the process used by DNA sequences to recover missing genetic information at the site of a double stand break (DSB). An essential aspect of HR that remains poorly understood is the mechanism of homology search. To study this aspect of HR in diploid yeast cells, a fluorescent chromosome tagging system was used to track chromosome mobility of the two homologs in response to DSBs. We previously found that yeast cells dramatically increase their chromosome mobility in response to DSBs. This response has two components: the first is a large "local" increase in the mobility of the cut chromosome; the second is a smaller "global" increase in mobility at other undamaged sites in the genome (including the homolog). The MRX complex, consisting of Mre11, Rad50, and Xrs2 proteins, plays multiple roles in HR; such as processing broken DNA ends and initiating DNA damage checkpoint signaling. Because of its multiple roles, we hypothesized that MRX would play a role in regulating chromosome mobility. To test this hypothesis we deleted Mre11, the protein-scaffolding component of the complex in cells with our chromosome tagging system. Chromosome mobility was assayed both before and after DNA damage. We find that when a site-specific DSB is induced with I-*Sce*I at the tagged locus in an *mre11Δ* strain, the local mobility of that site is greatly delayed. However, when the same mutant cells are treated with 40 Gy of ionizing radiation (IR), producing ~ 4 random DSBs in the genome, mobility of the tagged locus displays a normal global mobility response. This global mobility response can be blocked by inhibition of the PI3K checkpoint kinases using caffeine. In addition, we find that IR treatment of *mre11Δ* cells results in an increase in the number of both Rad51 and Rad52 foci that is indistinguishable from wild type cells. In contrast, accumulation of Rad51 and Rad52 foci after a site-specific DSB is delayed compared to a wild type strain. We propose that a single DSB requires resection initiation by the MRX complex to generate checkpoint dependent mobility, whereas, IR treatment rapidly results in checkpoint dependent DNA mobility due to the accumulation of multiple processed ends created by alternative means. Finally, we observe that pairing between tagged homologous chromosomes after induction of a site specific DSB is a delayed in a *mre11Δ* strain. This delay correlates with the observed delay in local mobility, supporting a model in which local mobility is necessary for pairing of homologous chromosomes.

Y3075C Unsolicited rDNA copy number variants frequently occur in yeast deletion collections and transformations. *Elizabeth X. Kwan*[1], Xiaobin S. Wang[1,2], Haley M. Amemiya[1], M. K. Raghuraman[1], Bonita J. Brewer[1]. 1) University of Washington, Seattle, WA; 2) Columbia University, New York, NY.

Ribosomal DNA (rDNA) is present in many copies in eukaryotic organisms and has been recently implicated in the regulation of gene expression, responses to replication stress, telomeric silencing, and aging. The budding yeast *S. cerevisiae* maintains 150 rDNA copies in a tandem array on chromosome XII. Instability of the yeast rDNA array is well documented, but the rDNA locus typically returns to wildtype copy numbers after perturbation, suggesting internal regulation of copy number maintenance. We sought to identify determinants of yeast rDNA copy number by performing a screen using the Yeast Knock-Out (YKO) single gene deletion collection. We also wanted to assess the relationship between rDNA number and yeast replicative lifespan and therefore examined the rDNA sizes of 434 YKO strains, 221 of which were reported to have extended replicative lifespans. We found no correlation between yeast longevity and rDNA copy number, but did identify 64 YKO candidates with significantly changed rDNA copy numbers. However, in the process of validating candidates using *de novo* gene deletions and tetrad analysis, we found that the altered rDNA phenotypes in the candidate YKO strains were not associated with the deleted genes. Instead, we found that rDNA copy number variants (CNVs) appeared at random within multiple transformants from each *de novo* gene deletion. Further examination revealed that cells taken through standard transformation protocols generated rDNA CNVs and that exposure to lithium acetate alone increased the rate of observed rDNA CNVs. Since lithium acetate transformation is commonly used in yeast strain construction, unanticipated rDNA CNVs could be potential passenger mutations that may have repercussions in the increasing number of reported cellular processes in which rDNA copy number matters.

Y3076A The Saccharomyces Genome Database Variant Viewer. *Olivia W. Lang*, Travis K. Sheppard, Benjamin C. Hitz, Stacia R. Engel, Giltae Song, J. Michael Cherry, The SGD Project. Stanford University, Palo Alto, CA.

The complete genome sequence of the budding yeast *S. cerevisiae*, and its annotation, is by the Saccharomyces Genome Database (SGD;http://www.yeastgenome.org), as a public resource for researchers. Until recently, the genome sequence displayed at SGD has been derived solely from the S288C strain background. We have now incorporated 11 additional *S. cerevisiae* genomes into SGD, as well as providing their annotation. We have also developed a new Variant Viewer to further support the community's analysis of these new data. Variant Viewer allows visualization and comparison of sequences from multiple strains. Users can quickly scan the entire genome, or a subset of genes, for overviews of both slight and significant sequence differences. SGD's Variant Viewer also includes a more detailed comparison of sequence differences between strains that highlights insertions, deletions, and SNPs that is available for both viewing and download. The Variant Viewer offers yet another way to explore the genomic sequence data available at SGD, as part of our continuing mission to educate students, enable bench researchers and facilitate scientific discovery. This work is supported by a grant from the NHGRI (U41 HG001315).

Y3077B The yeast Ty1 retrotransposon requires Nuclear Pore Complex subunits for transcription and genomic integration. *S. Manhas*, L. Ma, V. Measday. University of British Columbia, Vancouver, BC, CA.

Background: Nuclear pore complexes (NPCs) are molecular gateways that orchestrate cargo between the cytoplasm and nucleus and regulate cellular processes such as, gene expression. We utilized the Ty1 retrotransposon of *Saccharomyces cerevisiae* (*S. cerevisiae*) to study retroviral integration because Ty1 and retroviruses, including human immunodeficiency virus (HIV-1), have similar replication cycles and structurally and functionally conserved integrase (IN) enzymes required for genomic insertion of retrotransposons and retroviruses. Ty1 IN interacts with

subunits of RNA polymerase III to mediate insertion upstream of RNA Polymerase III transcribed genes such as tRNA genes. Since yeast tRNA genes are recruited to NPCs, we examined the role of NPC subunits, called nucleoporins (Nups), in Ty1 transposition.
Methods: We tested a panel of 19 Nup mutant yeast strains for Ty1 mobility defects by monitoring the formation of HIS+ colonies in Nup mutant strains carrying a plasmid with a *HIS3* marked Ty1 element. To determine if the defects in Ty1 mobility in Nup mutants were due to differences in the availability of Ty1 transposition intermediates, we quantified Ty1 mRNA levels in these yeast strains by quantitative PCR (qPCR), Ty1 cDNA levels by southern blotting, and Ty1 Gag protein levels by western blotting. We also examined Ty1 nuclear localization by fluorescence microscopy and tRNA gene expression by qPCR. We monitored endogenous Ty1 insertion events in our panel of Nup mutant strains by PCR to analyze Ty1 integration levels upstream of the glycine tRNA gene *SUF16*, which is a hot spot for Ty1 targeting. Because the *SUF16* locus is located within the pericentromere of chromosome III, which may have different targeting requirements than other chromosome regions, we also measured Ty1 insertion upstream of the serine *SUP61* tRNA gene which is located on the right arm of chromosome III.
Results: Of the 19 mutants tested here, 11 (*nup120Δ, sec13-1, nup170Δ, nup53Δ, nup188Δ, nup192-15, nup60Δ, mlp1Δ, mlp2Δ, nup159-1, pom34Δ*) Nup mutant yeast strains had Ty1 mobility defects and altered Ty1 element insertion upstream of the *SUF16* and *SUP61* loci. Interestingly, but unexpectedly, we discovered that Nup mutant yeast strains that had wild type levels of Ty1 mobility (*nup84Δ, nup133Δ, ndc1-4, nup42Δ, nup100Δ, pom152Δ, nup2Δ*), also had impaired Ty1 element insertion upstream of *SUF16* and *SUP61*. The *nup60Δ* strain had strikingly impaired levels of Ty1 mRNA resulting in minimal Ty1 Gag protein, and cDNA production whereas the remaining Nup mutant yeast strains had minimal defects in Ty1 transcription, translation, cDNA production or Ty1-IN localization. Taken together, our data suggests that the NPC may function as part of both the Ty1 element transcription and integration machinery. .

Y3078C A systematic appraisal of Cdc13's domain organization. *S. Y. Mersaoui*, R. J. Wellinger. Université de Sherbrooke, Sherbrooke, Québec, CA.

Budding yeast Cdc13p is essential and a key protein involved in telomere maintenance and genome stability. Genetic and high-resolution structural studies of several of its fragments reveal an architectural organisation with five distinct domains , which include four OB-fold domains and one recruitment domain. However, many details on the *in vivo* roles of those domains and their potential inter-domain interactions remained elusive. In this work we constructed tagged versions of the Cdc13 protein and then generated five alleles, where each one contains a single deletion of a proposed domain. To study the roles of each domain in telomere maintenance, we took advantage of *cdc13-independent* cells. Although viable, these strains "Adapt" and inactivate check-point signalling to bypass the accumulation of telomeric DNA damage. The results show:

1- The first 80 amino acids of the OB1 domain contribute to stabilization of the Cdc13 protein. *cdc13Δ*-cells with this mutated protein show a strong capping defect. However this capping defect can be rescued when this mutated protein is co-expressed with the hypomorphic *cdc13-1* allele. This result suggests a physical interaction and therefore supports a model where Cdc13 occurs as homodimer at the telomere. **2-** Co-IP experiments, using two tagged-versions of Cdc13 strongly argue for this homodimer model. Surprisingly, the hypomorphic *cdc13-1* allele doesn't display any sign of dimerization defect at restrictive temperatures. Our data rather support the idea that Cdc13 dimerization requires at least two interfaces where the DBD domain contains the core dimerization interface. **3-** The third domain (OB2) is essential for cell viability. *cdc13-ob2Δ* is unable to bind telomeric DNA *in vivo* and results in a capping deficiency in both *cdc13Δ* and *cdc13-1* (*ts*) strains. This mutated protein still behaves as a dimer, indicating that OB2 is not involved in dimer formation. However, immunofluorescence analysis shows a mis-localized protein residing in the cytoplasm. Re-inserting a heterologous NLS peptide in place of OB2 restores nuclear localization, *cdc13-independent* capping and suppresses the *ts* phenotype of *cdc13-1* mutant strain. Moreover, expression of the *cdc13-ob2Δ-NLS* results in hyper elongated telomere, suggesting an additional function. **4-** *Cdc13-independent* cells are sensitive to damage induced by genotoxic drugs. Remarkably, ectopic expression of Cdc13 cells restores a normal resistance to those drugs. This observation suggests an unexpected role of Cdc13 in DNA damage response at telomeres. Results obtained with the same deletions as described above, we conclude that this sensitivity to genotoxic drugs in the *cdc13Δ* cells may be due to the eroded state of the telomeres in these cells.

Y3079A Investigating genome instability induction mechanisms in yeast *DIS3* mutants. *K. Milbury*[1,2], P. Stirling[1,2,3]. 1) Terry Fox Laboratory, BC Cancer Research Centre, Vancouver, British Columbia, CA; 2) Genome Science & Technology, University of British Columbia, Vancouver, British Columbia, CA; 3) Department of Medical Genetics, University of British Columbia, Vancouver, British Columbia, CA.

Chromosome instability (CIN) is characterized by an increased rate of the unequal distribution of DNA between daughter cells. These large changes in chromosome structure or number can occur due to both mitotic defects leading to aneuploidy and DNA damage-induced chromosome rearrangements. Previous large-scale screens for CIN genes identified *DIS3*, which codes for a catalytic component of the core RNA exosome complex, as a novel CIN gene in the yeast *Saccharomyces cerevisiae*. Presumed reduction-of-function mutations in the human *DIS3* orthologue have been identified in roughly 11% of multiple myeloma (MM) cases. We sought to determine the mechanism of CIN in *DIS3* mutants and to recapitulate MM-associated point mutations at conserved sites in yeast cells, in order to understand potential connections of CIN to MM. We have found that MM-associated *DIS3* mutations induce DNA:RNA hybrid accumulation and increased rate of CIN, although immunofluorescence analysis of DNA damage foci revealed no increase in double-strand breaks. Microarray analysis of one MM mutant has additionally demonstrated downregulation of cell cycle components, consistent with the potential for mitotic defects. Further, genetic interaction profiling by synthetic genetic array indicates MM-associated *DIS3* mutations synthetically interact with rRNA processing proteins, as well as a host of mitotic regulators and metabolic pathways. Together, these results demonstrate extensive phenotypic consequences of MM-associated point mutations in *DIS3*, and support a model for CIN in *DIS3* mutants involving defects in cell cycle processes.

Y3080B Diverse Sites of Chromosome Breakage in Retrotransposon Overdose Yeast Strains. *L. Z. Scheifele*[1], C. M. Lanzillotta[1], C. McLeod[1], S. Minikel[1], N. Monteleone[1], B. Yang[1], S. J. Wheelan[2]. 1) Department of Biology, Loyola University Maryland, Baltimore, MD; 2) Department of Oncology, Division of Biostatistics and Bioinformatics, Center for Computational Genomics, Johns Hopkins School of Medicine, Baltimore, MD.

Fragile sites are frequent sites of chromosomal rearrangements. Human cells contain numerous fragile sites that differ remarkably in their propensity for instability (Glover 1984), yet we do not understand why a subset of fragile sites is more prone to instability and to rearrangement than the other fragile sites. We have used retrotransposon overdose (RO) yeast cells as a model system for fragile site stability; retrotransposon pairs are known to serve as sites of instability (Lemoine 2005), and RO strains contain many more single retrotransposon elements and retrotransposon pairs in a variety of genomic contexts. RO strains show an elevated level of instability under the same conditions as human fragile sites such as replication stress. When RO strains are subjected to treatment with methylmethanesulfonate (MMS) in combination with a temperature-sensitive polymerase-α allele (*pol1-17*) or deletion of the replication checkpoint protein *MEC1*, there is an increased incidence of chromosome rearrangement in RO strains relative to wild-type. While RO strains displayed a diverse complement of chromosome aberrations, a subset were recurrent among independent isolates, suggesting that particular chromosome loci were more susceptible to chromosome breakage than others. Genome sequencing of strains containing chromosome aberrations revealed that many aberrations were coincident with Ty1 and Ty2 retrotransposons, with particular retrotransposon elements more likely than others either to be present at rearrangement breakpoints or to be deleted follwing replication stress. When comparing the sites of rearrangement induced in *pol1-17* cells and *mec1* cells, there were few common chromosome aberrations, suggesting that different mechanisms of replication stress may induce rearrangement at distinct sites. The location of chromosome aberrations was also examined following experimental lab evolution. As expected, RO strains displayed both a greater number and a greater diversity of chromosome rearrangements following lab evolution. Due to the destabilizing effect of retrotransposons, we expected frequent loss of Ty elements following evolution, yet we discovered both new insertions of Ty elements as well as deletions; these deletions were just as likely to occur at single retrotransposon elements as at retrotransposon pairs. These data suggest that the arrangement of retrotransposons as pairs is itself insufficient to make a locus unstable, but rather that additional factors govern the varying stability of these repetitive regions.

Y3081C Rad51 regulates the global mobility response to double-strand breaks. *Michael Smith*, Rodney Rothstein. Columbia University Medical Center, Department of Genetics and Development, New York, NY 10032.

In *Saccharomyces cerevisiae*, chromosomal mobility increases after the formation of a double-strand break (DSB). Cut loci expand their radius of exploration substantially in a process termed local mobility. In addition, there is an increase in global mobility following a DSB, in which even undamaged loci expand their radius of exploration. Here, we examine the role of the RecA-like recombinase Rad51 in regulating the mobility of chromosomes in diploid budding yeast cells after DSB formation. We find that global mobility is dependent on *RAD51* throughout the cell cycle, and that Rad51 regulates mobility in G1 as well as S phase chromosomes. This regulation depends on a functional Walker A ATPase domain, but does not require dsDNA binding or strand exchange activities of Rad51 protein. Although some ssDNA binding is essential for global mobility, extensive filament formation is dispensable, as *rad52Δ* cells are still capable of promoting increased movement. Finally, we find that DNA damage checkpoint induction is both necessary and sufficient to induce global mobility in diploid cells. Interestingly, this induction, even in undamaged cells, is dependent upon the presence of Rad51. We propose that Rad51 serves as an important damage sensor that signals to the DNA damage checkpoint machinery to promote mobility.

Y3082A How telomeres are maintained: the role of Ku-mediated telomerase recruitment. *David C. Zappulla*, Evan P. Hass. Johns Hopkins University, Baltimore, MD.

The ends of linear eukaryotic chromosomes shorten with each cell cycle due to the end-replication problem, ultimately leading to senescence and death. Telomerase countervails this deficiency by synthesizing telomeric repeats by reverse transcribing a portion of its RNA subunit, thus providing cell proliferation potential, critical to aging and cancer. It has become apparent that telomerase provides telomere-length homeostasis by preferentially extending the shortest ends. However, it is not clear how this selective telomerase action is achieved. One major mechanism by which telomerase is regulated is its recruitment to telomeres. In *S. cerevisiae*, two subunits of the RNA-protein enzyme have been shown to be involved in recruitment: Est1 recruits telomerase to the telomeric end-binding protein Cdc13, whereas Ku recruitment was also known to occur, but it was not clear how. We have determined that telomerase recruitment by Ku requires the interacting protein, Sir4, which is an integral part of telomeric silent chromatin. Epistasis analysis puts Ku, Sir4 and the Ku-binding site of telomerase RNA, TLC1, in the same pathway. Additionally, we were able to bypass Ku in telomerase recruitment and telomere length regulation by tethering telomerase RNA directly to Sir4. Having established the Ku-Sir4 recruitment pathway, we then evaluated its role in telomere length regulation. Introducing multiple Ku-binding sites in telomerase RNA caused telomere hyperlengthening, demonstrating the acute sensitivity of telomere length to the Ku-mediated telomerase recruitment pathway. This phenotype reminded us of the runaway-telomeres of *rif1*Δ and *rif2*Δ mutants and since Rif proteins also directly compete with Sir4 for binding to the telomeric double-stranded DNA binding protein Rap1, we tested if hyperelongated telomeres in *rif*Δ mutants require Ku function in telomerase. We found that nearly wild-type telomere length returns to *rif*Δ cells upon deletion of the Ku-binding hairpin in TLC1. These results suggest that direct interplay between Rif and Sir4 proteins along the distal portions of chromosomes is key to sensing telomere length and, in turn, appropriately recruiting telomerase preferentially to the shortest telomeres.

Y3083B Combinatorial histone readout by the dual PHD domains of Rco1 mediates Rpd3S chromatin recruitment and the maintenance of transcriptional fidelity. *Julia DiFiore*[1], Stephen McDaniel[1], Jennifer Fligor[2], Chun Ruan[3], Haochen Cui[3], Joseph Bridgers[4], Angela Guo[4], Bing Li[3], Brian Strahl[1,4]. 1) Curriculum in Genetics and Molecular Biology, University of North Carolina at Chapel Hill, Chapel Hill, NC; 2) Northwestern

University Feinberg School of Medicine, Chicago, IL; 3) UT Southwestern Medical Center, Dallas, TX; 4) Department of Biochemistry and Biophysics, University of North Carolina at Chapel Hill, Chapel Hill, NC.

The PHD domain is found in many chromatin-associated proteins and functions to recruit effector proteins to chromatin through its ability to bind both methylated and unmethylated histone residues. Here, we show that the dual PHD domains of Rco1 – a member of the Rpd3S histone deacetylase complex recruited to transcribing genes – operate in a combinatorial manner in targeting the Rpd3S complex to histone H3 in chromatin. While mutations in either the first or second PHD domain allow for Rpd3S complex formation, the assembled complexes from these mutants cannot recognize nucleosomes or function to maintain chromatin structure and prevent cryptic transcriptional initiation from within transcribed regions. Taken together, our findings establish a critical role of combinatorial readout in maintaining chromatin organization and in enforcing the transcriptional fidelity of genes.

Y3084C Defects in the nucleosome entry-exit site impair transcription termination. *A. Elizabeth Hildreth*, Karen M. Arndt. University of Pittsburgh, Pittsburgh, PA.

In eukaryotes, the chromatin template acts as a restrictive barrier to RNA polymerase II (Pol II), the molecular machine that transcribes protein coding and some noncoding RNAs. Chromatin consists of repeating nucleosomes, which contain approximately 147 bp of DNA surrounding an octamer of histone proteins H2A, H2B, H3, and H4. Transcription is controlled by factors that remove or modify these nucleosome barriers, allowing Pol II to contact otherwise occluded DNA. The mechanisms by which chromatin is modified are well understood in regard to transcription initiation and elongation. Despite a few studies showing that transcription-coupled histone modifications and select chromatin remodelers are important for proper termination, little else is known about the role of chromatin at this final termination step. We are investigating the role of chromatin in transcription termination using *Saccharomyces cerevisiae* as a model. To screen for histone H3 and H4 residues required for proper termination, we have made use of a plasmid library encoding histones with all possible alanine substitutions and a well-characterized, growth-based termination reporter. Our unbiased screen has identified ten residues in H3 and H4, which when mutant, cause defects in termination. Interestingly, many of these residues reside in or near the DNA entry-exit site of the nucleosome. This protein surface, including portions of histones H3 and H2A, is responsible for coordinating the first 30 bp of DNA, thus regulating the stability of the protein-DNA complex. Analysis of strains harboring these mutant histones has revealed transcriptional read-through at endogenous genes, altered nucleosome occupancy at candidate loci, and defects in the placement of a transcription-coupled histone modification previously implicated in termination and repression of cryptic transcription. Research in other labs has shown that conditions that speed up the rate of transcription elongation cause termination factors that associate with Pol II to effectively miss the appropriate termination window. We have begun assessing the elongation rates of Pol II in mutant yeast strains to determine whether altered transcriptional rates contribute to the observed termination defects. Additionally, we have begun screening H2A residues within the DNA entry-exit site for similar defects. Together, these data implicate the DNA entry-exit site as an important player in proper termination of transcription.

Y3085A Controlling methylation during cell fate determination. *M. J. Law*, M. A. Finger. Rowan University-GSBS Stratford, NJ.

Cell fate decisions require integrating extracellular signaling cues into tightly regulated transcription programs. Communication between the RNA polymerase II holoenzyme complex and dynamic post-translational histone modifications is central for transcription. The RNA pol II holoenzyme is composed of two evolutionarily conserved yet functionally distinct complexes; the core mediator and the CDK8 submodule. In the budding yeast *Saccharomyces cerevisiae,* the CDK8 submodule, composed of cyclin C, Cdk8p, Med12p, and Med13p, plays important roles in mediating transcription of stress responsive and developmental genes. Histone Lysine methylation is a key regulator of transcription during cell differentiation. Histone H3Lys4 methylation ($H3K4^{Me}$), regulated by the opposing activities of the Set1p methyltransferase and the Jhd2p demethylase, is important for all phases of transcription. While much work has been done to investigate how $H3K4^{Me}$ regulates transcription, less is understood about how Set1p and Jhd2p are controlled during cell fate determination.

Work in my lab has uncovered an unexpected genetic interaction between the CDK8 submodule, the $H3K4^{Me}$ regulators, and yeast cell fates. When deprived of nutrition, diploid yeast can enter one of two partially overlapping differentiation pathways, meiosis or pseudohyphal growth (PH). We have recently published that both *CNC1*/*CDK8* and *JHD2* are required to inhibit PH while yeast are cultured in rich conditions. This study also revealed that Cnc1p/Cdk8p repress locus-specific $H3K4^{3Me}$ independently of *JHD2*, indicating that Cnc1p/Cdk8p can regulate transcription during differentiation by controlling $H3K4^{Me}$ levels.

To identify loci subject to *CNC1*-dependent $H3K4^{3Me}$ controls, we employed ChIP-seq. These experiments identified significant enrichment for $H3K4^{3Me}$ in metabolic promoters, which is consistent with a model in which *CNC1*/*CDK8* control $H3K4^{Me}$ of genes important for cell fate decisions. We further explored how *CNC1*-mediated $H3K4^{Me}$ controls are integrated into cell fate decisions by measuring $H3K4^{1Me, 2Me, 3Me}$ in rich and nutrient deprived growth conditions. These experiments revealed an important role for *CNC1*/*CDK8* inhibiting $H3K4^{Me}$ during nutrient deprivation, supporting a key function during cell fate determination. We determined that these methylation controls had a direct impact on target gene transcription using RT-qPCR. Finally, we queried whether *CNC1*/*CDK8* inhibit Set1p catalysis or recruitment by performing ChIP-qPCR directed towards Set1p or $H3K4^{3Me}$. These experiments found that Set1p recruitment is inhibited by *CDK8* as cells are poised to differentiate. These data support a model in which *CNC1*/*CDK8* control cell fate decisions by restricting Set1p recruitment in response to developmental cues.

Y3086B Histone H3K4 demethylase *JHD2* antagonizes the function of highly conserved histone chaperones FACT and Spt6 through the Rpd3S histone deacetylase complex. *K. Lee*, M. Meneghini. University of Toronto, Toronto, Ontario, CA.

Mammals encode a highly conserved family of histone H3 lysine 4 (H3K4) demethylases known as the JARIDs that have important roles in

regulating gene expression and controlling the balance between pluripotency and differentiation in stem cells. Gaining mechanistic and physiological insight on the consequences of JARID-mediated H3K4 demethylation has been challenging due the high level of redundancy in the mammalian JARID gene family. Methylated histones function as scaffolds for the recruitment of activating or repressive chromatin factors. The recruitment of specific factors is likely modulated by JARID-mediated H3K4 demethylation. We study Jhd2, the single JARID family H3K4 demethylase, in budding yeast *Saccharomyces cerevisiae*, using this simple model to investigate the consequences of JARID-mediated H3K4 demethylation. Genetic interrogation of *JHD2* revealed that temperature sensitive growth defects exhibited by mutants of the highly conserved histone chaperones Spt6 and FACT are rescued by *JHD2* deletion. Rescue is specific to loss of *JHD2* enzymatic activity and requires H3K4 trimethylation. *JHD2* deletion does not directly affect FACT protein stability or genomic localization, but genetic epistasis suggests that *JHD2* deletion rescues Spt6 and FACT temperature sensitivity indirectly through the modulation of the small Rpd3 histone deacetylase complex. In our working model, Jhd2-mediated H3K4 demethylation functions to regulate Rpd3S recruitment through its plant homeodomain containing subunit Rco1.

Y3087C Nutrient availability impacts chronological lifespan and Sir-based silencing in S. cerevisiae. *D. McCleary*, J. Rine. University of California at Berkeley, Berkeley, CA.

Sir2 is an NAD+-dependent protein deacetylase necessary for the formation of heterochromatin in the budding yeast Saccharomyces cerevisiae. It has been implicated in a number of important processes including the regulation of yeast aging. Sir2 function is also known to be influenced by a variety of nutrients, including nitrogen, phosphorus, and carbon source. Even though Sir2 regulates aging and can respond to changes in nutrient availability, it is unknown whether Sir2 is involved in the well-documented and evolutionarily conserved extension of lifespan resulting from calorie restriction. Past studies have produced conflicting results, possibly due to experimental constraints that require the use of unbuffered minimal media for all experiments.

We have now developed an assay whereby yeast chronological aging can be studied in any media, allowing for Sir2's aging role to be better understood. While Sir2 doesn't seem to be involved in calorie restriction-mediated lifespan extension in minimal media, it does seem to be necessary for full calorie restriction-mediated lifespan extension in complex media. We have also shown for the first time that increasing glucose concentration alters Sir2-mediated heterochromatic silencing at the mating type locus HML, and that the directionality of this effect is opposite on minimal and complex media. Deletion of SIR2 also leads to opposite aging phenotypes during growth on minimal and complex media, leading to the exciting hypothesis that the stability of Sir2-based heterochromatic silencing at HML or some other Sir2 deacetylation target links glucose availability to aging dynamics.

Y3088A The histone prolyl isomerases Fpr3 and Fpr4 regulate nucleolar chromatin architecture. *Christopher J. Nelson*, Neda Savic. University of Victoria, Victoria, BC, CA.

The structure of chromatin occludes much of the underlying DNA sequence. Accordingly, processes that impinge on DNA sequence, including the transcription of RNAs and the recombination, repair and replication of DNA, use histone chaperones and histone post-translational modifiers to overcome this barrier. Fpr3 and Fpr4 are yeast histone chaperones that also contain C-terminal FKBP histone prolyl isomerase domains. How these nuclear enzymes are used to regulate chromatin *in vivo* has not been well resolved.

Using reporter genes integrated throughout the yeast genome, as well as RNA-Seq, we find that Fpr3 and Fpr4 co-operate to establish a defined transcriptionally-silent chromatin domain within the rDNA locus. To obtain a global view of Fpr3 and Fpr4 function, we performed modified synthetic genetic interaction screens to query which biological processes are sensitive to these enzymes. These experiments revealed a synthetic lethality between Fpr4 and components of the RNA exosome; a complex that functions to degrade aberrant RNA transcripts. Together our results demonstrate that nuclear FKBPs and the RNA exosome co-operate to down-regulate RNAs generated from rDNA spacers. They also suggest that nuclear prolyl isomerases are particularly important at organizing rDNA chromatin. Finally, the effects of some chromatin modifiers on RNA expression may be masked by RNA exosome action.

Y3089B Chromatin regulation of pericentromic non-coding RNA in *Saccharomyces cerevisiae* and its effect on chromosome stability. *A. Ravi Shankar*, J. Gallagher. West Virginia University, Morgantown, WV.

Non-coding RNAs in higher eukaryotes are known to play important roles in genome stability, whereas in *Saccharomyces cerevisiae* any explicit roles are yet to be deciphered. Centromeres in eukaryotes are broadly classified as regional or point centromeres. *S. cerevisiae* contain point centromeres that do not exhibit centromeric silencing as regional centromeres do, but have specialized chromatin essential for function. In yeast, essential genes are often found near the centromere. Hence, non-coding RNA found near the centromere may be responsible for maintaining centromere function and prevent spreading of silencing chromatin. The minimal point centromeres are 125 base pairs in length with three conserved elements (CDE) and contain the centromere specific histone H3 variant, Cse4. Of the 16 yeast chromosomes almost half of them were found to have pericentromeric Stable Unannotated Transcripts (pSUTs) which were all found to be transcribed away from the CDEIII side of the yeast centromere. SUTs were discovered using genome-wide tiling arrays covering the entire yeast genome.
These pericentromeric noncoding RNAs were found to be regulated by Sir1 and Cac1, which are important for heterochromatic silencing at other regions of the genome. Studies on the interaction time of Sir1 at the centromere, and the cell cycle stage in which this takes place, will help fill the gap in knowledge regarding the silencing mechanisms involved. The Nonsense Mediated Decay pathway was mostly responsible for the degradation of these pericentromeric transcripts in the cytoplasm. Absence of pSUTs increases sensitivity to chemicals such as hydroxyurea when combined with *sir1, cac1* double mutants or with an NMD mutant suggesting that the pSUT itself may play a role in DNA

replication through centromeric DNA. The extent of conservation of this region within the *Saccharomyces* clade would emphasize its importance. Further studies will address the function of the pSUTs on chromosome stability and determine requirements for transcription.

Y3090C Interactions between variant histone H2A.Z and linker histone H1 in budding yeast. *J. Riggs*, J. Huang, P. Chen, L. Winston, M. Sica, S. Holmes. Wesleyan University, Middletown, CT.

Loss of variant histone H2A.Z in budding yeast cells leads to alterations in Sir protein-dependent transcriptional silencing, possibly due to impaired function of chromatin boundaries. We observed that deletion of *HHO1*, coding for linker histone H1, could suppress silencing defects seen in *htz1Δ* strains. We subsequently observed that loss of H1 also ameliorates the growth defects seen in strains lacking H2A.Z. *HTZ1* is synthetically lethal with several dozen yeast genes; these genes have widely varying functions. To examine the specificity of the H1-H2A.Z interaction we examined whether loss of H1 can restore viability to synthetically lethal *htz1Δ ykoΔ* strains. Preliminary evidence suggests that loss of H1 specifically rescues the viability or slow growth of strains combining *HTZ1* deletions with deletions of genes involved in histone deacetylation or ubiquitination. Finally, we have used chromatin immunoprecipitation to establish that strains lacking H2A.Z show reduced association of histone H1 with chromatin. Overall our experiments suggest that loss of H2A.Z triggers an H1-dependent disruption of normal chromatin structure.

Y3091A Association of CAF-1 and Rrm3p with paused replication forks. *Hollie Rowlands*, Brandon Wyse, Roxanne Oshidari, Ashley Cheng, Piriththiv Dhavarasa, Krassimir Yankulov. University of Guelph, Guelph, Ontario, CA.

Genes positioned close to telomeres are either fully active or fully silenced and infrequently convert between these two states, a phenomenon referred to as Telomere Position Effect. The mechanisms of epigenetic conversions at the telomeres, and in general, are not well understood. Recently we have shown that the destruction of Chromatin Assembly Factor – I (CAF-I) in *S.cerevisiae* reduces the frequency of such telomeric conversions. CAF-I is a histone chaperone which rebuilds nucleosomes from old and new histones immediately after the passage of the replication forks. It is believed that its nucleosome assembly activity is central to the transmission of epigenetic marks to the chromatin of daughter cells and that it acts as a key factor in the preservation of epigenetic states.

In this poster we show that the deletion of *RRM3*, a DNA helicase that releases paused replication forks, has a similar effect on the frequency of epigenetic conversions. We present our analyses on the occupancy of CAF-1 and Rrm3p at replication forks that are stably paused *in vivo* by the association of the Fob1p protein. We correlate these Chromatin Immuno-Precipitation (ChIP) analyses with analysis of the interactions of Rrm3p and CAF-1 with the fork clamp Pol30p (PCNA, Proliferating Cell Nuclear Antigen).

We propose that CAF-I, albeit being involved on the faithful transmission of epigenetic marks, is needed for epigenetic conversions when replication forks stall.

.

Y3092B Invasion of a heterochromatic locus during homologous recombination disrupts its transcriptional silencing. *Kathryn Sieverman*, Jasper Rine. Department of Molecular and Cell Biology, California Institute for Quantitative Biosciences, University of California at Berkeley, Berkeley, CA.

Eukaryotes from yeast to humans employ heterochromatin, a compact chromatin structure, to stably silence gene expression and ultimately influence cellular identity and genomic integrity. In the budding yeast *Saccharomyces cerevisiae*, the Silent Information Regulator (SIR) proteins impart heterochromatic silencing at the silent mating-type loci *HML* and *HMR*. Silencing at *HML* and *HMR* leads to a 1000-fold reduction in transcription over the expressed state, is stably inherited from mother to daughter cell, and is critical for maintaining haploid identity. Our lab recently developed a novel assay to capture the dynamics of heterochromatic silencing in budding yeast, which we have named the Cre-Reported Altered States of Heterochromatin, or CRASH, assay. We placed the *cre* recombinase gene at the *HML* locus to monitor heterochromatin stability. Lapses in silencing at *HML* allow Cre to excise a loxP-flanked RFP cassette, subsequently activating GFP expression and revealing for the first time rare and transient silencing losses in wild-type cells. In this study, we exploited the sensitivity of the CRASH assay to understand how homologous recombination within the silent *HML* locus impacts its ability to remain transcriptionally silent. Recombination within heterochromatin requires access to an otherwise occlusive chromatin structure, yet whether this invasive process also disrupts silencing is unknown. We introduced into cells equipped with the CRASH assay a double-strand break that induces homology-directed repair from *HML*. Interestingly, our results demonstrate that homologous recombination can occur in a heterochromatic donor without an obligate loss of silencing. However, it appears that many cells that template recombination at *HML* lose transcriptional silencing in the process. The reasons for these two distinct outcomes are under active investigation.

Y3093C Replication factors function in Cohesion and Condensation. *R. V. Skibbens*, Donglai Shen, Caitlin Zuilkoski. Lehigh University, Bethlehem, PA.

To ensure accurate chromosome segregation, the yeast genome undergoes dramatic structural changes that include DNA replication, sister chromatid cohesion and chromosome condensation. Numerous studies reveal that DNA replication factors impact cohesion establishment, but the molecular mechanism through which this regulation occurs and the extent that replication factors similarly regulate chromosome condensation remains unknown. Here, we investigate two DNA replication factors that regulate temporally distinct steps in cohesion. Chl1 is a DEAH-box DNA helicase that functions early during DNA replication to promote sister chromatid cohesion. The extent to which Chl1 promotes condensation, however, remains unknown. To address this deficit, we tested for Chl1-dependent condensation at both the rDNA locus and along the chromosome arm. Using both Net1-GFP and a modified FISH procedure to visualize rDNA locus structure, the results show that *chl1*

deletion strain exhibit significant levels of decondensation, relative to wildtype cells. We also tested for condensation defects along the chromosome arm using a two GFP assay kindly provided by Dr. Frank Uhlmann. Compared to wildtype cells, *chl1* mutant cells exhibited a significant increase in inter-GFP distances. These results reveal that Chl1 plays a critical role in condensation - extending the role of Chl1 beyond cohesion and identifying Chl1 as an early regulator of chromatin structure. PCNA is a sliding clamp that promotes processive DNA replication and interacts with the cohesion establishment factor Ctf7/Eco1. Previous results revealed that overexpression of PCNA rescues the conditional growth defects in *ctf7/eco1* mutant cells. The molecular basis of this rescue, however, remains unknown. We thus tested whether PCNA overexpression rescues either the cohesion or condensation defects present in *ctf7/eco1* mutant cells. The results reveal that PCNA overexpression rescues the cohesion defects, but not the condensation defects, of *ctf7/eco1* mutants. These results support prior findings from our lab that PCNA rescues the cohesion, but not the condensation, defects in *pds5* mutant cells. Thus, PCNA plays a critical role in regulating a unique and distinct aspect of cohesin biology. In combination with other findings from our lab, these results support a new model in which cohesin is deposited onto each sister chromatid early during DNA replication and that this deposition relies on Chl1 DNA helicase-dependent alterations of DNA structure. Later during DNA replication, and possibly signaled through completion of Okazaki maturation, PCNA promotes cohesin-dependent establishment of sister chromatin cohesion but not chromosome condensation. Thus, cohesin functions (and possibly structures) are separable and likely spatially regulated throughout the genome. .

Y3094A Nucleosomes Are Essential for Proper Regulation of a Multigated Promoter in *Saccharomyces cerevisiae*. *Robert Yarrington*, Jenna Goodrum, David Stillman. University of Utah, Salt Lake City, UT.

We have previously shown that transcription factor binding at *HO* follows a temporal cascade, with SBF bound at the left half of URS2 (URS2-L) serving to relay a signal from upstream chromatin changes at URS1 to the SBF bound at the right-half of URS2 (URS2-R) that ultimately activate gene expression. We show here that proper nucleosomal context of the URS2 promoter region is essential for this complex transcriptional regulation. Chromatin at the yeast *HO* promoter is highly repressive and numerous coactivators are required for expression. We modified the *HO* promoter with segments from the well-studied *CLN2* nucleosome-depleted region (NDR), creating chimeric promoters differing in nucleosome occupancy but with binding sites for the same activator, SBF. Nucleosome depletion resulted in substantial increases in both factor binding and gene expression and allowed activation from a much longer distance, presumably by allowing coactivators recruited at the upstream URS1 region to act further downstream. Nucleosome depletion also affected sequential activation of the *HO* promoter, resulting in promoters no longer requiring both URS1 and URS2-L, as either regulatory region alone is now sufficient to promote binding of the SBF factor to URS2-R. Furthermore, nucleosome depletion at URS2 altered the timing of *HO* expression and bypassed the regulation that normally restricts expression to mother cells. Our results reveal insight into how nucleosomes can create a requirement for ordered recruitment of factors to facilitate complex transcriptional regulation.

Y3095B The interactions between Pol30p (PCNA, Proliferating Cell Nuclear Antigen), Chromatin Assembly Factor -1 and Rrm3p: the role of the CDC28 and CDC7 protein kinases. *P. Dhavarasa*, B. Wyse, H. Rowlands, L. Fedak, M. Guilleman, K. Yankulov. University of Guelph, Guelph, Ontario, CA.

The interactions between Pol30p (PCNA, Proliferating Cell Nuclear Antigen), Chromatin Assembly Factor -1 and Rrm3p: the role of the CDC28 and CDC7 protein kinases

Piriththiv Dhavarasa, Brandon Wyse, Hollie Rowlands, Lauren Fedak, Mathew Guilleman and Krassimir Yankulov

Department of Molecular and Cellular Biology, University of Guelph, Ontario

The destruction of Chromatin Assembly Factor -1 (CAF-1) or the DNA helicase *RRM3* affect the frequency of epigenetic conversions at the telomeres of *S.cerevisiae*. CAF-I is a histone chaperone, which reassembles nucleosomes from old and new histones immediately after the passage of the replication fork. *RRM3* is a helicase that relieves replication forks that have paused at sites of tight protein binding or active transcription. Both Rrm3p and CAF-1 interact with Pol30p, the yeast homologue of the Proliferating Cell Nuclear Antigen (PCNA). These interactions are mediated by a dedicated conserved PCNA-Interacting-Peptide (PIP) consensus sequence present on both the largest subunit of CAF-1 (Cac1p) and on Rrm3p. Interestingly, there are many other proteins that interact with PCNA via PIPs thus suggesting an intriguing interplay of PCNA-binding factors at the replication fork. At the same time, the interaction between CAF-1 and PCNA is in part regulated by two Cyclin-Dependent Kinases, *CDC28* and *CDC7*.In an attempt to mechanistically decipher the effects of CAF-1 and Rrm3p on epigenetic conversions, in this poster we address two important issues:

The possibility of competition and/or cooperating between Pol30p, Cac1p, Rrm3p and several other PCNA-binding proteins.

The extent to which protein kinases regulate the stability of CAF-I and its association with PCNA.

We will show evidence from extensive competitive and non-competitive two-hybrid assays with *POL30*, *CAC1* and *RRM3*. The effect of mutations on multiple phosphorylation sites of Cac1p on the stability of CAF-I and its ability to associate with Pol30p in cell extracts will also be presented. Finally, we will show our analysis with recombinant proteins on the competition between Cac1p and Rrm3 for their interaction with Pol30p.

Y3096C Interaction between the HAT Gcn5 and the phosphatase PP2A-Rts1 at the yeast centromere. *Masha Evpak*, Emily Petty, Angela Nicholson, Lorraine Pillus. University of California, San Diego, La Jolla, CA.

DNA is wrapped around histone proteins, making up the fundamental unit of chromatin—the nucleosome. This organization is used to regulate diverse cellular functions and efficiently store the genetic code. The dynamic addition and removal of molecules on histones is catalyzed by various enzymes, including histone acetyltransferases—which add acetyl-CoA—and phosphatases—which remove phosphate

groups. These post-translational modifications represent a mode of regulating cellular processes. The enzyme Gcn5 is a conserved H3/H2B histone acetyltransferase with multiple established roles and a proposed role in centromeric function. The protein phosphatase 2A (PP2A) has a conserved regulatory subunit, Rts1, which regulates diverse processes including cell size, septin dynamics during cell division, and chromosomal biorientation. Our lab recently described a genetic interaction between *GCN5* and *RTS1*, whereby overexpression of *RTS1* rescues *gcn5* mutant phenotypes, and simultaneous loss of both genes is lethal. Due to reported connections of both Gcn5 and Rts1 to the centromere, we sought to determine whether the centromeric histone Cse4 is involved in the relationship between these two enzymes. We performed a screen of phosphorylatable and acetylatable Cse4 residues to determine whether any Cse4 residues are actively modified in the *GCN5/RTS1* relationship. We identified three Cse4 residues that are critical for the suppression of *gcn5Δ* phenotypes by *RTS1* overexpression. Mutating each of these identified residues to alanine interferes with rescue of *gcn5Δ* temperature sensitivity, DNA damage sensitivity, and cell cycle progression. Further studies will be conducted to determine how these Cse4 residues are used in the centromeric function of these conserved enzymes. Both Rts1 and Gcn5 regulate diverse processes and are frequently implicated in disorders including cancer and neurodegeneration, and understanding their role at the centromere will help elucidate their function in cellular regulation.

Y3097A Set6: A novel lysine methyltransferase in *Saccharomyces cerevisiae*. *D. Jaiswal*, Erin Green. University of Maryland Baltimore County, Baltimore, MD.

Histone methyl marks orchestrate programming of the genome, regulating gene expression programs that control growth, survival and differentiation in response to changing environmental cues. Thus, the discovery and functional characterization of new histone methylation marks holds great promise in expanding our understanding of how chromatin dynamics influence genomic programs. Characterization of evolutionarily conserved histone methylation sites in *Saccharomces cereviaise* has provided essential insight into the function of post translation modification in diverse eukaryotic systems, including humans. Taking advantage of the versatile molecular genetic tools available in yeast, we have investigated the biochemical and biological roles of the novel candidate histone methyltransferase, Set6, whose function is not known. Set6 contains a SET domain, a common signature of chromatin regulatory proteins that catalyzes lysine methylation. Here, we use genetic assays to show that Set6 participates in cell cycle regulation, and may specifically be important for progression through S phase. We further use biochemical approaches to demonstrate that Set6 is likely an active methyltransferase that may primarily target non-histone proteins. Overall, we hypothesize that Set6 is a key regulator of cell cycle progression in budding yeast that acts via its methylation activity on non-histone proteins.

Y3098B Fission yeasts DNA strands chirality *mat1*-switching mechanism explains development of diverse organisms. *A. J. S. Klar*. NCI-Frederick Cancer Res Fac, Frederick, MD.

The somatic selective chromatid-specific Imprinting mechanism produces sister cells with different cell-types in evolutionarily diverse fission yeasts (reviewed in[1]). Motivated by our yeast work that discovered this monochromatid gene expression phenomenon and the selective chromatid segregation phenomenon we discovered in mouse cells[2], we had proposed that DNA strands chirality can may be converted into a/symmetric gene expression of sister cells to provide a general mechanism for eukaryotic development. This mechanism has indeed explained the mathematics of developmental mutant phenotypes: (I) visceral organs asymmetry development in mice and of (II) neuronal left/right asymmetry in nematode[3,4]; (III) etiologies of human brain hemispheric laterality to cause mirror hand movements disorder in *rad51/RAD51* persons[5]; (IV) psychoses disorders by chromosome 11 translocations[6]; (V) the two-colored wing spots pigmentation of the *Bruchus* beetle piebald mutant[7]; and (VI) the split hand-/foot malformation by the chromosome 2 rearrangements[8]. So, just as mechanisms of cell cycle, cell biology, meiosis, recombination etc. are conserved from yeast to metazoans, DNA strand-based developmental mechanism has been conserved in diverse organisms. Results of *mat1* imprinting in yeast and newer support for this mechanism for human limb development will be presented. Note: the conventional morphogen model of development has been withdrawn[9].

Y3099C NADPH levels control sirtuin-dependent heterochromatin stability in *Saccharomyces cerevisiae*. *A. Plaza-Jennings*, R. Janke, J. Rine. University of California Berkeley, Berkeley, CA.

Many chromatin-modifying enzymes use common metabolites as cofactors, but the connections between central metabolism and epigenetics remain poorly explored. The link between NAD^+ levels and sirtuin function has been well established, but recent work for our lab has uncovered an unanticipated depth in the links between metabolism and epigenetics. We found that disruption of an early step in the pentose phosphate pathway affected heterochromatin stability in a spatially heterogeneous manner within yeast colonies. This spatial heterogeneity in silencing likely reflects spatial heterogeneity in metabolism within yeast colonies. The pentose phosphate pathway is a major source of both five carbon sugars and NADPH. Here, we present evidence that it is the cellular NADPH levels that affect the stability of heterochromatin at the yeast silent mating locus *HML*.

Y3100A Loss of gene silencing is not a feature of yeast aging. *Gavin Schlissel*, Jasper Rine. UC Berkeley, Berkeley, CA.

Yeast replicative aging involves myriad changes to the basic biology of the yeast cell. Previously it was reported that replicatively old yeast mother cells lose their ability to silence genes at *HML* and *HMR* loci, suggesting that the SIR complex becomes non-functional in old cells. Here

we performed pedigree analysis using a recently developed and exquisitely sensitive silencing reporter, in combination with a custom microfluidic device, to characterize age-associated loss of silencing. In hundreds of yeast pedigrees, we found no evidence that silencing loss at *HML* and *HMR* is related to yeast aging. Furthermore, when we quantified RNA from purified populations of replicatively old cells, we found that old cells' gene expression does not reflect silencing loss at *HML* and *HMR*. Although silencing was maintained in old cells, we successfully replicated previous experiments that showed that old *Mat**a*** cells fail to respond to α-factor. This result was originally interpreted to mean that silencing is lost in old cells; however, we found that this effect depends on the α-factor concentration, and that old *Mat**a*** cells respond efficiently to large doses of mating pheromone.

Y3101B Linking the critical functions of two essential NuA4 acetyltransferase subunits. *Naomi Searle*[1], Ana Lilia Torres Machorro[2], Lorraine Pillus[1]. 1) UC San Diego, La Jolla, CA; 2) National Institute for Respiratory Diseases, Mexico City, Mexico.

The eukaryotic genome is packaged into chromatin, which is composed of a nucleosome unit containing DNA wrapped around a histone octamer. Chromatin components are subject to various modes of post-translational regulation that have many established roles, including functions in recombination, DNA damage repair, and transcription. Acetylation is a key post-translational modification that is mediated by the opposing enzymatic activities of lysine acetyltransferases (HATs) and deacetylases (HDACs). HATs often exist in large multimeric complexes, such as NuA4 and SAGA, both of which are conserved across species. In humans, the essential catalytic subunit of NuA4, Tip60, along with additional essential subunits such as EPC1/2, are associated with multiple carcinomas. We recently reported that the requirement for *ESA1,* the *S. cerevisiae* ortholog of Tip60, could be bypassed by concurrent loss of Rpd3L, an opposing HDAC complex. This bypass is promoted by establishing a relatively balanced cellular acetylation state.

Here, we report on the analysis of the remaining essential components of NuA4, including Arp4, Act1, Swc4, Tra1, and Epl1. The bypass state is characterized by a reduction of cellular fitness, including sensitivity to high temperature and DNA damage, low histone H4 acetylation, and cell cycle defects. These phenotypes were selectively suppressed by loss of additional deacetylases such as *HDA1*. Whereas Esa1 and several other NuA4 subunits are well-described, there are subunits that remain to be fully characterized. Specifically, Epl1, the ortholog of human EPC1/2, although essential, is poorly understood *in vivo* across species, and is a focal point of interest in this study. Taking advantage of the bypass suppression, we present new functional studies of Epl1 in *S. cerevisiae* with the aim of better understanding the essential role of this crucial NuA4 subunit. Due to the conservation of Epl1 between budding yeast and humans, many of our basic findings in *S. cerevisiae* can be translated to human cellular function and biology.

Y3102C Epigenetic conversions at the telomeres of *S.cerevisiae* – links to DNA replication. *K. Yankulov*. Univ Guelph, Guelph, ON, CA.

The continuity of gene expression programs is in part maintained by the faithful transmission of exiting chromatin structures from the parental cells to the daughter cells. Replication-coupled processes ensure that the epigenetic marks on the old histones (and on DNA in metazoan organisms) are faithfully reproduced after the synthesis of the new strands of DNA and the deposition of new histones. At the same time, changes in chromatin structure are necessary during metazoan development and in the adaptation of *S.cerevisiae* and many pathogens to the changing or host organism environment. It is not clear if the same machinery is involved in these epigenetic changes between active and silent states of the genes. In reality, we know very little about how epigenetic conversions take place.

Recently we have developed an assay for the quantitative assessment of the frequency of epigenetic conversions at the telomeres of *S.cerevisiae*. We have documented that the destruction of Chromatin Assembly Factor -1 (CAF-1) or the DNA helicase *RRM3* substantially reduce the frequency of such conversions. CAF-I is a histone chaperone, which reassembles nucleosomes from old and new histones immediately after the passage of the replication forks. *RRM3* is a helicase that relives replication forks that have paused at sites of tight protein binding or active transcription.

Current models suggest that both Rrm3p and CAF-1 are recruited to replication forks via an interaction with the Proliferating Cell Nuclear Antigen (PCNA, *POL30*) and that this interaction is regulated by the DBF4-Dependent Kinase, DDK. I will present evidence that the Cyclin Dependent kinase CDK (Cdc28p) rather than DDK is a key regulator of the association of CAF-I with chromatin, while DDK affect its stability and its affinity to PCNA. Two separate posters will present details on these findings.

I will propose the model that CAF-I, albeit being involved on the faithful transmission of epigenetic marks, is also needed for epigenetic conversions at paused replication forks.

.

Y3103A A closer look on telomerase RNA biogenesis –Tlc1's "lasting" story. *E. Bajon*, Y. Vasianovich, N. Laterreur, R. Wellinger. Université de Sherbrooke, Sherbrooke, Québec, CA.

The telomerase holoenzyme acts as a reverse transcriptase to elongate shortened, non-functional telomeres. This enzyme is composed of several protein subunits and assembled onto a scaffolding non-coding RNA, called Tlc1 in budding yeast. Like some other protein subunits (Est1, Est2, Est3, Pop1), Tlc1 is essential for telomerase activity and telomere maintenance *in vivo*. However, the pathways and mechanisms leading to an assembled and functional telomerase complex are not understood. Telomerase biogenesis has been studied via genetics and biochemistry, but real time *in vivo* data are by and large missing. As a readout for telomerase biogenesis, Tlc1 is a target of choice, as it is the limiting subunit for telomerase activity in Saccharomyces cerevisiae (its expression was measured at 25-30 RNAs/cell). Previous work showed that Tlc1 can shuttle between nucleus and cytoplasm, although no canonical ncRNA maturation is known to happen in the cytoplasm in yeast. Our lab previously used the MS2-GFP system to study Tlc1 dynamics and recruitment to telomeres *in vivo*, and the results revealed telomere-associated clusters of telomerase, called T-Recs, correlated with telomere elongation (Gallardo et al.; Mol Cell 2011).

In order to gain more detailed insights into Tlc1 ncRNA biogenesis, we are using a combination of the MS2-GFP and the Cre-Lox systems. The endogenous TLC1 locus was floxed so that the expressed Tlc1 untagged. The MS2 tag can be inserted at will via and inducible Cre-EBD protein. The new TLC1-MS2 locus gives rise to Tlc1-MS2 RNAs, which can be visualized via the MS2-GFP fusion protein. These newly transcribed, GFP-bound Tlc1 RNAs can thus be followed from the transcription site to the final target at telomeres by time-lapse microscopy in living cells. It is also possible to IP these RNAs in order to decipher how the telomerase complex assembles. This construct, named TLC1-MS2-IN, thus has the potential to allow studies on the first biogenesis steps of Tlc1 and telomerase. A similar construct, dubbed TLC1-MS2-OUT, allows for the inducible removal of the MS2 tag. This second construct allows studies of Tlc1 degradation, half-life, and telomerase nucleocytoplasmic recycling. Preliminary Southern- and Northern-blots results with this latter setup show that there is a lag between the genomic recombination and the differential RNA expression, suggesting that Tlc1 is a stable RNA that can last for the duration of at least one cell cycle.

This study, apart from giving insight into Tlc1 biogenesis and telomerase assembly, could thus help better define ncRNA maturation or degradation pathways in budding yeast.

Y3104B Yeast RNA 3'-end processing factors promote RNA Polymerase II ubiquitination and degradation following UV-type DNA damage. *Jason N. Kuehner*[1], Jay Kaufman[1], Claire Moore[2]. 1) Emmanuel College, Boston, MA; 2) Tufts University School of Medicine, Boston, MA.

Genomic information is vital for the survival and reproduction of all living cells. The integrity of DNA is frequently challenged by damaging agents like ultraviolet (UV) radiation, which can ultimately lead to mutation and disease. The DNA Damage Response (DDR) is at the front lines of genomic defense, acting to promote recognition and repair of DNA lesions. A critical consequence of the DDR is a transient decrease in the levels of RNA Polymerase II (Pol II) and mRNA, during which time the cell can repair transcribed regions of the genome. UV irradiation of human cells reduces mRNA at least in part by inhibiting RNA 3' processing, and processing factors likewise promote Pol II ubiquitination and degradation. These data indicate that 3' processing factors provide an important link to the DDR, but the scope and mechanism of these interactions are as yet unknown.

Our labs have previously shown that UV-induced inhibition of RNA processing is a conserved response in yeast, and UV-type damage induces genome-wide variation in poly(A) sites. We sought to identify additional functional links between 3' processing factors and the DDR in the yeast model system in order to better characterize the mechanism of coordination. We have observed that yeast 3' processing mutants are sensitive to UV-type DNA damaging agents. Yeast 3' processing mutants exhibit unique genetic interactions with nucleotide excision repair mutants but not with factors in homologous recombination or post-replication repair pathways. Yeast 3' processing mutants also impair the ubiquitination and degradation of Pol II following DNA damage. In ongoing experiments we are testing the role of 3' processing factors in the recruitment of ubiquitination and DNA repair machineries following UV damage. Overall these results suggest that 3' processing factors promote DNA repair by removing Pol II stalled at UV-type DNA lesions, a functional interaction that is conserved between yeast and human cells.

Y3105C mRNAs accumulate near transcription sites, nuclear pore complexes, or within the nucleolus when RNA processing is disrupted. *B. Paul*, B. Montpetit. Department of Cell Biology, University of Alberta, Edmonton, Alberta, CA.

Many proteins interact with a newly synthesized RNA to mediate biogenesis and maturation. These temporally and spatially regulated interactions facilitate individual processing events and direct each RNA to a specific fate (e.g. nuclear export or decay). To further characterize mRNA biogenesis and export, we performed a fluorescent in situ hybridization (FISH) screen of >1000 essential gene mutants in *Saccharomyces cerevisiae* that resulted in the identification of 29 mutants that exhibited poly(A)-RNA accumulation in the nucleus. Gene ontology places the majority of the genes into three biological processes: RNA export from nucleus, nuclear RNA catabolic processes, and chromosome segregation.

It is known that defects in the processing of various non-coding RNAs (e.g. rRNA, snRNA, snoRNA, and tRNA) can lead to the stabilization of polyadenylated RNA species; therefore, mutants may accumulate poly(A)-RNA due to disruptions in RNA biogenesis that are independent of mRNA. To identify mutants that specifically alter mRNA biogenesis and export, single-molecule FISH (smFISH) assays were performed on all 29 mutants using probes against three different mRNAs (e.g. *GFA1*, *ACT1* and *CCW12*). Based on transcript localization and abundance, we identified defects in mRNA processing and export in 26 of 29 mutants.

By employing smFISH and markers for various subdomains of the nucleus (e.g. Ndc1-GFP for the nuclear envelope, *ITS1* for the nucleolus, and a LacO/LacI-GFP marked gene locus), we could further subdivide mutants into three classes based on the accumulation of poly(A)-RNA and mRNA within discrete regions of the nucleus. This included: (1) mRNAs and mRNA binding proteins becoming enriched in the nucleolus when nucleocytopalsmic transport, rRNA biogenesis, or RNA processing and surveillance was disrupted, (2) the buildup of mRNAs near transcription sites in 3' end processing and chromosome segregation mutants and (3) transcripts being enriched near nuclear pore complexes when components of the mRNA export machinery were mutated. These data demonstrate that alterations in a broad set of nuclear processes leads to the accumulation and possible retention of mRNAs at discrete locations within the nucleus. This may reflect common failure points in mRNA export and/or active mechanisms to protect the cell against cellular stress and dysfunction.

Y3106A A Genetic Screen of the Yeast Kinome Reveals Gin4p Regulation of mRNPs. *Eric E. P. Cosky*, Nebibe Mutlu, Anuj Kumar. University of Michigan, Ann Arbor, MI, USA.

Eukaryotes from yeast to metazoans respond to cellular stressors through a precisely coordinated interplay between regulatory and signal transduction pathways controlling gene expression. The regulation of mRNA translation is an important aspect of the eukaryotic gene expression program, and the assembly of cytoplasmic mRNA-protein (mRNP) complexes is presumably a significant mechanism by which post-transcriptional control is achieved. Among eukaryotes, mRNPs are well conserved and form in response to numerous stressors, such as heat

shock, osmotic or oxidative stress, and starvation. In yeast, processing bodies and stress granules are among the most well-studied mRNPs, but their exact functions and regulation remain to be fully resolved.

Previous studies have identified that Snf1p (AMPK) phosphorylation activates the RNA processing Xrn1p exonuclease and Ste20p (PAK) phosphorylation of Dcp2p affects both its decay of certain mRNAs and its localization to p-bodies. However, the extent to which kinase signaling pathways regulate mRNP activity is likely much broader. Under the hypothesis that kinase phosphorylation events regulate mRNP dynamics, we performed a genetic screen on homozygous yeast mutants deleted for kinase genes. For this screen, mRNPs were initially visualized by live-cell imaging using a *PGK1* reporter mRNA containing binding sites in its 3'-UTR for the U1A-GFP fusion protein. Plasmids encoding the modified *PGK1* gene and U1A-GFP were transformed into 114 yeast strains, each deleted for a single kinase gene. This kinomic screen identified eight deletion mutants exhibiting mRNP localization phenotypes upon acute glucose deprivation. These mRNP phenotypes were validated using an integrated fusion of mCherry to sequence encoding the mRNP marker protein Dcp2p.

In particular, a homozygous strain deleted for *GIN4* exhibited a striking loss of mRNPs. Under conditions of heat shock, osmotic or oxidative stress, and starvation, mRNPs form in wild type but not *gin4 Δ/Δ* cells. Interestingly, Gin4p is involved in bud growth and septin ring assembly with several kinase-dependent and independent functions. When a plasmid bearing *GIN4* and its native promoter is re-introduced, wild type levels of mRNPs are restored in *gin4 Δ/Δ*. The kinase dead $Gin4^{K48A}$ mutant displays wild type numbers of mRNPs, which suggests that a Gin4p kinase-independent function is modulating mRNP activity. Notably, inhibition of bud growth and septin ring assembly does not perturb wild type levels of mRNPs. Therefore, our data imply a novel Gin4p kinase-independent function affecting mRNP formation, which we are actively investigating further.

Y3107B Molecular genetic tools for manipulation of the oleaginous red yeast *Rhodotorula toruloides*. *S. J. Aves*, A. M. B. Johns, J. Love. University of Exeter, Exeter, UK.

Rhodotorula toruloides (*Rhodosporidium toruloides*) is a red, basidiomycete yeast. When grown under nitrogen limited conditions it can accumulate lipid to over 70 % of its dry biomass making it of interest for production of biofuels as well as having other potential uses in biotechnology. In order to be able to fully investigate and exploit this organism, genetic tools for manipulation of this yeast are required.

The *R. toruloides* genome has a high genomic GC content which can cause cloning problems, making *in vitro* genetic manipulations difficult. To overcome this, plasmid vectors have been constructed for *Agrobacterium tumefaciens*-mediated transformation of *R. toruloides*, incorporating elements for yeast *in vivo* assembly in *Saccharomyces cerevisiae*. These vectors have been developed to facilitate easy exchange of promoters and genes to be expressed, and can be used with either antibiotic or auxotrophic selection.

To permit controlled expression of genes in *R. toruloides*, we have identified four homologous inducible promoters. Their properties and basic structure have been characterized by fusion to a codon-optimized EGFP reporter gene, measuring fluorescence by flow cytometry. Each promoter can give tight regulation with induction times of between 4 and 16 hours. Because each promoter uses different induction and repression conditions, this provides a toolset of regulatable promoters such that for any given experiment there should be suitable promoter(s) for which conditions should not affect the results.

We have developed a suite of molecular genetic tools for recombinant DNA technology and controlled gene expression which will facilitate molecular genetic investigation and biotechnological exploitation of oleaginous red yeast.

Y3108C Analysis of the pseudokinase domain of the SAGA and NuA4 component Tra1. *M. Berg*, J. Karagiannis, C. Brandl. University of Western Ontario, London, Canada.

Tra1 is a 433 kDa component of the *Saccharomyces cerevisiae* SAGA and NuA4 transcriptional co-activator complexes. Tra1 interacts with transcriptional activators to recruit the complexes to specific promoters. As a PIKK (phosphoinositide three-kinase-related kinase) family member, Tra1 is characterized by a C-terminal phosphoinositide 3-kinase (PI3K) domain. Unlike other PIKK family members, Tra1 lacks kinase activity. The PI3K domain is still essential and mutations in this domain result in altered gene expression. To investigate the structure and function of Tra1's PI3K domain, we are characterizing an allele we call $tra1_{Q3}$ where three conserved arginine residues within the PI3K domain are mutated to glutamine. This allele results in slow growth under stress and decreased transcription activation. The protein mislocalizes to the cytoplasm and has decreased association with SAGA and NuA4. Pull downs of the mutant complexes also show altered interactions with SAGA-interacting proteins. Suppressors of $tra1_{Q3}$ fall into the cleft of the kinase domain when mapped onto the known mTOR PI3K structure. Based on the reduced nuclear localization and failure to associate with SAGA and NuA4 demonstrated by this mutant, we believe the PI3K domain of Tra1 is important for the biosynthesis of Tra1 into SAGA and NuA4.

Y3109A Role of chromatin modulators during polymerase switch for ribosomal RNA synthesis in *Saccharomyces cerevisiae*. *KUSHAL BHATT*, Heather Conrad-Webb. TEXAS WOMAN'S UNIVERSITY, DENTON, TX.

Ribosomal RNA synthesis consumes major portion of the cellular resources necessitating its strict regulation. Under non-stress conditions RNA polymerase I (Pol I) synthesizes a 35S precursor rRNA, but during stress (nitrogen deprivation) synthesis also occurs by RNA polymerase II (Pol II) from a cryptic site upstream of Pol I binding site. This polymerase switch has been observed in higher eukaryotes leading to the hypothesis that the switch serves as back up mechanism for rRNA synthesis during stress allowing the survival of the cell. Pol II rRNA synthesis may be followed using an rDNA-LacZ reporter construct. Nitrogen deprivation leads to a three-fold increase in the b-galactosidase activity. The corepressor Ssn6-Tup1 is known to repress transcription, when recruited to target promoters by repressor proteins. Absence of this corepressor leads to an increase in enzyme activity under normal and stress conditions. Furthermore, the absence of repressor proteins Sko1, Nrg1, Sut1 that are known to recruit Ssn6-Tup1 also showed an increase in b-galactosidase activity. Hmo1, a High Mobility Group protein, binds

to rDNA to regulate pol I rRNA synthesis. As expected b-galactosidase activity increases significantly in the absence of Hmo1 in both non-stress and stress conditions . We hypothesize that stress signaling pathways will signal these repressors to inhibit their silencing function. Repressor complexes will be investigated during normal growth and stress for secondary modifications and their binding to rDNA. These studies will help dissect the regulation of rRNA synthesis and cell survival mechanisms under stress conditions.

Y3110B Investigating a novel function of snRNP assembly factor Prp24 in regulating H2B monoubiquitylation. *Katie S. Bolling*, A. Gregory Matera, Brian D. Strahl. Curriculum in Genetics & Molecular Biology, University of North Carolina, Chapel Hill, NC.

Investigating a novel function of snRNP assembly factor Prp24 in regulating H2B monoubiquitylation

A key step in regulation of eukaryotic gene expression is the removal of introns through splicing. While it has been well-established that the majority of splicing occurs co-transcriptionally, many questions remain regarding the coupling of these processes. It has been shown that altering rates of transcription leads to changes in splicing efficiency; however, the mechanism underlying these effects is not well understood. Post-translational modifications (PTMs) of histone proteins are a key regulator of chromatin structure, and several histone PTMs have been associated with transcription and splicing. One such PTM is mono-ubiquitylation of H2B (H2Bub1) at a conserved lysine residue (K123 in S. cerevisiae). A very tight correlation between H2Bub1 levels and active transcription has been demonstrated, and recent studies have linked H2Bub1 to splicing as well. In S. cerevisiae, loss of H2Bub1, either by deletion of the E3 ubiquitin ligase which places the mark (Bre1) or by mutation of the ubiquitylated residue, leads to an increase in intron retention and synthetic growth defects with splicing factor mutants. Additionally, studies in human cells have shown that knockdown of a conserved small nuclear ribonucleoprotein (snRNP) recycling factor, SART3, lead to an increase in H2Bub1. Our investigations have shown this effect is conserved in S. cerevisiae, and is mediated by a highly conserved residue in the first RNA Recognition Motif (RRM) of Prp24, the SART3 ortholog. Interestingly, although RRM1 does not bind snRNAs, mutation of this residue causes significant growth defects and severe temperature sensitivity. Mutations of other RRMs in Prp24, known to affect its ability to bind the snRNA U6, do not affect H2Bub1. These results suggest that Prp24 has a previously uncharacterized role in regulation of H2Bub1. Future experiments will reveal if Prp24's influence on H2Bub1 is connected to its association with splicing factors. Additional studies will test for genetic and physical interactions between Prp24 and Bre1, as well as deubiquitylating enzymes Ubp8 and Ubp10. Finally, investigation of Prp24's effects on transcription elongation rate, splicing, and the cell cycle will uncover potential indirect influences on H2Bub1 levels. Together, the results of this investigation will shed light on a novel, likely conserved role of Prp24 in regulating H2Bub1 and contribute new insight into the link between chromatin, transcription, and splicing.

Y3111C Regulation of *S. cerevisiae* in response to 4NQO by the polymorphic transcription factor, Yrr1. *J. Gallagher*, X. Rong-Mullins. West Virginia Univ, Morgantown, WV.

As we enter the era of whole-genome sequencing, cataloging genetic variation between individuals in a species falls short in understanding the functional impact of this variation on an individual's phenotype. There is variation of tolerance among different *S. cerevisiae* strains to the DNA damaging drug, 4-nitroquilione 1-oxide (4NQO). A clinical yeast isolate, YJM789, is very tolerant to 4NQO while S288c, a laboratory yeast strain, is sensitive. The genetic variation in 4NQO response is due Yrr1, a polymorphic transcription factor that shift the cellular response in resistance to 4NQO by changing rates of respiration which changes the metabolism of 4NQO. In ChIP-seq and RNA-seq we find that variation in transcription of genes required for response to 4NQO are poorly correlated with variation in Yrr1 binding upstream of these genes. *SNQ2* encodes an ABC transporter which is strongly transcriptional induced in response to 4NQO with no change in Yrr1 binding. How the variation in transcription factors change RNA pol II transcription is under investigation. All the Yrr1 polymorphisms are outside the Zn-finger DNA binding domain and cluster at the C-terminus. By comparing the conservation of Yrr1 across yeast strain, a one residue in the C-terminus stood out as a potential phosphorylation site in $Yrr1^{YJM789}$ and a second one changes the charge near a second phosphorylation site. Converting that site to a phosphomimic amino acid in the 4NQO-sensitive allele of $Yrr1^{S96}$ confers 4NQO resistance similar to $Yrr1^{YJM789}$. Yet how these single amino acid differences change the transcriptional outcome is unclear. We have used transcriptome, mutational analysis and protein-protein interactions to understand how these polymorphisms change the function of Yrr1.

Y3112A Pdc2 and Thi3 in *Candida glabrata* regulate both amino acid and thiamine starvation and mediate the switch of biosynthetic capacity in response to starvation. *C. L. Iosue*, J. Nahas, D. Sens-Castet, E. Lang, D. D. Wykoff. Villanova Univ, Villanova, PA.

Transcription factor specificity is different for some signal transduction pathways in *Saccharomyces cerevisiae* and *Candida glabrata*. For the thiamine signal transduction (THI) pathway there are a number of differences between the two species at the level of signaling and transcription. By comparing the THI pathways in the two species, we have uncovered a novel molecular switch that alters the expression of thiamine and amino acid biosynthesis genes. In *S. cerevisiae*, *PDC2* encodes a transcription factor that activates the transcription of both thiamine biosynthetic genes and glycolytic genes. Proper regulation of thiamine responsive genes requires the additional regulators Thi2 and Thi3. *C. glabrata* is missing *THI2*; however, *C. glabrata* is still capable of inducing THI genes, indicating a difference in transcriptional requirements. Deletion of *ScPDC2* appears lethal in *S. cerevisiae* because cells are unable to utilize glucose effectively. In *C. glabrata*, there is no apparent growth defect in a *Cgpdc2*Δ strain, suggesting that Pdc2 regulates different genes between the two species. RNA-seq experiments with wild-type, *Cgpdc2*Δ, and *Cgthi3*Δ strains indicate that *Cg*Pdc2 regulates both thiamine and amino acid biosynthesis genes and not pyruvate decarboxylase genes. Interestingly, in wild-type *C. glabrata*, amino acid biosynthesis genes are upregulated in thiamine-replete conditions and ~10-fold repressed during thiamine starvation. This repression is lost in a *Cgthi3*Δ, suggesting *Cg*Thi3 plays a role in recruiting *Cg*Pdc2 to THI promoters in thiamine-limited conditions. We are exploring the altered regulation of genes by *Cg*Pdc2 by identifying the cis element(s) that *Cg*Pdc2 binds using promoter-YFP fusions with flow cytometry as well as *in vitro* EMSA experiments. We are also performing cross-

complementation studies to determine whether *Cg*Pdc2 is capable of rescuing the lethality of the *Scpdc2*Δ strain. This work should uncover a novel mechanism by which *C. glabrata* cells partition energy to either synthesize amino acids or synthesize thiamine, using the occupancy of promoters by *Cg*Pdc2 as the switch.

Y3113B Understanding the molecular interactions mediating transcriptional and demethylase activities of Gis1. *P. Konduri*, T. Wang, S. Lal, J. Comer, L. Zhang. University of Texas at Dallas, Richardson, TX.

Heme plays versatile and fascinating roles in controlling fundamental biological processes. Heme serves as a signaling molecule for oxygen levels in yeast, as heme function is entwined to molecular oxygen. Heme and oxygen regulate the expression of many genes in eukaryotes by modulating activity of regulatory proteins. In yeast, Gis1 is a DNA-binding transcriptional regulator belonging to the JHDM3/JMJD2 subfamily of demethylases. It is highly homologous to the mammalian JmjC domain containing protein JMJD2b, which plays an important role in histone demethylation, oxygen regulation and hormonal signaling. This study aims to dissect the molecular interactions regulating Gis1 activity by determining the effect of heme, oxygen and Gis1 interacting proteins on regulation of transcriptional activity and demethylase activity of Gis1. Notably, recent experiments in our lab showed that Gis1 senses changes in oxygen and heme levels, and its transcriptional activity is controlled stringently by heme concentration. Gis1 is a unique transcriptional regulator containing 894 amino acid residues with multiple domains and complex biological functions. Our biochemical studies indicate that heme binds directly to Gis1 and JMJD2b proteins. We also identified via mass spectrometric analysis that Gis1 interacts with different set of proteins under conditions of hypoxia, low heme and high heme. Together, our results show that Gis1 represents a novel class of complex transcriptional regulators mediating heme signaling.

Y3114C Understanding heme regulation of JmjC domain containing transcription factor Gis1. *S. Lal*, C. Konduri, T. Wang, J. Comer, L. Zhang. The University of Texas at Dallas, Richardson, TX.

Heme is an important signaling molecule that mediates the effect of oxygen on several cellular processes. In yeast, heme serves as a secondary messenger of oxygen as production of heme requires oxygen. Gis1 is a transcription factor containing the highly conserved JmjC domain. JmjC domain containing proteins belong to JHDM3/JMJD2 subfamily (lysine-specific) of histone demethylases which can function as oxygen sensors. Studies in our lab has shown that Gis1 is regulated by oxygen and heme. Protein localization studies showed that under hypoxia Gis1 is retained in the cytoplasm and oxygen is required for the nuclear localization of Gis1. Interestingly, a putative heme-responsive cysteine-proline sequence (CP motif) is present in the JmjC domain. Upon further investigation, we found that Gis1 binds heme directly, and its transcriptional activity is regulated by heme levels in the cell. Further work is being carried out to pinpoint the domain(s) mediating the effect of heme on the transcriptional activity of Gis1. Additionally Gis1 has a paralog, Rph1 which also contains the JmjC domain. Gis1 and Rph1 are 34% similar, and their zinc finger domains are almost identical. Rph1 is a repressor of autophagy-related genes in nutrient-rich conditions, which is independent of its histone demethylase activity. It is also a repressor of DNA repair gene *PHR1*. We are investigating if Rph1 is also regulated by heme.

Y3115A Investigating the role of the *S. cerevisiae* Paf1 complex in global regulation of transcription. *Alex R. Lederer*[1], Mitchell Ellison[1], Travis Mavrich[1], Lawrence E. Heisler[2], Marinella Gebbia[2], Corey Nislow[3], Karen M. Arndt[1]. 1) Department of Biological Sciences, University of Pittsburgh, Pittsburgh, PA 15260; 2) Terrance Donnelly Centre and Banting & Best Department of Medical Research, University of Toronto, Toronto, Ontario, Canada; 3) Department of Pharmaceutical Sciences, University of British Columbia, Vancouver, British Columbia, Canada.

In eukaryotes, the organization of DNA into a highly compact chromatin structure presents an obstacle for RNA polymerase during transcription. Consequently, organisms have evolved molecular machines that alter the chromatin template through a variety of mechanisms. This machinery includes the conserved Polymerase-Associated Factor 1 Complex (Paf1C), which associates with RNA polymerase II, promotes specific chromatin modifications, and regulates expression of certain genes. Past work has shown that Paf1 plays an important role in mediating transcription of genes across diverse pathways of cellular biology; however, its effects on transcription of noncoding DNA have not been thoroughly investigated. Genome-wide studies have revealed extensive noncoding DNA transcription across the yeast genome. Some of this noncoding transcription impacts the expression of neighboring genes, while giving rise to unstable transcripts that face rapid degradation by the TRAMP complex and its poly-A polymerase subunit, Trf4. To investigate the impact of the Paf1C on the greater transcriptome, whole genome tiling array studies were performed on RNA prepared from *paf1Δ*, *trf4Δ*, *paf1Δtrf4Δ*, and wild-type strains. Using differential expression analysis, we have identified classes of protein-coding genes whose expression is strongly dependent on Paf1. Notably, we observed decreased expression of phosphate signaling genes and increased expression of iron transport genes in *paf1Δ* cells, as validated by northern blot analysis and reverse transcription quantitative polymerase chain reaction (RT-qPCR). We have also confirmed previous findings that *paf1Δ* cells have severe transcription termination defects at snoRNA genes, which encode a class of noncoding RNAs involved in ribosome assembly. Finally, preliminary analysis of *paf1Δtrf4Δ* and *trf4Δ* cells has provided new insights on transcription of other noncoding RNAs, including CUTs, and antisense transcription. These findings confirm that Paf1 is a major participant in regulation of the global transcriptome. Moving forward, we aim to identify the specific mechanisms by which Paf1 regulates these diverse gene classes and further elucidate the impact of these defects in the cell.

Y3116B Magnification of negative allelic effects by environmental stress renders yeast segregants unable to grow at 37°C on ethanol. *T. Matsui*, I. Ehrenreich. U. of Southern California, Los Angeles, CA.

The budding yeast *Saccharomyces cerevisiae* is a valuable model system for characterizing the genetic and molecular mechanisms that enable fungal growth at human body temperature (37°C). However, most work on this topic has been performed on glucose, the organism's preferred

carbon source. In contrast, much less is known about the mechanisms that enable growth at 37°C on non-preferred carbon sources, such as ethanol. To provide new insights into this problem, we comprehensively dissected the genetic basis of inability to grow at 37°C on ethanol (37e) in a cross of the BY4716 (BY) lab strain and the YJM789 (YJM) clinical isolate. In total, we detected 15 loci, with roughly half of the causal alleles contributed by each cross parent. We then cloned and measured the quantitative growth effects of four loci that, in an otherwise YJM genetic background, result in a broad spectrum of growth levels at 37e. Based on this work, we resolved three of these loci to a kinase (*IKS1*), a component of the vacuolar protein sorting machinery (*VPS70*), and a stress granule-associated RNA binding protein (*YGR250C*). We found that these loci mainly contribute to inability to grow at 37e through large additive effects. However, the effects of these four loci are not specific to 37e, as each locus also shows a significant, but appreciably weaker growth effect on ethanol at standard culturing temperature (30°C) and on glucose at 37°C. This latter finding suggests that inability to grow at 37e is caused by additive genetic variants that show effects that are intensified in a more stressful environment.

Y3117C High-resolution phenotypic landscape of the RNA Polymerase II trigger loop. *Chenxi Qiu*, Olivia Erinne, Ping Cui, Huiyan Jin, Alvin Tang, Nandhini Mutukrishnan, Craig Kaplan. Texas A&M University, College Station, TX.

The conserved trigger loop (TL) lies in the RNA polymerase II (Pol II) active site, multi-tasking in substrate selection, catalysis, and translocation. To dissect TL function at individual-residue resolution, we quantitatively phenotyped nearly all possible TL single substituted mutants *en masse* in *Saccharomyces cerevisiae*. Three major mutants classes were revealed by clustering of growth phenotypes linked to transcription defects or various stresses. TL phenotypic classes have distinct distributions within the TL, and distinguish previously characterized catalytically fast and slow mutants. Substitutions in residues A1076, M1079, T1080, and L1101 support the proposed function of an intra-TL hydrophobic pocket in stabilizing the open TL conformation. Disruption of this pocket confers phenotypes consistent with hyper-activation of Pol II. In addition, allele-specific suppression/exacerbation between newly characterized TL mutants and mutants in the TL adjacent domains is consistent with the contribution of the TL adjacent funnel and bridge helices to TL dynamics. Our phenotyping platform, which is readily applicable to other yeast proteins, enables incorporation of structural and phenotypic data to dissect the Pol II active site with high functional resolution.

Y3118A Comprehensive analysis of the *SUL1* promoter of *Saccharomyces cerevisiae* . *Matthew S. Rich*[1], Celia Payen[1], Alan F. Rubin[4], Giang T. Ong[1], Monica R. Sanchez[1], Nozomu Yachie[5], Maitreya J. Dunham[1], Stanley Fields[1,2,3]. 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Department of Medicine, University of Washington, Seattle WA; 3) Howard Hughes Medical Institute, University of Washington, Seattle, WA; 4) Bioinformatics Division, The Walter and Eliza Hall Institute of Medical Research, Melbourne, Australia; 5) Research Center for Advanced Science and Technology, University of Tokyo, Tokyo, Japan.

In the yeast *Saccharomyces cerevisiae*, beneficial mutations selected during sulfate limited growth are typically amplifications of the *SUL1* gene which encodes the high affinity sulfate transporter, resulting in fitness increases of >35%. *Cis*-regulatory mutations have not been observed at this locus; however, it is not clear whether this absence is due to a low mutation rate such that these mutations do not arise, or they arise but have limited fitness effects relative to those of amplification. To address this question directly, we assayed the fitness effects of nearly all possible point mutations in a 493 base segment of the gene's promoter through mutagenesis and selection. While most mutations were either neutral or detrimental during sulfate-limited growth, eight mutations increased fitness more than 5% and as much as 9.4%. Combinations of these beneficial mutations increased fitness only up to 11%. Thus, in the case of *SUL1,* promoter mutations could not induce a fitness increase similar to that of gene amplification. Using these data, we identified functionally-important regions of the *SUL1* promoter and analyzed three sites that correspond to potential binding sites for the transcription factors Met32 and Cbf1. Mutations that create new Met32 or Cbf1 binding sites also increased fitness. Some mutations in the untranslated region of the *SUL1* transcript decreased fitness, likely due to the formation of inhibitory upstream open-reading frames. We plan to extend this methodology to study the effect of mutagenesis on other yeast promoters.

Y3119B The role of the Mediator complex in Ty1 retrotransposition in *S. cerevisiae*. *Alicia Salinero*[1], M. Joan Curcio[1,2], Randall Morse[1,2]. 1) University at Albany School of Public Health, Albany, NY; 2) Wadsworth Center, NYSDOH, Albany, NY.

Retrotransposons are mobile genetic elements that replicate via an RNA intermediary. These elements have been known to drive evolutionary rearrangements and contribute to genomic instability. In *Saccharomyces cerevisiae*, the most abundant and active retroelement is Ty1. This 6 kb element encodes Gag, protease, integrase, and reverse transcriptase, and relies on numerous additional host factors to successfully complete all stages of its mobility cycle. One such set of host factors is the 25 subunit Mediator transcriptional co-activator complex. The Mediator complex is organized into the core head, middle, and tail domains, with a transiently associated kinase domain. The tail domain functions mainly as a target of DNA binding transcriptional activator proteins, while the head and middle recruit the RNA polymerase II machinery to the transcription start site. With the exception of the kinase domain, deletion of non-essential subunits from all Mediator domains has a drastic impact on Ty1 mobility. Disruption of the Mediator tail module in *med2Δ*, *med3Δ*, and *med15Δ* yeast decreases Ty1 activity to undetectable levels, while disruption of the head module (*med 18Δ* and *med20Δ*), and middle module (*med1Δ*, *med5Δ*, and *med31Δ*) increase Ty1 mobility substantially. However, these changes in overall Ty1 mobility do not correspond with significant differences in Ty1 transcription or Gag translation. It is only at the level of viral like particle assembly and reverse transcription of Ty1 cDNA that Mediator subunit deletions exhibit any observable alteration to Ty1 mobility. While Mediator affects Ty1 mobility post-translationally, the process depends on the presence of the Ty1 promoter, as determined by measuring the activity of Ty1 driven by a TEF1 promoter. Recent work from the Garfinkel lab has identified a truncated form of the Gag protein (p22) that disrupts VLP formation and prevents reverse transcription of Ty1

cDNA. Translation of p22 relies on increased levels of an internal transcript known as Ty1i. Mediator tail mutant strains show an increase in this Ty1i RNA. Thus, Mediator plays a substantial role in Ty1 mobility by controlling levels of Ty1i mRNA. Further research is underway to determine the mechanism by which this occurs.

This work was supported by NSF grants MCB0949722 and MCB1516839 to RHM and NIH grant GM52072 to MJC.

Y3120C Transcriptional regulation of quiescence state promoting factor Saf1p by MADS box motif protein Rlm1p in *S.cerevisiae*. *Meenu Sharma*, Vijeshwar Verma, Narendra Kumar Bairwa. Shri Mata Vaishno Devi University, Katra, Jammu and Kashmir,India.

Abstract:

RLM1 gene encodes for the MADS box transcription factor and involved in the cell wall integrity checkpoint in *S. cerevisiae*. RLM1p protein is phosphorylated and activated by the MAP-kinase Slt2p. RLM1 has been reported as activating transcription factor during stress. Nutrient limitation stress leads to situation where yeast cells enter into the quiescence state. During this stress the quiescence state promoting factor SAF1 gene product which constitutes the SCF E-3 ligase complex, recruits adenine deaminase factor Aah1p for ubquitination and subsequent degradation by 26S proteasome in *S. cerevisiae*. Here we investigated the association between RLM1 and SAF1 gene at transcriptional level for regulation during stress to understand the mechanism of cell cycle transition from active division to quiescence state in response to stress stimuli. For this we analyzed the expression profiling database (GEO) and yeast stress expression database ((http://www.ystrexdb.com) of *S.cerevisiae* cells for expression status of the RLM1, SAF1 genes in stress conditions. We observed that in variety of stress conditions (drug, pH, temperature, microbial toxin, inorganic compound) the RLM1 and SAF1 was constitutively over expressed at log2FC>1 and adjusted p-value < 0.05 setting in comparison to control cells. Further we analysed the association matrix between SAF1 gene and RLM1 using yeastextract (http://www.yeastract.com/) web tool for the association between genes and transcription factors. The analysis predicted the regulation of SAF1 gene by RLM1 transcription factor during stress conditions. Based on analysis we hypothesized that double knockout of saf1 and rlm1 genes cells may be resistant to stress condition which need to be tested experimentally.

Y3121A Impairment of cell signalling in *Saccharomyces cerevisiae* as a result of suboptimal *PRPP* synthetase activity. *Eziuche A. Ugbogu*[1], Lilian M. Schweizer[2], Michael Schweizer[3]. 1) Abia State University, Uturu, Abia State, Nigeria; 2) School of Life Sciences, Heriot-Watt University, Edinburgh, UK; 3) School of Life Sciences, Heriot-Watt University, Edinburgh, UK.

PRPP (phosphoribosyl-pyrophosphate) is a key metabolite that plays a central role in many life processes, such as in the *de novo* and salvages biosynthesis of purine and pyrimidine nucleotides and therefore is essential for life. The *Saccharomyces cerevisiae* genome contains five paralogous *PRS* genes which exist as two complexes, one of which is a heterodimer, Prs1/Prs3 and the other, a heterotrimer, Prs2/Prs4/Prs5. Prs1 and Prs5 are distinguished by the presence of one and two NHRs (Non-Homologous Regions), respectively. Physical evidence for the genetically-defined Prs1/Prs3 complex was obtained by showing that in the absence of Prs3, Prs1 is unstable. In addition to interacting with Prs3, Prs1also interacts with Slt2, the MAPK of the Cell Wall Integrity (CWI) pathway. Point mutations in *PRS1* corresponding to missense mutations associated with human neuropathies or in the signature divalent cation- and/or PRPP-binding sites of Prs polypeptides interfere with CWI signalling resulting in temperature and/or caffeine sensitivity. The C-terminally located NHR5-2 of Prs5 is unusual in that it contains three potential phosphorylation sites. Mutation of these amino acid residues impinges on the expression of the transcription factor, Rlm1, an endpoint of the CWI pathway and reduces the temperature-dependent transcription of *FKS2*, the gene encoding the stress-induced catalytic subunit of 1, 3-β-glucan synthase essential for maintaining CWI. The results of our study support the hypothesis that the *PRS* gene family links, as a result of gene duplication and acquisition of NHRs, primary metabolism with CWI signalling in *S. cerevisiae*.

Y3122B Roles of Gis1-interacting Proteins in Heme Regulation of Gis1 Activity. *T. Wang*, P. Konduri, S. Lal, J. Comer, L. Zhang. The University of Texas at Dallas, Richardson, TX.

Heme is a cofactor for many important proteins that act in multiple cellular processes including aerobic respiration, biosynthesis, and small molecule processing. Previously, it has been shown that heme binds to regulatory and signaling proteins such as Hap1 in yeast, and Bach1 and Rev-erbα in mammals and controls their transcriptional activity. Recently, our studies investigated the regulatory role of heme in JmjC-domain-containing protein Gis1. Analysis of *lacZ r*eporter driven by a PDS (post diauxic shift) element showed a significant increase in Gis1 transcriptional activity under high heme concentration. Spectrophotometric analysis demonstrated direct interaction of heme with Gis1 and JmjN/C domain of Gis1 mammalian homologous JMJD2B. Given that a high number of unique interaction partners have been identified for Gis1 previously, it is conceivable that Gis1-interacting proteins can mediate heme regulation of Gis1 activity. By performing pull-down assay followed by mass spectrometry, *in vitro*, we identified a group of proteins that interact with Gis1 under high heme concentration. Knocking out of encoding genes of the identified interacting proteins led to a substantial decrease in heme activation of Gis1. Our studies indicate that Gis1 transcriptional activity is heme dependent, and Gis1-interacting proteins can promote the heme activation of Gis1 activity.

Y3123C A new method for inferring the genetic architecture of expression variation from allele-specific expression experiments. *X. Zhang*, J. Emerson. University of California, Irvine, Irvine, CA.

Allele-specific expression (ASE) reveals the mechanism of expression variation between two differentially expressed alleles. Expression variation can be classified as *trans*-acting when the variation is due to diffusible elements such as transcription factors or *cis*-acting when it is caused by mutations in regulatory sequences such as enhancer elements. Knowing the relative contribution of *cis*- and *trans*-acting variation to total expression variation is crucial in understanding the evolution of gene regulation. We predict that poorly replicated experiments and

experiments employing an unsuitable model underestimate the variance among independent biological replicates, and ignore the effect of hybrid-specific expression due to novel cis-trans interaction, leading to high rates of false positives for inferring differential ASE. We propose a new model which is statistically well-justified both from first principles as well as from empirical work. This method takes advantage of higher replication and appropriate reference genomes.

We introduce an R package which implements our model based on beta-binomial sampling of expression at two alleles. With this package, we test both our model and a previous binomial model using yeast expression data from recent work permitting testing of 48-fold replication. We show that our model estimates *cis*/*trans* expression differences with a type I error rate of approximately 5% when the significance level is set to 0.05. The binomial model underestimates the variance in the data and exhibits a much larger type I error rate of 0.15-0.45. This model will significantly revise conclusions from previous allele-specific expression studies; a large proportion of previous differential expression results are likely false positives, and we probably still do not have a very accurate picture of the nature of allele specific expression even in model systems.

Y3124A Bypassing quality control in 60S Ribosome Biogenesis. *S. Patchett*, Arlen Johnson. The University of Texas at Austin, Austin, TX.

In an actively growing yeast cell, thousands of ribosomes are synthesized per minute. After rapid assembly, these intricate molecular machines must faithfully translate genetic information into all cellular proteins. Quality control mechanisms during ribosome biogenesis are therefore critical to ensure that immature subunits and functionally defective subunits do not enter the translating pool.

During ribosome biogenesis, ribosomal subunits are pre-assembled in the nucleus and exported to the cytoplasm in an inactive state. Before they can engage in protein synthesis, the immature pre-60S subunits must first undergo cytoplasmic maturation. This pathway involves a series of ATPase and GTPase-driven steps that load critical ribosomal proteins, including Rpl10, and remove accessory factors that block ribosome function. These steps are critical for both the final structure of the ribosome and to ensure ribosomal subunits are competent for translation.

The release of Tif6, an accessory factor that blocks 40S joining, and the release of Nmd3, an export adaptor, are the final known steps in 60S maturation. Two proteins, Sdo1 and Efl1, cooperate to release Tif6 from the pre-60S subunit. Intriguingly, Sdo1 binds in the ribosomal P-site and is a structural mimic of tRNA, while Efl1 is closely related to elongation factor eEF2. We have suggested that this “translation-like” binding of Efl1 and Sdo1 is a functional check of the integrity of the 60S peptidyl-transferase center before its first round of translation. Ribosomes that fail this test do not release Tif6 or Nmd3, and are therefore prevented from engaging in translation.

We have shown that ribosomes carrying mutations in *RPL10,* including T-cell leukemia associated *rpl10-R98S,* specifically fail in this quality control step. To understand the consequences of bypassing quality control, extragenic suppressing mutations of *RPL10* mutant alleles were isolated. Importantly, the suppressing mutations bypass the biogenesis defect, but allow mutant ribosomes to engage in translation. Through the characterization of extragenic suppressors, we have uncovered several distinct pathways of bypassing 60S quality control.

Y3125B Early branching *Saccharomyces* for understanding the genetics and evolution of an industrially important genus. *EC. Baker*, W. G. Alexander, D. Peris, Q. Langdon, C. T. Hittinger. University of Wisconsin - Madison, Madison, WI.

In the last several years the relationships among the strains previously referred to as *Saccharomyces bayanus,* have been clarified. This has led to the splitting of these strains into the sister species *Saccharomyces uvarum* (formerly *S. bayanus var. uvarum*) and *Saccharomyces eubayanus* (previously the unknown *S. bayanus*-like contributor to hybrid lager yeasts), and a complex of multi-species hybrids. Hybrids of *S. eubayanus* and *S. uvarum* display more than 10x the spore viability of any other *Saccharomyces* hybrid pair, greatly facilitating genetic studies. Intriguingly, while these species are roughly 10% diverged at the nucleotide level, they are sympatric in nature and, apparently, very physiologically similar. Despite this however, brewing strains of each species (always *Saccharomyces cerevisiae* hybrids or introgressed strains) are strongly allied with different types of fermentations: wines and ciders for *S. uvarum* and lager style beers for *S. eubayanus.* To better understand what separates these industrially important yeasts we have begun exploring the phenotypic and genetic diversity within and between *S. eubayanus* and *S. uvarum*. By comparing the whole-genome sequences of hybrid lager yeasts with their parent species we found that the *S. eubayanus* portion of the lager yeast genomes has experienced pronounced and pervasive relaxation of selective pressure. In addition, we also identified several gene clusters that are likely to be important for *S. eubayanus’* contribution to maltose consumption, which is essential for efficient fermentation. With gene knockout and replacement studies we are further exploring this essential industrial trait. To determine the genetic and phenotypic basis of separation between *S. uvarum and S. eubayanus,* both in nature and in human related fermentations, we are using genome comparisons and analysis of hybrids. Preliminary studies of hybrids indicate possible difference in RNA metabolism, potentially providing insight into the functions of RNA metabolism in ancestral *Saccharomyces* and extant yeast lineages. By studying the diversity contained both within and between these species we not only increase our understanding of this pair of industrially important yeasts, but as an early branching lineage of the *Saccharomyces* they can shed light on the evolution of some peculiar traits, such as the early loss of RNAi, in this important model genus.

Y3126C High-throughput investigation into the evolutionary forces underlying sequence divergence. *Drew T. Doering*, Chris Todd Hittinger. University of Wisconsin-Madison, Madison, WI.

Predicting the relationship between protein sequence and function remains a major challenge in genomics. Homologs that are divergent in sequence often have conserved functions, while rare single nucleotide polymorphisms in a population are the basis of many human diseases. Variation in protein-coding sequence can impact function in various ways, such as by altering folding, enzyme kinetics, binding affinity, or other factors. Here I present a method I am developing to investigate the effects of sequence divergence on the functions of proteins from both

retrospective and prospective viewpoints. This method will enable the characterization of full-length protein variants expressed from the native genomic locus through quantification of variant frequencies in response to competitive growth in selective conditions. Here, using *Saccharomyces* as a model genus, I show how this method will illuminate the evolutionary fitness landscape of a small protein (Atx1) from all *Saccharomyces* species and homologs from other yeasts and multicellular eukaryotes, including humans. Using established genome-editing technologies, I will generate strain libraries that are completely isogenic, except at the *ATX1* locus. I will then conduct pooled competitions of cells expressing *ATX1* variants in selective conditions and monitor the changes in variant frequencies by high-throughput sequencing. Deriving fitness values from these frequency changes enables the comparison of the effect of a given genetic variant on protein function and, ultimately, illuminates the constraints present in the fitness landscape of *ATX1*. Thus far, measuring growth of yeast strains expressing individual Atx1 homologs in selective conditions has revealed differences in fitness, including a general trend toward greater sequence divergence resulting in lower fitness. Notably, *HAH1* (the human homolog of *ATX1*) is able to complement the yeast deletion. Pooled competitive growth assays will further reveal the fitness consequences of genetic variation as cells expressing Atx1 homologs compete for limited resources. Additionally, testing rare *ATX1* variants generated by saturation mutagenesis will ultimately enable the characterization of a fitness landscape for *ATX1*. This technology could be used to study genes implicated in human disease and serve as a platform for diagnosis of heritable diseases that are due to hypomorphic alleles that are present at low frequencies in humans. With the emergence of precision medicine enabled by affordable genome sequencing, physicians could use data generated by this type of study to diagnose a wide variety of genetic diseases using only the patient's genome sequence.

Y3127A The making of biodiversity across the yeast subphylum. *C. T. Hittinger*[1,2], D. A. Opulente[1], A. B. Hulfachor[1], J. DeVirgilio[3], J. Kominek[1], M. Kuang[1], A. Rokas[4], C. P. Kurtzman[3]. 1) Laboratory of Genetics, Genome Center of Wisconsin, Wisconsin Energy Institute, J. F. Crow Institute for the Study of Evolution, University of Wisconsin-Madison, Madison, WI, USA; 2) DOE Great Lakes Bioenergy Research Center, University of Wisconsin-Madison, Madison, WI, USA; 3) Bacterial Foodborne Pathogens and Mycology Research Unit, National Center for Agricultural Utilization Research, Agricultural Research Service, US Department of Agriculture, Peoria, IL, USA; 4) Department of Biological Sciences, Vanderbilt University, Nashville, TN, USA.

Yeasts offer a unique opportunity to understand the genetic mechanisms that generate biodiversity. Their remarkably diverse heterotrophic metabolisms have allowed them to partition nutrients in every major aquatic and terrestrial biome and to inhabit every continent. They have evolved radically different carbon metabolisms and energy management strategies. Most yeasts prefer respiration, but some species, such as the genetic model system *Saccharomyces cerevisiae*, have evolved highly fermentative lifestyles. A handful of clades can accumulate over half of their dry weight as fatty acids, while several species can ferment pentose carbon sources, such as xylose, which is the second most-abundant sugar in plant biomass. The Y1000+ Project (http://y1000plus.org) seeks to determine the genetic basis of yeast metabolic diversity across the subphylum Saccharomycotina. Here we report progress on generating and analyzing functionally annotated genome sequences for all ~1,000 known species of yeasts, as well as comparing their genome contents with rich functional, ecological, and metabolic data. By creating and analyzing the first comprehensive genomic dataset and catalog of metabolic diversity for a high-level taxonomic rank, the Y1000+ Project will illuminate how key genetic innovations and convergent genetic changes have driven diversification across half of billion years of evolution. Comprehensive taxon and genome sampling will allow us to determine how metabolic diversity is encoded in their genomes; the tempo and mode of change; and which phenotypic traits and genetic changes lead to niche expansion, clade diversification, and long-term survival. The genetic features that cause some yeasts to brew beer, others to proliferate on cacti, and still others to blight crops or cause lethal infections are gradually coming into focus.

Y3128B Uncovering rules governing gene replacement between humans and yeast. *Jon M. Laurent*[1], Aashiq H. Kachroo[1], Christopher M. Yellman[1], Austin G. Meyer[1,2], Claus O. Wilke[1,2,3], Edward M. Marcotte[1,2,4]. 1) Center for Systems and Synthetic Biology, Institute of Cellular and Molecular Biology, University of Texas at Austin, Austin, TX; 2) Center for Computational Biology and Bioinformatics, University of Texas at Austin, Austin, TX; 3) Department of Integrative Biology, University of Texas at Austin, Austin, TX; 4) Department of Molecular Biosciences, University of Texas at Austin, Austin, TX.

Owing to its ease of manipulation and rapid growth, the baker's yeast *Saccharomyces cerevisiae* is a popular model organism for studying many aspects of eukaryotic biology. Due to the functional conservation still present between much of the human and yeast proteome, yeast has served an important role in the study of human biology and disease. Inspired by these studies, our lab has been systematically testing which essential yeast proteins are replaceable by their human counterparts, screening for functionality by the human genes' ability to rescue growth in the absence of the yeast proteins. We have found that replacement of genes with 1:1 orthology is governed largely by gene modules, such that pathways or complexes are similarly replaceable or not (Kachroo et al. (2015) *Science*, 348:921-925).

We have now begun to expand our replacement set to include all other essential yeast-human orthologs, covering all ortholog classes (e.g., many:1, 1:many, many:many). We have now tested over 700 pairs of orthologs between the two species. We have observed a variable pattern of replaceability across different ortholog classes, with an obvious bias towards differential replaceability inside gene families, rather than all members of a family being similarly able to replace. In order to determine which properties of co-orthologs can potentially explain this differential replaceability, we have assembled a set of quantitative features of the genes and gene families, including calculated properties of the genes' sequences (e.g., gene and protein lengths, sequence similarities, codon usage) and other properties such as protein interactions, mRNA and protein abundances, and transcription and translation rates. We then quantify how well each feature can predict replaceability, while differentiating between co-orthologs. Further, given our comprehensive results of individual replacements and the rules governing them (e.g. modularity, expression levels), we have now begun to integrate multiple members of human pathways or complexes into the yeast genome, with the goal of building entirely 'humanized' processes.

The letter preceding the number is the community. A, B, C after the number is presentation time.
W – *C. elegans*, C – Ciliates, D – Drosophila, M – Mouse, P – PEQG, Y – Yeast, Z – Zebrafish

These data demonstrate that a substantial portion of conserved yeast and human genes perform much the same roles in both organisms even after >1 billion years of evolution, and provide a direct test of the ortholog-function conjecture across gene familes. Many of the genes that can be replaced have important roles in human disease, including cancer. 'Humanized' strains will simplify drug discovery against human proteins, enable studies of the consequences of human genetic polymorphisms, and empower functional studies of entire human cellular processes in a simplified organism.

Y3129C Evolutionary dynamics of second beneficial mutations via a double-barcoding platform. *F. Li*[1,2], X. Liu[2,3], E. Coutsias[1,2], JR. Blundell[2,3,4], SF. Levy[2,3]. 1) Department of Applied Mathematics and Statistics, Stony Brook University, Stony Brook, NY; 2) Laufer Center for Physical and Quantitative Biology, Stony Brook University, Stony Brook, NY; 3) Department of Biochemistry and Cell Biology, Stony Brook University, Stony Brook, NY; 4) Department of Applied Physics, Stanford University, Stanford, CA.

We have previously built an ultra-high resolution barcoding system that can be used to simultaneously track the evolutionary dynamics of millions of yeast lineages in real time. By evolving an initially isogenic barcoded population, we identified and characterized tens of thousands of mutations that provide a benefit to the initial genotype. Describing the mutation rate spectrum of these first beneficial mutations, the fitness effect of each mutation and the rate to that fitness effect, allowed us to predict the evolutionary dynamics of the population for ~80 generations. However, making predictions out to longer times is challenging because the evolutionary dynamics will depend heavily on second beneficial mutations and how these interact with first mutations. With this technology, second mutations are difficult to detect because they are most likely to occur in lineages that have already expanded to large sizes. Here, we develop a new double-barcode lineage tracking system that allows us to measure the fitness effects and occurrence times of thousands of first and second mutations in the same evolving yeast population. This system consists of a double landing-pad capable of accepting two large barcode libraries that can be inserted at different times during an evolution. The addition of second barcodes late in an evolution allows us to break up large lineages containing a first mutation in order to quantitatively study the second mutations that occur on top. Using this system, we are evolving presumably isogenic haploid and diploid yeast libraries containing ~200,000 first barcodes in carbon-limited media at two temperatures. At a time when most cells contain a first beneficial mutation but few contain a second, we will insert the second library of ~2M barcodes and evolve for another 200 generations. Amplicon sequencing of double barcodes will be used to track lineage trajectories following re-barcoding. Mathematical models will be used to estimate the occurrence times and fitness effects of second mutations, and how they depend on the first mutation. This high resolution and large scale evolution experiment will enable us to better understand macroscopic epistasis by systematically characterizing the relationship between first mutations and potential for further adaptation.

Y3130A Quantitative evolutionary dynamics of a large number of yeast segregants. *Xianan Liu*[1,2], Fangfei Li[1,3], Takeshi Matsui[4], Ian Ehrenreich[4], Sasha Levy[1,2]. 1) Laufer Center for Physical and Quantitative Biology, Stony Brook University, Stony Brook, NY; 2) Department of Biochemistry and Cell Biology, Stony Brook University, Stony Brook, NY; 3) Department of Applied Mathematics and Statistics, Stony Brook University, Stony Brook, NY; 4) Molecular and Computational Biology Section, Department of Biological Sciences, University of Southern California, Los Angeles, CA.

The distribution of fitness effects (DFE), or beneficial mutation rate spectrum, is the rate at which mutations of each fitness effect occur in a particular genotype. We have previously characterized the DFE in an initially isogenic yeast population using high-resolution lineage tracking and shown that it can be used to predict the evolutionary dynamics of large populations in the lab. In more complex evolutionary scenarios where initial genotypes are heterogeneous, the evolutionary dynamics depends on both the fitness and the DFE of each genotype. Yet, little is known about how the DFE varies across genotype space. Here, we focus on measuring how the DFE depends on the genotype using a novel tandem integration double barcoding system. This system relies on two incompatible loxP variant sites in the genome, which sequentially bring two barcoded plasmid libraries (BC1 and BC2) to the common genomic location. The trajectory of each double barcode lineage can subsequently be monitored by pooled growth and amplicon sequencing. We have generated a large haploid segregant pool from a cross between genetically divergent strains, the lab strain BY4741 and the pathogenic clinical isolate YJM789. We have picked and verified ~200 segregants, each barcoded with a unique BC1, and measured their fitness by pooled competition to find a subset that represent a broad spectrum of initial fitnesses. To measure the DFE of many segregants, we are barcoding each with ~100,000 BC2 barcodes and generating ~5 pools that contain overlapping segregants. The construction of segregant pools are guided by numerical simulations to maximize the number of segregants for which the DFE can be estimated. Serial batch evolution with these pools in three different environments will be used to examine how much the DFE varies between segregants, and if and how much the DFE depends on the initial fitness. Next, we will sequence the genome of each segregant to perform a quantitative trait loci (QTL) analysis for various features of the DFE. This QTL study will test the hypothesis that some genetic loci explain some variance in the DFE and thereby modulate evolvability.

Y3131B Mining *Saccharomyces* diversity and experimental evolution for cellulosic biofuel production. *D. Peris Navarro*[1*], R. V. Moriarty[1], W. G. Alexander[1], K. Sylvester[1], M. Sardi[1], D. Libkind[2], P. Gonçalves[3], J. P. Sampaio[3], Q. M. Wang[1,4], F. Y. Bai[4], J. B. Leducq[5], C. Landry[5], K. Hyma[6], J. Fay[6], T. K. Sato[1], C. T. Hittinger[1]. 1) University of Wisconsin-Madison, Madison, WI, USA; 2) CONICET-UNComahue, Bariloche, Argentina; 3) Universidade Nova de Lisboa, Caparica, Portugal; 4) Chinese Academy of Sciences, Beijing, China; 5) Université Laval, Québec, Canada; 6) Washington University, St. Louis, MO, USA.

In the last decade, the application of new molecular techniques has helped to identify *Saccharomyces* species and unravel their diversity. Indeed we present a poster related to wild and industrial dynamics of *S. eubayanus* lineage (see Langdon Q.). Mining nucleotide variation and the translated effect on different levels of stress tolerance, sugar consumption rates, or compound production, might be the first step to

unravel interesting industrial traits from strains. Here, we screen 510 *Saccharomyces* strains, exploring diversity levels on par with the diversity between human and birds, in AFEX-Corn Stover Hydrolysate (ACSH) and report the performance of the best candidates during microaerobic fermentations in ACSH, YPDX and YPDX + Feruloyl Amide. Our results show a potential application for lineages such as *S. paradoxus* and *S. mikatae* which show tolerance to ACSH conditions, and *S. uvarum* for their xylose consumption rates. In addition, we mimic the process of brewing hybrid domestication in this biofuel media. We studied the performance of 8 artificial hybrids and compared them to their parents. We also subjected the hybrids to experimental evolution during microaerobic fermentations in ACSH for 50 generations. We observed a great potential for hybridization, and developed a new system for generating efficiently hybrids, called HyPr (Hybrid Production). Now, to explore more diversity we are generating new hybrids with chassis strains and selected *Saccharomyces* lineages; together with experimental evolution and whole genome sequencing, we expect to unravel the genetic components underlying interesting traits, which could be integrated in artificial gene networks in chassis strains to improve their performance in industrial conditions.

Y3132C Condition-dependent differentiation and division of labor in clonal *Saccharomyces cerevisiae* biofilms. *B. Regenberg*, K. E. Hanghøj, K. S. Andersen, J. J. Boomsma. Department of Biology, University of Copenhagen, Denmark.

How multicellularity with division of labor between cell types evolved is one of the most fundamental questions in biology, but previous studies have hardly explored single-gene pre-adaptations that may allow differentiation to be realized. We show that differential expression of *FLO11* produces an evolutionary stable division of labor trait in clonal *S. cerevisiae* biofilm colonies on medium with intermediate viscosity. Differentiated Flo11$^{+/-}$ colonies obtain a 4-fold growth advantage over undifferentiated colonies by overgrowing glucose resources instead of depleting them as undifferentiated Flo11^{-} colonies do, and they maintain their differentiated state by switching non-adhesive cells to adhesive cells with predictable probability in the growing edge. Our results demonstrate how differentiation allows fitness advantages by preemptive territory acquisition and robustness against invading free-riding strains. *S. cerevisiae* biofilm thus represents a suitable model for studying the very first evolutionary steps towards clonal multicellularity.

Y3133A Using the experimental evolution of long-lived yeast species for testing evolutionary theories of aging. *V. Titorenko*, A. Gomez-Perez, A. Arlia-Ciommo, Y. Medkour. Concordia Univ, Montreal, PQ, CA.

We use the yeast *Saccharomyces cerevisiae*, a unicellular eukaryote amenable to high-throughput molecular analyses, as a model organism for empirical validation of evolutionary theories of programmed or non-programmed aging and age-related death. We found that lithocholic bile acid (LCA) is a geroprotector which significantly delays the onset and reduces the rate of yeast chronological aging. Unlike mammals, yeasts do not synthesize bile acids. Our analysis of how LCA and other anti-aging compounds (including resveratrol, caffeine, and rapamycin) synthesized and released into the environment by one species of the organisms composing an ecosystem extend longevity of other species within this ecosystem suggests that these interspecies chemical signals may create xenohormetic, hormetic and cytostatic selective forces driving the evolution of longevity regulation mechanisms at the ecosystemic level. To test this hypothesis, we carried out the LCA-driven experimental evolution of long-lived yeast species. Our selection yielded three yeast strains with greatly extended lifespans. As an empirical test of the antagonistic pleiotropy and life history optimization theories of aging, we analyzed the trade-offs between early-life fitness and longevity by measuring the relative fitness of each of the laboratory-evolved long-lived yeast species in a direct competition assay with the parental wild-type strain. The assay was carried under caloric restriction (CR) conditions, which mimic the natural stressful environment of cyclical starvation, as well as under non-CR conditions in a more favorable environment. We found that, if cultured under field-like CR conditions, each of the three long-lived yeast species exhibits reduced fitness. Such a trade-off between early-life fitness and longevity was significantly less pronounced under laboratory-like non-CR conditions. Our studies of the mechanisms underlying the observed trade-off between early-life fitness and longevity revealed that 1) none of the laboratory-evolved long-lived yeast species has reduced fecundity; and 2) the decreased relative fitness of each of these species was not due to a reduction in growth rate early in life. Our monitoring of the age-dependent dynamics of changes in mitochondrial composition, morphology, and function implies that the longevity-associated fitness defect in each of the three laboratory-evolved long-lived yeast species is a dominant genetic trait attributed to specific lifespan-extending alterations in mitochondria. Based on our findings, we propose a hypothesis of the natural selection forces and underlying mechanisms that drive the evolution of yeast longevity and maintain a finite yeast lifespan within ecosystems.

Y3134B Does antifungal drug resistance potentiated by Hsp90 arise from stress-induced mutations? *A. E. Yuan*, D. F. Jarosz. Stanford University, Stanford, CA.

Theory holds that the capacity of a population to evolve in response to a selective pressure is due to the enrichment of pre-existing adaptive variants. That is, successful alleles are not produced by selection itself. This line of thinking has recently been challenged by the observation that some types of selection can induce mutations that confer an adaptive advantage. Although the generality of such findings is controversial, a number of induced mutagenesis systems have now been characterized at the genetic level in bacteria. Much less is known about whether and how such processes might operate in eukaryotic cells. The highly conserved molecular chaperone Hsp90, which assists in the folding of many proteins that are critical for growth and development, has been proposed to broadly influence the capacity of mutations to produce new phenotypes. Because the activity of Hsp90 is stress-regulated, we investigated whether it might provide a means through which the environment could influence acquisition of adaptive phenotypes. Using the classic statistical assay known as the fluctuation test, we observed that a modest change in Hsp90 activity altered the mechanisms by which yeast cells acquire resistance to the commonly prescribed antifungal drug fluconazole. The distribution of resistant variants we obtained suggested that fluconazole exposure itself likely induced the acquisition of resistant phenotypes. This process strongly depended upon Hsp90 activity; induced resistance was not observed in cells with reduced Hsp90

activity. Furthermore, pre-exposure to fluconazole increased the frequency at which cells acquired resistance to the unrelated selective agent 5-fluoroorotic acid, supporting the idea that fluconazole can induce genetic diversification. We observed similar results with the evolutionarily distant human pathogen *Candida albicans*. Our findings establish a means through which environmental stress might influence the fundamental mechanisms of adaptation in eukaryotes and further point to an unappreciated benefit of modulating Hsp90 activity as a strategy to overcome drug resistance in fungi.

Y3135C Evolutionary and functional analysis of dubious open reading frames suggest a functional role in yeast genomes. *G. Arora*[1], A. G. Rosenwald[2]. 1) Gallaudet University, Washington, DC-20002; 2) Georgetown University, Washington DC-20057.

The *Saccharomyces cerevisiae* genome has been studied extensively since it was first sequenced 20 years ago. A number of open-reading frames in this genome, are still classified as "dubious" including those that overlap open-reading frames known to encode functional proteins. We reexamined whether this status is still warranted given the large increase in data from numerous sources. These data include genomic information from other members of the *Saccharomyces* clade and transcriptome information from *S. cerevisiae* grown under a number of different conditions. Using genomic data we first examined the conservation of these ORFs compared to other members of the clade. Second, we examined existing data from tiling microarray and RNA-seq experiments. Our data show that these ORFs are in fact conserved and many of them are differentially expressed, suggesting a functional role.

Y3136A Genomic approaches in *Saccharomyces cerevisiae* reveal that response to the toxic spill chemical 4-methylcyclohexanemethanol is mediated by genes involved in pleiotropic drug response, in reactive oxygen species protection, and in UAS *INO* inositol biosynthetic regulation. *M. Ayers*, X. Rong-Mullins, C. Nassif, J. Gallagher. West Virginia University, Morgantown, WV.

In the aftermath of the January 2014 MCHM spill into the Elk River of Kanawha county, West Virginia, the lack of knowledge concerning the mode of action of this chemical within the cell became clear. The budding yeast is a key model organism with conserved eukaryotic biochemical and genetic pathways, as well as convenient functional genomics tools with which to identify how the cell responds to chemicals. Investigations into MCHM cellular response included growth assays of wild type strains, viability assays, growth assays of knockout strains, RNA-seq analysis, quantitative trait loci, and GFP-labeled protein localization microscopy. Viability and growth assays of wild type yeast revealed sensitivity to MCHM in the concentration range of approximately 0.04-0.06%, though defect in growth appears to be from inhibition of growth instead of lethality. RNA-seq analysis for differential expression of genes with MCHM treatment indicated that genes for transcription factors and ABC transporters in the pleiotropic drug response are affected. Knockout strains for drug response and oxidative stress genes were also grown in MCHM, revealing several mutants in these pathways were sensitive, and therefore required for MCHM response. The RNA-seq data also pointed to the inositol biosynthetic pathway, which is normally tightly regulated by a certain set of proteins. One gene in particular, the major negative regulator of UAS *INO* genes, *opi1*, showed sensitivity to MCHM. Many of the genes regulated by the Opi1 protein are downregulated by MCHM. Microscopy of the GFP-labeled Opi1p revealed relocalization of the negative inhibitor protein into the nucleus due to MCHM treatment in media lacking inositol, the normal signal for relocalization. Future investigation into the effects of MCHM must involve investigation of pleiotropic drug response, oxidative stress, and the inositol biosynthetic pathway to reveal mechanisms of toxicity and targets of treatment for exposure.

Y3137B Comparisons of the genomes of *Holleya sinecauda* and *Ashbya gossypii* – closing in on the minimal gene set for a free-living fungus. *Fred S. Dietrich*. Duke Univ, Durham, NC.

The filamentous fungus *A. gossypii* and the related dimorphic fungus *H. sinecauda* have compact genomes of less than 10Mb. They have small intergenic regions frequently less than 100 bases in length, no transposable elements, and short telomeric and centromeric regions. We have recently completed the genomic sequence of *H. sinecauda* and deposited it in Genbank. A comparison of the genomes identifies approximately 30 genes whose presence or absence differs between these two species. While *A. gossypii* has over 5000 protein coding genes and genes producing an RNA product, comparison with *H. sinecauda* and other hemiascomycete species suggests the minimal gene set for a hemiascomycete to grow robustly on salts, ammonia, carbon source, water is around 4800 genes.

Combining this analysis with the recent analysis of 100 *S. cerevisiae* genes (Strope et al, 2015) suggests a set of core genes in *S. cerevisiae*, a set of additional genes beyond the core set, and a set of genes found in only a subset of *S. cerevisiae* genomes. In addition to variation in the gene set adding functionality to the genome, gene duplication, horizontal gene transfer, and introgression are all contributing to the genomic plasticity of *S. cerevisiae*..

Y3138C Chromosome-specific and global effects of aneuploidy revealed by Synthetic Genetic Array analysis. *Stacie Dodgson*[1], Stefano Santaguida[1], Sharon Kim[1], Michael Costanzo[2], Anastasia Baryshnikova[3], Charles Boone[2], Angelika Amon[1]. 1) Koch Institute for Integrative Cancer Research, HHMI, Dept. of Biology, MIT, Cambridge, MA; 2) The Donnelly Centre and Dept. of Molecular Genetics, Univ. of Toronto, Toronto, Canada; 3) Lewis-Sigler Institute for Integrative Genomics, Princeton University, Princeton, NJ.

Aneuploidy, an unbalanced karyotype in which one or more chromosomes are present in excess or reduced copy number, causes an array of known phenotypes including proteotoxicity, genomic instability and slowed proliferation. However, the molecular consequences of aneuploidy are poorly understood and an unbiased investigation into aneuploid cell biology was lacking. We performed high-throughput screens for genes whose deletion has a synthetic fitness cost in aneuploid *Saccharomyces cerevisiae* cells containing single extra chromosomes. This analysis identified genes that when deleted decrease the fitness of specific disomic strains as well as those that impair the proliferation of a broad range of aneuploidies. In one case, a chromosome-specific synthetic growth defect could be explained fully by the specific duplication of a single gene

on the aneuploid chromosome, highlighting the ability of individual dosage imbalances to cause chromosome-specific phenotypes in aneuploid cells. Deletion of other genes, particularly those involved in protein transport, however, confers synthetic sickness on a broad array of aneuploid strains. Indeed, aneuploid cells, regardless of karyotype, exhibit protein secretion and cell wall integrity defects. Additionally, we identified a deubiquitinase, Ubp3, whose deletion broadly impairs aneuploid yeast cell fitness, and this synthetic effect is conserved in human cells. Thus, we were able to use this screen to identify novel cellular consequences of aneuploidy across organisms, which are dependent on both specific chromosome imbalances as well as caused by many different aneuploid karyotypes. Interestingly, the vast majority of cancer cells are highly aneuploid, so this approach could be of further use in identifying both karyotype-specific and nonspecific stresses exhibited by cancer cells as potential targets for the development of novel cancer therapeutics.

Y3139A Toxicogenomic approaches for profiling resistance to P450-activated food carcinogens and phenotyping human P450 polymorphisms in budding yeast. *Michael Fasullo*, Nicholas St. John, Julian Freedland, Cinzia Cera. State Univ New York Polytechnic Institute, Albany, NY.

The human response to environmental carcinogens is highly variable, depending upon environmental, lifestyle, and genetic factors. Genetic factors include polymorphic P450 and DNA repair genes; however, epidemiological studies may lack significance due to inadequate patient numbers. We used budding yeast (*Saccahromyces cerevisiae*) as a model organism to determine genetic susceptibility to food-associated carcinogens, including benzo[a]pyrene dihydrodiol (BaP-DHD), aflatoxin (AFB_1) and heterocyclic aromatic amines (HAAs). Budding yeast does not contain P450s that convert these compounds into genotoxic metabolites, so we introduced expression vectors that contain specific human P450 and NAT2 genes into yeast deletion library collection.. In yeast, either CYP1A2 or CYP1A1 activates AFB_1, while both CYP1A2 and NAT2 are required for activation of 2-amino-3-methylimidazo[4,5-f]quinoline (IQ). To measure genotoxic effects, we measured recombination and mutation frequencies, Rad51 foci, growth inhibition and DNA adducts. To determine resistance genes, we used a high throughput approach for screening the yeast deletion library expressing specific P450 genes. Screens for aflatoxin resistance identified checkpoint, RNA metabolism, and mitochondrial maintenance genes, several of which are risk factors in cancers. We are now performing screens to identify genes involved in resistance to IQ. Preliminary data identified both recombinational repair and DNA damage tolerance genes. Further high throughput analysis will be performed using other food carcinogens, including 2-amino-1-methyl-6-phenylimidazo[4,5-*b*]pyridine (PhIP) and 2-amino-3,8-dimethylimidazo[4,5-*f*]quinoxaline (MeIQx). These studies thus represent a novel approach for phenotyping P450 polymorphisms and open new avenues for exploring resistance to P450-activatable compounds. Grant Support: National Institutes of Health, 1R15ES023685-01.

Y3140B Polygenic Analysis of Ethanol Tolerance and Maximal Ethanol Accumulation capacity in *Saccharomyces cerevisiae*. *Annelies Goovaerts*[1,2], Steve Swinnen[1,2], Thiago Pais[1,2], Maria Foulquié-Moreno[1,2], Johan M. Thevelein[1,2]. 1) KU Leuven, Leuven, Belgium; 2) VIB, Leuven, Belgium.

Introduction

Most traits of industrial importance in yeast are polygenic, therefore complex and difficult to study. In our laboratory, we have developed a technology called 'pooled-segregant whole-genome sequence analysis', which has been successfully applied to complex traits such as high ethanol tolerance and maximal ethanol accumulation capacity. The aim of this study was to identify new genes underlying high ethanol tolerance and maximal ethanol accumulation capacity by combining both pooled-segregant whole-genome sequence analysis and pooled-segregant RNA expression analysis.

Methods

A haploid strain displaying the superior trait of interest was crossed with a haploid inferior lab strain. Segregants of this cross showing the phenotype of the superior parent were selected and pooled together. The genomic DNA of the pool and the parents was extracted and sequenced by Illumina HiSeq2000. The SNP variant frequency of the pooled DNA was plotted against the SNP chromosomal position, to map the quantitative trait loci (QTLs). Reciprocal hemizygosity analysis (RHA) was applied to identify the causative genes in the QTLs. Genome-wide gene expression analysis at a fermentation time-point where the ethanol concentration was 13.8% (v/v) was performed for the superior pool and parent strains via RNA-Seq. The new identified genes are introduced in a second-generation bio-ethanol producing strain with the Crispr/Cas9 method in order to improve the ethanol tolerance and maximal ethanol accumulation.

Results and discussion

Several QTLs were identified for the traits ethanol tolerance and maximal ethanol accumulation. Fine-mapping and RHA identified several specific causative genes for these traits of interest. RNA sequence analysis revealed 37 genes that were overexpressed in the pool of segregants and superior parent in comparison with the inferior parent. Most of these genes have a biological function related to stress tolerance. Our results reveal that a combination of pooled-segregant whole-genome sequence analysis and gene expression analysis is a promising approach to understand the genetic basis of complex traits.

Y3141C The evolutionary constraints of gene expression levels in *S. cerevisiae*. *M. J. Hickman*, A. Jackson, A. Tursi, J. Thornton, A. Smith. Rowan University, Glassboro, NJ.

It has been widely reported that some genes are expressed at a higher level than others. However, it has not been shown whether each gene is expressed consistently between studies and at the same level compared to all other genes. Here, we examined nine RNA-seq datasets and found that the mRNA level of each gene is indeed consistent relative to all other genes. The mRNA levels were also highly correlated to protein levels measured by different methods, though translational and protein turnover regulation likely prevent a perfect correlation. The consistency of gene expression level implies that there are evolutionary pressures that drive genes to maintain either low or high expression. In

order to identify these pressures, we compared expression level to the features of each gene (or associated protein), such as protein function, localization, essentiality and number of interactions. We found many possible pressures; for example, genes involved in translation or the ribosome were highly expressed while genes involved in chromosomal activities, such as replication and transcription, were lowly expressed. Furthermore, we optimized an artificial neural network, using several of these features as inputs, and could predict gene expression level with ~80% accuracy. In conclusion, these results show that gene expression level is likely constrained by several evolutionary pressures, including the biological process and cellular localization of the associated protein.

Y3142A An Integrated platform to characterize neurodegenerative disease associated proteins in yeast. *S. Ju*, S. Chen, A. Koesters, E. Hayden, Q. Zhong. Wright State University, Dayton, OH.

The molecular underpinnings of neurodegenerative disease are gradually emerging following biochemical characterization of protein aggregates in disease tissues, and the identifications of causal genes in certain familial forms of neurodegenerative disorders. With the vast majority of disease cases being sporadic and causes unknown, however, our understanding of neurodegeneration remains vastly incomplete. Becoming increasingly appreciated is also the difficulty to evaluate the extent to which a given risk factor identified in human genomes may alter susceptibility of any individual to a specific type of neurodegenerative disorder. This is largely due to a critically missing aspect of our understanding of neurodegenerative disease from the perspective of complex networks of gene-gene interactions. Such networks may consist of genes with causal or modifier effects and interactions that can be specifically targeted by gene mutations. Here we present three proof-of-principle studies using yeast as a model system to map and characterize biochemical and genetic interactions of neurodegenerative disease-associated proteins. Our studies demonstrate the feasibility to i) systematically profile functional alterations of human gene alleles associated with neurodegenerative disease; ii) to rapidly identify, at the genome scale, genes that exert effects the disease-associated protein aggregation and toxicity at the cellular level; and iii) to measure changes in protein-protein interactions by both disease-causing and putative mutations. Our long-term goal is to interpret phenotypic consequences of genetic variations associated with neurodegenerative disease from the global integrated network perspective.

Y3143B Investigating the effects of gene overexpression on genome stability in Saccharomyces cerevisiae. *Krystal Laframboise*, Grant W. Brown. Department of Biochemistry, Donnelly Centre for Cellular and Biomolecular Research, University of Toronto, Toronto, Ontario, Canada.

Accurate replication of the genome is essential for survival. The combination of both exogenous and endogenous sources of replication stress and DNA damage serve as a constant threat to the fidelity of this process. Fortunately, eukaryotic cells have a highly conserved DNA damage and replication checkpoint, which acts to recognize and repair damage to prevent genome instability. Though the mechanisms of genome maintenance have been extensively studied in *Saccharomyces cerevisiae*, almost all previous screens used to identify novel genes involved in these processes have employed loss-of-function alleles, subsequently ignoring the consequences of gene overexpression. These consequences are of particular interest as several disease states are associated with gene overexpression or gain-of-function mutations, including many human cancers. Here, we assay expression of the DNA damage-inducible gene, *RNR3*, using reporter synthetic genetic array methodology to identify genes causing genome instability when overexpressed. We find 41 of ~5100 genes screened result in increased *RNR3* expression, including known DNA repair genes and transcriptional regulators of *RNR3*, confirming the capability of our screen to robustly identify genes of functional relevance. 58.5% of genes inducing *RNR3* in our screen had no reported connection to genome stability when compared to previous overexpression studies, leaving 24 novel, putative genome maintenance genes for follow-up. We are currently using fluorescence microscopy to visualize the formation of various DNA damage-specific foci to ensure the mechanism of *RNR3* induction caused by these novel candidates is related to genome instability and is not the result of transcriptional regulation. Furthermore, since 17 of our candidates have human homologues, our data will not only provide insight into novel pathways involved in genome maintenance in *S. cerevisiae*, but may also reveal novel pathways promoting oncogenesis in humans.

Y3144C Analyzing Terminal Phenotypes in *Saccharomyces cerevisiae* Using Synthetic Genetic Array and High-Content Screening. *D. Lo*[1], O. Kraus[2], A. Verster[3], C. Boone[1,3], B. Andrews[1,3]. 1) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, CA; 2) Department of Electrical and Computer Engineering, University of Toronto, Toronto, Ontario, CA; 3) The Donnelly Centre for Cellular and Biomolecular Research, University of Toronto, Toronto, Ontario, CA.

What happens as a cell dies? How does the breakdown of one organelle impact other subcellular compartments and structures, and how does this lead to the death of the cell? In order to further our mechanistic understanding of how cells die, we aim to study this subcellular chain of events that occur as a cell is dying, also termed a terminal phenotype. To examine terminal phenotypes, we developed methods that integrate the Synthetic Genetic Array (SGA) method with high-content screening (HCS) to enable the high-throughput, quantitative assessment of changes in subcellular morphology that occur as a cell is dying. We introduce fluorescent markers of key subcellular compartments into strains carrying temperature-sensitive (ts) alleles of essential genes, and then image cells using high-throughput confocal microscopy. We introduced a panel of 23 diagnostic GFP markers, which monitor major compartments and functions in the cell, into a representative array of 384 different ts mutants using SGA, and imaged the resulting mutants over 24 hours at the non-permissive temperature. Markers tailored towards observing cell death pathways include the metacaspase Mca1-GFP, the endonuclease Nuc1-GFP, and the putative necrosis factor Nhp6a-GFP. This analysis generates rich phenotypic profiles of essential gene mutants that capture the changes in subcellular morphology that span the time from first inactivation of the gene product to the death of the cell. Preliminary results indicate that terminal phenotypes are temporally dynamic, reflecting multiple early changes in subcellular morphology that tend to be specific to the mutated gene, and later defects that are more generally associated with cell death. Furthermore, mutants that display defects in multiple subcellular compartments point

towards possible unexplored functional connections between subcellular compartments and structures. These assays will provide us with new information that will allow us to determine the mechanisms behind terminal phenotypes, and to gain further insight into the functional wiring diagram of the cell.

Y3145A Independent origins of yeast associated with coffee and cacao fermentation. *Catherine L. Ludlow*[1], Gareth A. Cromie[1], Cecilia Garmendia-Torres[2], Amy Sirr[1], Michelle Hays[3,4], Colburn Field[5], Justin C. Fay[6], Aimée M. Dudley[1]. 1) Pacific Northwest Diabetes Research Institute, Seattle, WA; 2) Institut de Génétique et de Biologie Moléculaire et Cellulaire, Strasbourg, France; 3) Fred Hutchinson Cancer Research Center, Seattle, WA; 4) Molecular and Cellular Biology Program, University of Washington, Seattle, WA; 5) Montana State University, Bozeman, MT; 6) Washington University School of Medicine, St. Louis, MO.

Because of its profound importance in the fermentation of foods and beverages, the link between humans and the yeast *Saccharomyces cerevisiae* is tight and ancient. Yeast strains associated with modern winemaking reflect a history of dispersal by human activity, which has produced a population of limited genetic diversity that resides in vineyards around the globe. Here, we examine whether the same might be true of the microorganisms associated with other crops that have been transported by humans and whose products rely on fermentation, specifically coffee and cacao. We focus on one of these microbes and show that live strains of *S. cerevisiae* can be isolated from unroasted coffee and cacao beans long after they have been processed by fermentation in their countries of origin. Unlike the wine strains, coffee and cacao yeasts are genetically diverse and form discrete populations, demonstrating independent origins of distinct populations of yeast from the same human-associated activity. These populations show evidence of admixture events between three previously characterized populations, one of which is the wine population itself. Thus, our study suggests that human-associated fermentations and migration have affected the distribution and abundance of yeast used for the production of coffee and chocolate. While human transport of cultivated plants is well documented, our impact on associated microbes is only now becoming apparent.

Y3146B Design and assembly of synthetic chromosomes *VIII* and *I*. *Jingchuan Luo*[1,2], Leslie A. Mitchell[1], Kun Yang[3,4], Karen I. Zeller[4], Joel S. Bader[3,4], Jef D. Boeke[1]. 1) NYU Langone Medical Center, new york, NY; 2) Johns Hopkins School of Medicine, Baltimore, MD; 3) Department of Biomedical Engineering and Institute of Genetic Medicine, Whiting School of Engineering, JHU, Baltimore, MD 21218, USA; 4) High Throughput Biology Center, JHU School of Medicine, Baltimore, MD 21205, USA.

Synthetic biology, by definition, is to design and construct new biological parts, circuits, and pathways, or introduce biological parts, or pathways into a new system, which do not exist in nature. In 2011, Dymond *et al.* synthesized the first synthetic eukaryotic chromosome arms *synIXR* and semi-*synVIL*. In 2014, Annaluru et al synthesized the first synthetic eukaryotic chromosome *synIII. SynIII* is functional in *Saccharomyces cerevisiae*. The synthetic yeast grows as well as wild type. As part of *Saccharomyces cerevisiae* (Sc) 2.0 project, I am working on assembly of synthetic chromosomes *VIII* and *I*. So far, 84% of *synVIII* was completed. *SynI* is one of the "coolest" chromosomes in Sc2.0, because we plan to attach it to the end of another synthetic chromosome. I have developed a CRISPR based method to fuse one chromosome to another chromosome. I have fused *chrI* to the longest chromosome arm (*chrIV* right arm, ~1MB) or shortest chromosome arm (*chrIX* right arm, 90KB) in budding yeast. Interestingly, the relocation of *chrI* did not affect yeast growth. Currently I am studying those fusion chromosomes.

Y3147C Genome sequence of W303 provides insight into diverse evolutionary past. *Kinnari Matheson*, Lance Parsons, Alison Gammie. Princeton University, Princeton, NJ.

W303 is a laboratory strain of *Saccharomyces cerevisiae* that has been employed to study a multitude of biological processes. Many of these studies require a reference quality genome sequence for single nucleotide polymorphism identification and other high-throughput or hybridization-based molecular analyses. In this work, we present a high quality genome sequence that can be utilized for genome-wide studies. Comparative analysis with an ancestor of W303, S288c, provides insights into the evolutionary past of this laboratory strain. About 91 % of the genome sequence of W303 is identical to S288c; however, several divergent gene families have been analyzed. Selective pressures acting on flocculation genes were characterized, these represent selection against invasive strains. Remnants of ancestor wine strains have been identified on several chromosomes.

Y3148A Synthesis, debugging and consolidation of synthetic chromosomes in yeast: *synVI* and beyond. *Leslie A. Mitchell*[1,2], Ann Wang[3,4], Giovanni Stracquadanio[3,5], Zheng Kuang[1,2], Xuya Wang[1,2], Sarah Richardson[3,5], J. Andrew Martin[1,2], Roy Walker[6], Yisha Luo[6], Hongjiu Dai[7], Kang Dong[7], Zuojian Tang[8], Yizhi Cai[6], David Fenyo[8], Junbiao Dai[4], Joel S. Bader[3,4], Jef D. Boeke[1,2]. 1) Department of Biochemistry and Molecular Pharmacology, New York University Langone School of Medicine, New York City, NY 10016, USA; 2) Institute for Systems Genetics, New York University Langone School of Medicine, New York City, NY 10016, USA; 3) High Throughput Biology Center, Johns Hopkins University School of Medicine, Baltimore, MD 21205, USA; 4) Key laboratory for Industrial Biocatalysis (Ministry of Education), Key laboratory of Bioinformatics (Ministry of Education), Center for Synthetic and Systems Biology, School of Life Sciences, Tsinghua University, Beijing 100084, China; 5) Department of Biomedical Engineering and Institute of Genetic Medicine, Whiting School of Engineering, Johns Hopkins University, Baltimore, MD 21218, USA; 6) Center for Synthetic and Systems Biology, School of Biological Sciences, University of Edinburgh, Edinburgh EH9 3JL; 7) GenScript, Piscataway, NJ 08854, USA; 8) Center for Health Informatics and Bioinformatics, New York University Langone School of Medicine, New York City, NY 10016, USA.

The Synthetic Yeast Genome project, Sc2.0, aims to build a designer genome to power growth of the yeast *Saccharomyces cerevisiae*. Here we describe the design, rapid assembly, and characterization of Sc2.0 chromosome *VI*, dubbed *synVI*. Growth defects observed in the *synVI* strain

were mapped to the synthetic chromosome, including one that affected mitochondrial behavior. We mapped the mitochondrial defect to a series of synonymous coding sequence changes in the essential gene *PRE4*, encoding a proteasomal subunit; coding changes reduced Pre4 protein accumulation by about half. Completing Sc2.0 necessitates a method to backcross synthetic chromosome strains to wild type and to combine multiple synthetic chromosomes into a single strain. We developed a method to rapidly cross synthetic chromosomes to any strain of interest without sequence alteration and built a poly-synthetic strain encoding *synIII*, *synVI*, and *synIXR*. This work sets the stage for completion of the world's first synthetic, designer eukaryotic genome.

Y3149B Bar-seq analyses to determine the mode of action of compounds derived from feijoa fruit. *M. Mokhtari*[1], D. Miller[2], D. Gresham[2], A. Munkacsi[1]. 1) Centre for Biodiscovery, School of Biological Science, Victoria University of Wellington, Wellington, New Zealand; 2) The Center for Genomics and Systems Biology, Department of Biology, New York University, New York.

The feijoa fruit (*Feijoa sellowiana*) is a rich source of bioactive compounds such as tannins, terpenoids, alkaloids, and flavonoids. Of the 95 compounds reported thus far, these compounds exhibit a diverse suite of bioactivity including antimicrobial, antifungal, anticancer, and antiviral activity. To characterize the genetic and cellular mechanisms of action of two potentially novel compounds derived from feijoa fruit, we used Bar-seq analyses to identify the genes and pathways mediating the bioactivity of these compounds. Next-generation sequencing was used to sequence the barcodes in the heterozygous and homozygous diploid libraries. The barcode sequences were mapped to the reference barcodes and differential abundance analyses were used to compare barcode abundance in treated and untreated genomic libraries. The least represented genes in the heterozygous diploid library will be identified as candidate primary targets of the compounds, while the least represented genes in the homozygous diploid library will be identified as candidate targets downstream of the primary target. The results of our Bar-seq analyses will be presented at the meeting via experiments in yeast and mammalian cells. .

Y3150C A possible role for eIF5A post-translational modification in yeast Ty1 retrotransposition. *Alexis Morrissey*, Jill Keeney. Juniata College, Huntingdon, PA.

Retrotransposons are genetic elements capable of forming a virus-like particle after translation and inserting their sequence into other parts of the genome. This insertion can result in mutations, remove mutations, or even alter the overall length of the genome. Retrotransposons are found in all eukaryotic organisms, including humans. It has been hypothesized that transposons help to create genetic variation and may have a role in aging. Ty1, the most frequently found retrotransposon in S*accharomyces cerevisiae,* provides a model for studying retrotransposition mechanisms in yeast. We observed an increase in the retrotransposition of Ty1 when the gene *FMS1* was overexpressed. *FMS1* is an enzyme that catalyzes the formation of spermidine, a molecule used for the post-translational modification of the elongation factor eIF5A. This elongation factor has been shown to play an important role in the efficient translation of polyproline motifs, specifically those containing three or more prolines in a row. We hypothesize that the connection between *FMS1* and Ty1 transposition is due to the presence of polyproline motifs in Ty1. Using Ty sequences from UniProt and a constructed Java program, we were able to analyze all classes of Ty retrotransposons (1-5). We found that Ty1 retrotransposons have the highest number of polyproline motifs with an average of 2.3±0.7, the second highest being the Ty2 class with an average of 1±0. Our study is specifically looking at Ty1-H3 due to its extensive use in genetic screenings. Ty1-H3 has a total of three polyproline motifs in its protein sequence. Using another constructed Java program, we were able to analyze a fasta file from the Saccharomyces Genome Database containing the yeast proteome for the number of polyproline motifs in each individual protein. We found that <1% of proteins contained three or more polyproline motifs, showing that Ty1-H3 was unique when compared to the whole proteome. Additionally, we created a gene ontology map of the genes with three or more polyproline motifs using the BiNGO extension in Cytoscape. Viral gene ontology terms had notably low p-values (10^{-5}), showing the overrepresentation of this group of proteins. Current and future experiments are aimed at determining whether specific polyproline motifs within the Ty1-H3 sequence impact transposition rates.

Y3151A High-copy number gene expression in different *Saccharomyces cerevisiae* strains reveals the impact of natural variation in wild yeast. *D. Robinson*, A. Gasch. University of Wisconsin-Madison, Madison, WI.

Organisms need to have the ability to respond to external environmental changes and stresses in order to thrive in nature. *Saccharomyces cerevisiae* has the ability to respond to stresses through the environmental stress response (ESR), where the expression of stress defense genes is induced and the expression of genes involved in growth is reduced. Most of the current work examining stress-activated gene expression is done using laboratory strains of yeast. However, gene functions can vary in different genetic backgrounds, which is why it is important to explore the effects of natural variation. In this project, we transformed several different natural isolates of yeast have with a molecular barcoded yeast open reading frame (MoBY-ORF 2.0) high copy number plasmid library. These transformed wild strains were grown in the presence of various stresses (ethanol, salt, or DTT) to identify which high-copy number genes increase or decrease fitness during periods of stress. Of particular interest are high-copy number genes that have different effects on fitness in different wild isolates versus genes that produce common effects across many wild strains. Examination of the effects of gene amplification in natural yeast isolates could provide insight to the genetic diversity of the stress response and how natural variation relates to gene function.

Y3152B Investigation of the genetic basis of hybrid vigor in yeast. *N. Sampaio*, J. L. Argueso. Colorado State University, Fort Collins, CO.

Highly heterozygous organisms often display enhanced phenotypic manifestations, a phenomenon known as hybrid vigor. Despite the economic importance of hybrid vigor, the genetic mechanisms that promote these superior phenotypes are still unknown. The genomic complexity typically observed in crop plants and livestock often hinders the investigation of the specific role of heterozygosity in the superior phenotype of the hybrid progeny. Thus, this type of analysis would be greatly facilitated by the use of a tractable model organism, such as the

yeast *Saccharomyces cerevisiae*. The natural hybrid diploid yeast strain JAY270 is widely adopted in sugarcane-based bioethanol production. Our group has determined that heterozygous alleles are present in about 60% of JAY270's genome, suggesting that its robust growth and high fermentative performance may be associated with hybrid vigor. In this study, we are establishing JAY270 as a model for investigating the mechanisms through which heterozygosity may promote fitness. We are developing an approach to identify individual heteroalleles in the JAY270 genome that contribute to hybrid vigor in this strain. The genomes of 56 haploid derivatives of JAY270 (14 full tetrads) were sequenced. The haploids were then intercrossed to create a systematic collection of inbred diploids, containing varying known fractions of the original heterozygosity present in JAY270. The whole-genome information from all the parental haploids provided precise genome-wide maps of where each inbred diploid is still heterozygous and where they are homozygous for either parental allele. The relative fitness of 78 of such inbred diploids was assessed using a high throughput flow cytometry-based growth competition assay against the fully heterozygous JAY270 parent strain. In addition, the inbred diploid collection was challenged with various growth stress conditions (high temperature, salt, DNA damage, etc.). Alignment of the genomic of heterozygosity maps and correlation to high or low fitness in the inbred diploids will allow us to identify genomic regions where allele-dependent contributors to hybrid vigor reside. We will present the results of the phenotypic characterization of the inbred diploid collection, and will discuss progress in the mapping of specific loci in the genome associated with hybrid vigor. The characterization of these heteroalleles will shed new light on the genetic basis of this complex process, contributing discoveries that could have important practical implications for human health, agriculture, biotechnology, as well as for genome sciences.

Y3153C Deciphering mutational signatures of DNA repair deficiencies and cisplatin in yeast. *R. Segovia Ugarte*[1,2], Y. Shen[3], S. Jones[1,3], P. Stirling[1,2]. 1) Depart. of Medical Genetics, Univ. of British Columbia, Vancouver, Canada; 2) Terry Fox Laboratory, BCCA, Vancouver, Canada; 3) Canada's Michael Smith Genome Sciences Centre, BCCA, Vancouver, Canada.

Introduction: Maintenance of genome integrity is critical to the cell, however exogenous and endogenous stresses menace the integrity of the genome. Overwhelming a cell's DNA repair capacity can expose the cell to the accumulation of mutations and, in humans, predispose to cancer development. Understanding the consequences of defective DNA repair pathways and their association with specific mutational processes in tumor genome sequences is difficult to achieve. A powerful method to study the effect of defects in DNA repair mechanisms is the extraction of mutational signatures from whole-genome sequencing of model organisms carrying defined genetic alterations or exposed to mutagens. We hypothesized that mutation accumulation in *S. cerevisiae* caused by deletions of *RAD1, MUS81,* or *SGS1* genes, coupled with exposure to cisplatin will result in specific mutational profiles that can be used to inform repair mechanism and potentially mutation signatures in cancer.

Methods: We sequenced whole genomes of 104 populations of diploid *S. cerevisiae* that were WT or carried homozygous deletions of *RAD1, MUS81,* or *SGS1*. For each genetic background 12 parallel lines were propagated for 1000 generations through single-cell bottlenecks or exposed for 3 hours to 100 uM cisplatin. Genomic DNA was isolated from single clones for whole-genome sequencing.

Results and conclusions: We identified 985 SNVs, 123 indels, 107 CNVs, and 36 aneuploidies. Rad1-deficient genomes exposed to cisplatin were characterized by an increase in single nucleotide substitutions at C/G base pairs. C to N mutations were defined by a GpCpN sequence context, which indicates that the surrounding sequence influences the base to be inserted on the opposite strand. Moreover, these genomes featured dinucleotide substitutions, particularly CpT to TpA. This data reflects the chemistry of cisplatin and indicates Rad1/XPF critically protects the cell against platinum hypermutation. Sgs1-deficient genomes propagated for 1000 generations revealed CNV events with the majority of breakpoints mapped to transposable element loci and other genetic features with high transcriptional frequency. Overall the data indicates the role of Sgs1/BLM in maintaining genomic regions difficult to replicate like retroelements. Together these data define new mutation signatures for DNA repair deficient cells whose mechanism are now under investigation.

Y3154A The yeast mating pathway as a model for complex trait genetics. *Stephanie Zimmerman*[1], Michael Dorrity[1], Josh Cuperus[1], Christine Queitsch[1], Stanley Fields[1,2]. 1) Department of Genome Sciences, University of Washington, Seattle, WA; 2) Howard Hughes Medical Institute, University of Washington, Seattle, WA.

Genome-wide association studies have identified many variants associated with complex traits, but in general these variants explain only a small fraction of the estimated heritability of the trait. Several hypotheses have been proposed to explain this "missing heritability." Complex traits could be caused by rare undiscovered variants with relatively large effect sizes, by the additive action of many individually small-effect variants, or by significant gene-by-gene or gene-by-environment interactions that modify otherwise small-effect variants. We are using the yeast mating pathway as a model complex trait to experimentally assess the relative impact of additive and epistatic genetic variation. Yeast mating is controlled by a well-characterized pheromone-responsive MAP kinase pathway. We used a technique called deep mutational scanning to profile the effect on mating of thousands of variants in three mating pathway genes: *STE5* (scaffold protein), *STE7* (MAP kinase kinase) and *STE12* (transcription factor). We transformed yeast null for one of these genes with a library of ~100,000 plasmids, each carrying a variant of the gene. We mated the transformants, selected for diploids, and sequenced the population of variants before and after mating by high-throughput sequencing. Mutations that impair gene function are depleted in the population after mating, while mutations that allow a wild-type level of mating are enriched. From these experiments, we identified variants in all three genes with the full spectrum of effect sizes, from null to wild-type. In addition, we tested the mating ability of the same population of variants in the presence of an Hsp90 inhibitor and at high temperature. Hsp90 is a chaperone protein that buffers the effects of mutations in many genes. From these data, we will identify variants that are sensitive to a known genetic modifier and the environment (high temperature), and determine the prevalence of buffered genetic variation in these genes. Finally, we identified ~600 small-effect variants in each gene, and in future experiments we will combine these small-effect variants in two mating pathway genes at a time. This experiment will allow us to assess simultaneously the degree of epistasis between tens of thousands of variants in both physically interacting and non-interacting proteins.

Y3155B Global analysis of genes and metabolites influencing chronological lifespan. *Haley Albright*[1], Daniel Smith[1], John Rodgers[1], Rick White[2], John Hartman[1]. 1) University of Alabama at Birmingham, Birmingham, Alabama; 2) University of British Columbia, Vancouver, Canada.

We are using phenomic analysis of the *S. cerevisiae* yeast gene deletion strain (YGDS) library to systematically investigate genes, pathways, and environmental factors that influence aging, using the chronological lifespan (CLS) model of aging for post-mitotic cells. Phenomic analysis consists of quantitative high-throughput cell array phenotyping (Q-HTCP) of the YGDS, which yields growth curve parameters associated with every gene that are used to estimate their contribution to CLS. The *met17-Δ0* or *MET17* allele status can influence CLS, and methionine restriction is known to extend lifespan in higher eukaryotes. The genomic collection of deletion strains libraries exists for both genetic backgrounds and we recently completed genome-wide CLS analysis using Q-HTCP for both libraries. Growth curve parameters, from Q-HTCP analysis, were plotted for each gene deletion strain against the parameters for the reference (background) strain. CLS phenotypes were then assigned based on the shift in growth curve parameters for the deletion strains with respect to the reference strain. We identified 1,379 long-lived strains and 277 short-lived strains out of 5,664 total strains in the *met17-Δ0* deletion library. In the *MET17* deletion library, we identified 1,285 long-lived and 367 short-lived strains out of 5,464 total. In depth analysis of these results is ongoing to confirm CLS phenotypes assigned from preliminary data and to gain insight about effects of methionine pathway interactions on CLS.

To further investigate the *met17-Δ0* effect on CLS, metabolite profiling is being used to gain additional insight about possible physiological correlates. Preliminary analysis reveled 234 metabolites with significant 3-term (time, media, genetic background) interactions. When only two-terms are considered, time and media or genetic background, we identified 335 and 157 differentially expressed metabolites, respectively. We are developing a method using isotopic labeling to predict chemical formulas for the observed metabolite masses, which will aid the effort to integrate data from the genome-wide CLS screens and metabolite profiling experiments. The ultimate goal is to understand how genetic and metabolic pathways are connected with respect to influencing cellular aging, to better explain how mitochondrial function, nutrient sensing, calorie restriction and other phenomena constitute what appear to be aging mechanisms conserved broadly across eukaryotic evolution.

Y3157A Homology curation at SGD: budding yeast as a model for eukaryotic biology. *Stacia R. Engel*, Robert S. Nash, Edith D. Wong, J. Michael Cherry, The SGD Project. Stanford University, Palo Alto, CA.

The foundation for much of our understanding of basic cellular biology has been learned from the budding yeast *Saccharomyces cerevisiae*. Studies with yeast have also provided powerful insights into human genetic diseases and the cellular pathways in which they are involved. Here we present an update on new developments at the *Saccharomyces* Genome Database (SGD; http://www.yeastgenome.org/), the premier community resource for budding yeast. We are expanding the scope of SGD to include high quality manually curated information regarding functional complementation between yeast and human homologs. This new information is provided in meaningful ways allowing data mining and discovery by integrating these data into this encyclopedic online resource. In addition to introducing our presentation of these newly curated data we will highlight other new developments, such as written summaries about yeast genes and their mutant phenotypes, their human homolog disease associations, and presentation of the yeast/human ortholog set. We also associate sequence changes with variations in cellular phenotypes and protein function. SGD maintains these different datatypes, and distributes them to the scientific community via the web and file transfer. These expanded efforts are part of our continuing mission to educate students, enable bench researchers and facilitate scientific discovery. This work is supported by a grant from the NHGRI (U41 HG001315).

Y3158B Systematic identification of human/yeast complementation pairs to create a platform for testing tumor-specific variants. *A. Hamza*, E. Tammpere, M. Kofoed, C. Keong, J. Chiang, G. Giaever, C. Nislow, P. Hieter. University of British Columbia, Vancouver, BC, CA.

While the pace of discovery of somatic mutations in tumor genomes has rapidly accelerated, deciphering the functional impact of these variants has become rate-limiting. Furthermore, linking somatic variants to specific cancer hallmarks, such as chromosome instability (CIN), is a major challenge in the cancer field. The budding yeast, *Saccharomyces cerevisiae*, has been utilized to define cellular pathways and catalog a comprehensive list of yeast genes required for the maintenance of chromosome stability (yeast CIN genes). Human orthologs of these yeast genes are candidate CIN genes whose tumor-specific variants may contribute to chromosome instability and tumorigenesis. By 'humanizing' a yeast strain using cross-species complementation, yeast can facilitate direct screening of these somatic mutations with the dual benefit that the variants are characterized in the context of the human gene and screened rapidly in a model eukaryote. Here, we outline an experimental approach to identify a list of human genes that can replace their yeast orthologs and complement a loss-of-function phenotype. We report the screening of essential and non-essential yeast CIN deletion mutants for complementation by their human counterparts. Replaceability was scored by examining rescue of growth defects caused by deletion of the essential yeast gene or by assaying for rescue of drug sensitivities for non-essential yeast genes. The resultant list of human gene/ yeast mutant complementation pairs has been used to test the functional consequences of cancer somatic mutations directly in yeast, while also providing a list of complementing genes as a resource to the field.

Y3159C Anticancer ruthenium complex KP1019 induces metabolic retooling in *Saccharomyces cerevisiae*. *Pamela Hanson*[1], Laura Stultz[1], Sarah Sharman[1], Avery Newcomb[1], James Mobley[2]. 1) Birmingham-Southern College, Birmingham, AL; 2) University of Alabama at Birmingham, Birmingham, AL.

In early clinical trials the anticancer ruthenium complex KP1019 (*trans*-[tetrachlorobis(1*H*-indazole)ruthenate(III)]) stabilized disease in five of six evaluable patients and displayed no dose-limiting toxicity, suggesting that this drug may be a viable alternative to platinum-based chemotherapeutics. Although KP1019 has been shown to damage DNA in both cancer cell lines and the budding yeast *Saccharomyces cerevisiae*, this ruthenium complex's mechanism of action remains unclear. Alternative explanations for KP1019's toxicity stem from the drug's ability to induce oxidative stress and to bind to diverse small molecules and proteins within cancer cells. Here we use an unbiased proteomic

approach to characterize *S. cerevisiae*'s response to KP1019. Bioinformatic analysis of induced proteins confirmed that KP1019 activates DNA damage and oxidative stress response pathways. Clustering and analysis of both induced and repressed proteins revealed complementary metabolic retooling. Observed changes in protein expression suggest increased synthesis of methionine and the antioxidant glutathione. Moreover, yeast treated with KP1019 increased expression of evolutionarily conserved enzymes of the pentose phosphate pathway (PPP), including the glucose-6-phosphate dehydrogenase Zwf1, the 6-phosphogluconolactonase Sol4, and the transketolase Tkl2. KP1019-dependent induction of the rate-limiting PPP enzyme Zwf1 was verified by flow cytometry of Zwf1-GFP yeast treated with varying concentrations of the drug. Culturing yeast in media containing the PPP substrate xylose both induced Zwf1-GFP and increased resistance to KP1019, suggesting that upregulation of the PPP contributes to drug tolerance. This conclusion was further supported by KP1019-dependent repression of the PPP regulator Pho13. Deletion of the phosphatase-encoding gene *PHO13* has previously been shown to upregulate the PPP, and here we show that *pho13Δ* yeast are more resistant to KP1019 than an isogenic wild-type control. Since glutathione and the PPP have well-established roles in cellular adaptation to oxidative stress, these data suggest that oxidative stress contributes to KP1019 toxicity and that metabolic re-tooling is an important contributor to cellular tolerance of this drug. Ultimately, metabolic biomarkers may prove suitable for use in predicting patient responses to this promising chemotherapeutic.

Y3160A Yeast RNA-binding protein Ssd1 and human FUS, implicated in ALS, share localization and features in yeast. *C. Kurischko*[1,2], G. Petsko[1], J. Broach[2]. 1) Weill Cornell Medicine, New York, NY; 2) College of Medicine, Penn State Univ., Hershey, PA.

Ssd1 is a nucleo-cytoplasmic shuttling protein with multiple roles in the life of its target mRNAs, from transcription and maturation to polarized localization, translation and decay. Interaction between Ssd1 and its target mRNAs initiates during transcription in the nucleus and, depending on the extent of its phosphorylation by the RAM kinase Cbk1, results in subsequent localization of the mRNAs either to the bud for translation or to stress granules (SG) and P-bodies (PB) for mRNA storage or decay. Ssd1 lacking a nuclear localization signal ($Ssd1^{(417\text{-}427)11A}$), and thus excluded from nuclear entry, forms large cytoplasmic aggregates that colocalize with Hsp104 and Sis1, markers of "Insoluble Protein Deposition" sites (IPOD). Overexpression of $Ssd1^{(417\text{-}427)11A}$ enhances the mild toxicity of wild type Ssd1. Activation of a separate cryptic NLS within Ssd1 or deletion of its prion-like domain suppresses IPOD formation of $Ssd1^{(417\text{-}427)11A}$. Thus, nuclear shuttling of Ssd1 is required to prevent prion-like, non-productive aggregate formation.

The human RNA-binding protein Fused in Sarcoma (FUS) is implicated in ALS, a fatal neurodegenerative disease. While not a homolog of Ssd1, FUS shares domain structures with Ssd1 and, when expressed in yeast, localizes in the same pattern as Ssd1, including formation of IPODs upon overexpression. Accordingly, our studies on Ssd1 provide a framework for understanding the molecular basis of FUS structure. We use these observations to obtain insight into processes in which FUS may be involved in mammalian cells, particularly neurons. This could help to understand the underlying causes of neurodegenerative diseases, in which mutated RNA-binding proteins play a central role.

Y3161B Unbiased functional annotation of compound libraries using yeast chemical genomics. *Sheena C. Li*[1], Scott W. Simpkins[2], Justin Nelson[2], Jeff S. Piotrowski[3], Hamid Safizadeh[2], Karen Kubo[4], Nikko Torres[6], Grant Brown[6], Yoshikazu Ohya[4], Ming-Wei Wang[5], Minoru Yoshida[1], Chad L. Myers[2], Charles M. Boone[1,5]. 1) RIKEN Center for Sustainable Resource Science, Wako, Saitama, JP; 2) Computer Science and Engineering, University of Minnesota, MN, USA; 3) Yumanity Therapeutics, Cambridge, MA, USA; 4) University of Tokyo, Kashiwa, Chiba, Japan; 5) The National Center for Drug Screening, Shanghai, China; 6) Donnelly Centre for Cellular and Biomolecular Research, University of Toronto, ON, Canada.

To elucidate the molecular mechanism of bioactive compounds in an unbiased manner, we used chemical genomics in budding yeast to systematically screen very large and diverse compound collections, with the goal of linking unknown compounds to their cellular targets.

A high-throughput pipeline using various barcoded yeast mutant collections in a drug hypersensitive genetic background was developed. We designed a diagnostic pool of 310 non-essential deletion mutants to minimize the amount of compound required for screening and to maximize dynamic range. In addition, we constructed temperature-sensitive and heterozygous diploid mutant collections for all essential genes to obtain higher resolution chemical genetic information. Chemical genetic signatures for thousands of compounds were efficiently and rapidly generated via highly multiplexed next generation sequencing of DNA barcodes in the mutant strains. Targets were predicted using two strategies: For the diagnostic non-essential pool and the essential temperature-sensitive collection, we compared chemical genetic signatures with genome-wide synthetic lethal data to predict compound functionality at the biological process level. We complemented this analysis with a drug-induced haploinsufficiency approach to determine precise gene targets using the heterozygous diploid collection.

We applied this system to screen eight diverse compound libraries. Using the diagnostic pool approach, we assessed over 18,000 compounds for target specificity, and identified high confidence target process predictions for ~2000 unique compounds. Functional diversity of different compound libraries was characterized by mapping predicted targets onto the global yeast genetic interaction network. We then used the set of compounds with high confidence predictions for further chemical genetic screens with temperature-sensitive and heterozygous diploid collections for essential genes. Validation studies have confirmed predictions at the biological process level and also at the specific gene target level, including compounds with multiple predicted modes of action.

Y3162C Identifying novel small molecules for improved antifungal drug treatment. *Kevin F. Murphy*[1], Dina Wassaf[2], Angela N. Koehler[3], Martha L. Bulyk[4,5]. 1) Department of Biology and Health Sciences, McNeese State University, Lake Charles, LA; 2) Broad Institute, Cambridge, MA; 3) Koch Institute for Integrated Cancer Research at MIT, Cambridge, MA; 4) Division of Genetics, Department of Medicine, Brigham and Women's Hospital and Harvard Medical School, Boston, MA; 5) Department of Pathology, Brigham and Women's Hospital and Harvard Medical School, Boston, MA.

The letter preceding the number is the community. A, B, C after the number is presentation time.
W – *C. elegans*, C – Ciliates, D – Drosophila, M – Mouse, P – PEQG, Y – Yeast, Z – Zebrafish

Invasive fungal infections (IFIs) are associated with high rates of morbidity and mortality and pose a serious health concern for severely immunocompromised patients. Fungal resistance to current drug therapies is largely due to the transcriptional upregulation of membrane associated efflux pumps, which expel from the cell a myriad of structurally diverse molecules, including antifungal drugs, thus severely reducing their effectiveness against these pathogens. Additionally, resistance can arise by overexpression of drug target genes within the ergosterol biosynthesis pathway. The fungal-specific zinc cluster (Zn_2Cys_6) family of transcription factors (TFs) is primarily responsible for the upregulation of these efflux pumps and ergosterol biosynthesis enzymes and thereby mediating pleiotropic drug resistance (PDR) in yeast. Thus, these TFs offer an attractive and rational target for the development of new antifungal drugs.

In pursuit of this goal, we aimed to identify small molecules capable of inhibiting the DNA-binding ability of Zn_2Cys_6 TFs regulating PDR in yeast. An initial screen utilizing small molecule microarrays (SMM) was employed to identify compounds capable of binding the DNA-binding domain of Zn_2Cys_6 TF Pdr1p from *Candida glabrata*. In our initial SMM-based screen, a library of 15,000 different compounds was examined and yielded 76 unique compounds that specifically bound to Pdr1p. Small-molecule "hit" compounds consisted of several different structural classes, including 44 azetidine and sulfonamide-based compounds. Future studies will examine the potential of these lead compounds for development of improved antifungal drugs in the treatment of IFIs.

Y3163A Discovering Novel Inhibitors of Deubiquitinases *in vivo*: Strategies using Budding Yeast. *N. Pascoe*[1], Michael Costanzo[2], Sachdev Sidhu[1,2,3], Charles Boone[1,2,3]. 1) Department of Molecular Genetics, University of Toronto, Toronto, Ontario, Canada; 2) Terrance Donnelly Center for Cellular and Biomolecular Research, University of Toronto, Toronto Ontario, Canada; 3) Banting and Best Department of Medical Research, University of Toronto, Toronto, Ontario, Canada.

Deubiquitinating enzymes (DUBs) are key regulators of the ubiquitin pathway that catalyze the removal of ubiquitin from target substrates. Hence, these enzymes affect a wide variety of cellular processes by influencing the localization, stability and function of their targets. Importantly, inhibition of DUB activity has emerged as a promising therapeutic strategy to treat several diseases including various cancers & Alzheimer's. Despite this, a paucity of specific and potent inhibitors aimed at DUB pathways has hindered attempts to exploit them for therapeutic benefit.

To address this issue, we developed a strategy using ubiquitin (Ub) as a scaffold to engineer specific & potent DUB inhibitors, called Ub variants (UbV). We have generated massively diverse and combinatorial libraries, comprising >$7x10^{10}$ unique UbVs. Using phage-display we have screened our library to identify inhibitors of ~8/95 human DUBs. Although effective, an inability to purify many disease-relevant DUBs has limited the applicability of our *in vitro* screening system. Thus, we have developed a method based on the yeast two-hybrid (Y2H) system to detect UbV-DUB interactions *in vivo*. In a pilot study using a smaller library consisting of 10^5 unique UbVs, we identified UbVs that bind the DUB USP2 specifically, thus validating our approach. We are currently adapting this system to allow for the high-throughput screening of massive UbV libraries *in vivo*. In conjunction with established *in vitro* screening methods, we will use our *in vivo* screening platform to discover novel inhibitors against the full panel of human DUBs. Together, this work will make seminal contributions towards furthering our understanding of DUB function and alleviate a formidable bottleneck that obstructs the development of more powerful therapeutics aimed at the ubiquitin system.

Y3164B Modulation of yeast chronological lifespan by TOR signaling in the context of replication stress. *Sean M. Santos*[1], Chandler Stisher[1], Darryl Outlaw[1], Haley Albright[1], John Rodgers[1], Rick White[2], John L. Hartman, IV[1]. 1) University of Alabama at Birmingham, Birmingham, AL; 2) University of British Columbia, Vancouver, Canada.

The target of rapamycin (TOR) pathway is an evolutionarily conserved nutrient sensing pathway that is repressed during caloric restriction, which is associated with extension of lifespan in yeast and higher eukaryotes. Replication stress, induced by inhibition of RNR and depletion of dNTP pools, shortens yeast chronological lifespan (CLS), which can be alleviated by glucose restriction or deletion of *SCH9* (a downstream mediator of TOR signaling). To further investigate possible interaction between TOR signaling and replication stress, we used quantitative high throughput cell array phenotyping (Q-HTCP) of the complete collection of the yeast knockout and knockdown (YKO/KD) strains to identify genes that influence the TOR and RNR pathways. Based on this analysis and evidence from the literature, we hypothesize vacuolar acidification is a process where the TOR and RNR pathways functionally intersect, and suspect this gives rise to genetic interaction that could be important in determination of lifespan. There are several observations we are trying to relate with one another: Vacuolar acidification in glucose depleted media is optimal at pH = 7, and neutral pH is also associated with increased CLS, but whether increased vacuolar function affects, or is affected by, CLS is unclear. Interestingly, HU treatment can be associated with higher pH over time. We developed a high throughput pH assay to better associate pH and CLS across the deletion collection and CLS. Although hydroxyurea-treated yeast exhibit decreased viability initially, we found CLS to be paradoxically greater with increasing age, depending on MET17/met17-Δ0 status. Deletion of *MET17* extends CLS, yet it shortens late CLS after HU treatment whereas having a functional *MET17* increases lifespan after HU treatment. Based on these findings, we are investigating a model whereby perturbation of RNR activity damages/kills some cells in S-phase, but may also induce inhibition of TOR signaling that facilitates G1/G0 arrest of surviving cells, which ultimately promotes extension of CLS.

Y3165C Using Yeast to Screen for Drugs for the Treatment of Inherited Parkinson's Disease. *K. A. Strynatka*[1], P. P. Poon[1], C. R. McMaster[1,2]. 1) Department of Biochemistry and Molecular Biology, Dalhousie University, Halifax, Nova Scotia, CA; 2) Department of Pharmacology, Dalhousie University, Halifax, Nova Scotia, CA.

Current therapies for Parkinson's disease (PD) are limited to managing signs and symptoms; there is no treatment available that prevents or significantly delays progression of the disease. Approximately 10% of PD cases are inherited forms of the disease. Specifically, mutations in the

kinase LRRK2 have been shown to cause PD. Previous studies showed that LRRK2 kinase activity is regulated by ArfGAP1 and that decreasing ArfGAP1 expression results in a decrease in toxicity of mutant LRRK2. Therefore, small molecules that inhibit ArfGAP1 may be a potential therapy for PD. To that end, we screened for compounds that inhibit human ArfGAP1. We expressed human ArfGAP1 under the control of a titratable promoter in the yeast *Saccharomyces cerevisiae*. Expression of human ArfGAP1 in yeast proved toxic to the cell. This toxic phenotype was exploited to perform a high-throughput small-molecule screen for compounds that inhibit ArfGAP1, which would restore viability to the cell. A panel of small molecules was screened, including 5000 pharmacologically active compounds and off-patent FDA-approved drugs, and 100 000 novel small molecules. Six compounds were identified as potential inhibitors of ArfGAP1, all with a similar core structure suggestive of inhibition of the same target. These are being tested for their capacity to inhibit ArfGAP1 directly, and reduce LRRK2 toxicity *in vitro* and *in vivo*.

Y3166A Discovery of plant extracts that greatly delay yeast aging by targeting certain signaling pathways and modulating lipid metabolism. *V. Titorenko*, V. Lutchman, V. Svistkova, P. Dakik, A. Arlia-Ciommo, Y. Medkour. Concordia Univ., Montreal, Canada.

The yeast *Saccharomyces cerevisiae* has been successfully used as a model organism for discovering signaling pathways and chemical compounds that modulate cellular aging, define organismal lifespan, and influence organismal fitness not only in yeast but also in various multicellular eukaryotes. Using a robust quantitative assay for measuring yeast chronological lifespan, we screened a library of plant extracts (PEs) for extracts that can extend longevity of chronologically aging yeast. We identified six PEs (i.e. PE4, PE5, PE6, PE8, PE12 and PE21) whose longevity-extending efficiencies greatly exceed those of currently known anti-aging compounds, such as resveratrol, rapamycin, spermidine, caffeine, and metformin. Our analysis of the Gompertz mortality function revealed that each of these six PEs is a geroprotector which delays the onset and reduces the rate of yeast chronological aging by eliciting a hormetic stress response. Our genetic, biochemical, and mass spectrometry-based lipidomic analyses uncovered the following mechanisms by which these PEs delay yeast chronological aging by targeting certain signaling pathways and modulating lipid metabolism: 1) PE4 attenuates the inhibiting effect of the pro-aging TOR (target of rapamycin) signaling pathway on the anti-aging AMP-activated protein kinase (AMPK/Snf1), increases the intracellular concentration of phosphatidic acid (PA), and decreases the concentration of triacylglycerols (TAG; the major form of energy storage in yeast and other eukaryotes); 2) PE5 mitigates the pro-aging cAMP/PKA (cAMP/protein kinase A) signaling pathway, elevates the concentration of PA, reduces the concentration of TAG, and rises the concentration of cardiolipin (CL; a phospholipid synthesized only within mitochondria in yeast and other eukaryotes); 3) PE6 targets currently unknown pro- and/or anti-aging pathways of longevity regulation, increases the concentration of PA and phospholipids other than CL, and decreases the concentration of TAG; 4) PE8 weakens the inhibiting effect of cAMP/PKA signaling pathway on the anti-aging AMPK/Snf1, enlarges the concentrations of PA, CL and all other phospholipids, and lessens the concentration of TAG; 5) PE12 activates the anti-aging protein kinase Rim15 (on which the pro-aging TORC1 and cAMP/PKA signaling pathways converge), and decreases the concentrations of CL and TAG; and 6) PE21 attenuates the pro-aging protein kinase Sch9 (which is activated by the pro-aging TOR and Pkh1/2 signaling pathways), elevates the concentrations of PA and phospholipids other than CL, and reduces the concentration of TAG.

Y3167B Identification of a Natural Product that Disrupts the Fungal Cell Wall Integrity Pathway by Targeting Hsp90. *Siddharth Tripathi*, Qin Feng, Melissa Jacob, Xing-Cong Li, Alice Clark, Ameeta Agarwal. University of Mississippi, University, MS.

Due to the narrow activity spectrum of echinocandin antifungal drugs and the emergence of drug resistance, new therapies are needed to potentiate echinocandins such as caspofungin (CAS). We have identified a sesquiterpene quinone compound named puupehenone (PUUP) that enhances CAS activity in CAS-resistant strains of *Candida albicans* and also in the inherently CAS-insensitive pathogen *Cryptococcus neoformans*. To investigate PUUP's CAS-potentiating mechanism, we conducted a transcript profiling study in the model yeast *Saccharomyces cerevisiae*. Cells were exposed to solvent, PUUP, CAS, and PUUP + CAS, and the RNA extracted was subjected to RNA-Seq analysis. To further investigate PUUP's mechanism of action, a fitness profiling study was performed to monitor the sensitivity of whole-genome yeast deletion mutants to PUUP. To confirm PUUP's effect on Hsp90, a well-established promoter-reporter assay system was used that monitors the rat glucocorticoid receptor (GR), an Hsp90 client protein. An additional client protein, Mpk1 was monitored by Western analysis. Transcript profiling with CAS + PUUP revealed that genes in the cell wall integrity pathway (CWIP) that were strongly induced by CAS alone were not induced by CAS + PUUP; thus, PUUP synergizes with CAS by preventing cell wall repair through the CWIP. Further studies revealed that PUUP targets Hsp90. The transcript profile of PUUP was similar to that of the Hsp90 inhibitor celastrol. Genes encoding chaperones and co-chaperones involved in heat shock response were strongly induced by PUUP. To confirm that PUUP targets Hsp90, we monitored the rat GR, an Hsp90 client protein, and observed that PUUP inhibited GR induction in a concentration-dependent manner. Our fitness profiling experiment identified 28 mutants with increased hypersensitivity to PUUP. Of these, 14 mutants have been previously reported to show hypersensitivity to other Hsp90 inhibitors. We also showed that the overexpression of four different Hsp90-related proteins resulted in significant resistance to PUUP. We also observed that PUUP inhibited the activation of the yeast protein Mpk1, another Hsp90 client protein. Because Mpk1 is a critical kinase in the CWIP pathway, this result demonstrates that PUUP inhibits the CWIP by disrupting Mpk1 activity. In summary, we have identified a natural product that disrupts the fungal cell wall integrity pathway by targeting Hsp90.

Y3168C *Saccharomyces* Genome Database: How to find what you are looking for. *Gail Binkley*, Travis K. Sheppard, Kalpana Karra, Pedro H. R. de Assis, Shuai Weng, Edith D. Wong, J. Michael Cherry, The SGD Project. Stanford University, Department of Genetics, Palo Alto, CA.

Everyone has experienced the frustration of being unable to find the information you want on a website because you have only a vague idea what you are looking for and don't know what search term(s) to use. Here we present several ways to find and explore data at SGD using new search methods. "Exact match" searches are effective and fast when it is already known that specific information exists. However, "exact match" searches do not allow browsing of all available data, and can sometimes obscure the context of the returned results, making it difficult

to discover new connections and uncover novel relationships. To address these issues, the *Saccharomyces* Genome Database (SGD; http://www.yeastgenome.org) has recently implemented several new ways to find and explore yeast data. SGD's "exact match" search has been replaced with a new faceted search based on Elasticsearch, which allows filtering in multiple categories and speeds query performance. Faceted navigation provides immediate feedback and easy navigation so users can quickly refine and refocus their search based on the returned results. Other recent website additions include SGD's Variant Viewer, which employs a combination of data filters and visualizations to display novel sequence variants for open reading frames within a reference panel of 12 widely used *S. cerevisiae* genomes. Datasets are also now easier to find in SGD. Over 225 expression and other high-throughput datasets can now be filtered by curated metadata and displayed using JBrowse, a JavaScript- and HTLM5-based genome browser. This work is supported by a grant from the NHGRI (U41 HG001315).

Y3169A Classifying Microscopy Images with Deep Learning. *Oren Kraus*[1,3], Jimmy Ba[1], Charles Boone[2,3,4], Brenda Andrews[2,3,4], Brendan Frey[1,3,4]. 1) Electrical and Computer Engineering, University of Toronto, Toronto, Ontario, Canada; 2) Department of Molecular Genetics, University of Toronto, Ontario, Canada; 3) Donnelly Centre for Cellular and Biomolecular Research, University of Toronto, Toronto, Ontario, Canada; 4) Banting and Best Department of Medical Research, University of Toronto, Canada.

High content screening (HCS) technologies have enabled large scale imaging experiments for studying cell biology and for drug screening. These systems produce hundreds of thousands of microscopy images per day and their utility depends on automated image analysis. Recently, deep learning approaches that learn feature representations directly from pixel intensity values have dominated object recognition challenges. The recognition tasks in these challenges typically consist of a single centered object and existing models are not directly applicable to microscopy datasets. Here we develop an approach that combines deep convolutional neural networks (CNNs) with multiple instance learning (MIL) in order to classify and segment microscopy images using only whole image level annotations. MIL is a framework that enables supervised learning models to train on datasets that only have labels for sets of data points.

We introduce a new neural network architecture that uses MIL to simultaneously classify and segment microscopy images with populations of cells. Building supervised classifiers based on segmented single cells remains time consuming and difficult for researchers. Combining CNNs with MIL enables training classifiers with whole microscopy images, even images containing mixed populations, using whole image level labels. We base our approach on the similarity between the aggregation function used in MIL and pooling layers used in CNNs. We show that training end-to-end MIL CNNs outperforms several previous methods on both mammalian and yeast datasets without requiring any segmentation steps. On a publically available drug screen of MFC-7 breast cancer cells (Broad Bioimage Benchmark Collection, image set BBBC021v1) we achieve 97% accuracy at predicting the mechanism of action of different treatments. On a yeast protein localization dataset, we achieve 96% accuracy at predicting localization for proteins that localize to a single subcellular compartment.

Y3170B Saccharomyces Genome Database: Outreach and online training services. *Kevin A. MacPherson*, Kyla S. Dalusag, Olivia Lang, Sage T. Hellerstedt, Stacia R. Engel, J. Michael Cherry, The SGD Project. Stanford University, Stanford, CA.

The Saccharomyces Genome Database (SGD; http://www.yeastgenome.org) is the leading community resource for the budding yeast S. cerevisiae. SGD provides high-quality, manually curated information on the yeast genome and offers a wide variety of tools and features that have made it an indispensable resource for many researchers. However, lack of familiarity with the SGD interface and tools can present a significant barrier to new users and prevent current users from making full use of these resources. To inform our user community about new developments at SGD, improve familiarity with SGD features and tools, and increase public awareness of the importance of yeast to biological and biomedical research, SGD has engaged in a variety of online training services and outreach efforts. Here we present the SGD Webinar Series, a series of interactive webcasts aimed at demonstrating the SGD website and the value of yeast as a model organism, and the SGD YouTube channel, which currently provides over 30 useful help videos and quick tutorials (http://www.youtube.com/SaccharomycesGenomeDatabase). We will continue to develop these services to provide outreach to students and scientists on the significance and beauty of biology, and facilitate greater use and understanding of the resources made available by SGD. This work is supported by a grant from the NHGRI (U41 HG001315).

Y3171C A Morphology Profile Pipeline for Genome-wide Screens in *Saccharomyces cerevisiae*. *N. Sahin*[1,2], E. Styles[1,2], A. Verster[3], Q. Morris[1,2], B. Andrews[1,2]. 1) University of Toronto, Toronto, Canada; 2) The Donnelly Centre, Toronto, Canada; 3) University of Washington, Seattle, Washington.

Synthetic genetic array (SGA) analysis coupled with high-content screening (HCS) in *Saccharomyces cerevisiae* has provided a wealth of information on functional genomics. Until recently, genetic interactions in SGA analysis have used colony size as a proxy for cellular fitness. Although this metric has proven to be robust, higher resolution phenotypes such as subcellular morphology cannot be assessed. Since there are various perturbations in *S. cerevisiae* in which mutant growth is normal despite morphological abnormalities within subcellular compartments, it would be of great benefit to the yeast community to complement existing colony size data with cell morphology data. Using the SGA-HCS approach, the Boone and Andrews Labs at the University of Toronto, have produced an image-based dataset of subcellular mutant phenotypes in the context of genome-wide perturbations. To analyze these massive datasets of 900,000 images, our labs have developed a machine learning strategy that has been able to successfully detect and classify about half of all the observed and published phenotypes. However, it is challenging to computationally analyze and model a total number of 100 classifiers for all the expected phenotypes with the existing pipeline. Thus, to complete the analysis, I expanded on optimizing the existing pipeline by constructing classifiers for missing phenotypes, and score the genes generating aberrant morphologies. So far, the optimized pipeline can classify a substantial amount of the mutant phenotypes as

preliminary. In order to validate genes resulting with similar mutant phenotypes, I generated the morphology profiles for each gene and performed a preliminary trend analysis on morphology profiles by comparing them to the genetic interaction network to identify genes with high fitness but aberrant morphology. By obtaining complete profiles, we can construct a new informative network for our collections to use alongside the fitness scores from genetic interaction networks. Comparing the biological interpretations of the genetic interaction network and the morphology profiles can reveal further information on biological enrichment and functional analysis that might have been overlooked by the multiplicative model of the fitness measurements alone. This analysis will allow for the identification of connections between discrete biological processes, the prediction of novel gene function, and the generation of a clearer understanding of basic eukaryotic cell biology.

Y3172A HSF-type transcription factors regulate morphogenesis in the human fungal pathogen *Candida albicans*. *V. Basso*, S. Znaidi, V. Lagage, C. d'Enfert, S. Bachellier-Bassi. Institut Pasteur, Paris, FR.

Candida albicans is a diploid fungus, commensal of most healthy individuals, but also one of the most prevalent human fungal pathogens. *C. albicans* has the ability to switch between a unicellular yeast form and filamentous forms (pseudohyphae or hyphae). This switch is important for virulence: yeast cells contribute to the colonization of mucosa and dissemination into the bloodstream, hyphal forms are important for crossing barriers, invasion of tissues and formation of biofilms. The transition is triggered by environmental cues (temperature, pH, CO_2 …) and leads to the activation of hypha specific genes (HSGs). The transcriptional network behind the morphogenetic switch is very complex. Here, we report the role of the HSF-type transcription factors (TF) Sfl1, Sfl2 and Skn7.

Sfl1 and Sfl2 antagonistically regulate the morphogenetic switch: Sfl1 has a negative role, whereas Sfl2 enhances filamentation in response to temperature. On the other hand, deletion of *SKN7* is impairing hyphal growth on solid inducing media, while its overexpression (OE) triggers filamentation in the absence of hypha-inducing cues. We performed genome-wide ChIP analyses to uncover chromosomal regions bound by these TFs, and transcript profiling to identify genes regulated differentially upon their OE. Sfl1 and Sfl2, through divergent motifs, positively and negatively regulate a common set of targets, including repressors of hyphal growth (*SSN6*, *NRG1*, *RFG1*), activators of hyphal development (*UME6*, *BRG1*, *TEC1*) and yeast specific genes (*RME1*, *RHD1*, *YWP1*). Additionally, Sfl2 binds to and turns on the expression of many HSGs. We have shown that Sfl1 and Sfl2 interact with other regulators of morphogenesis (*EFG1*, *UME6*, *TEC1*, *BRG1*). Strikingly, Efg1 binds to targets of Sfl1 and Sfl2, and immunoprecipitates with either proteins. Furthermore, Skn7 binds to regions on the *C. albicans* genome, that also exhibit binding sites for other morphogenesis regulators, including Efg1, Ndt80, Sfl1 and Sfl2. Epistatic studies led us to a model where Skn7 modulate genes involved in hyphal growth, including several key factors of filamentation (*DEF1*, *UME6*, *CPH1* and *CZF1*). Moreover, because Skn7 is also necessary for adaptation of *C. albicans* to oxidative stress, we measured intracellular Reactive Oxygen Species (ROS) levels upon induction of filamentous growth, and showed that Skn7 limits the increase of ROS associated with filamentation on solid media. In conclusion, we propose a regulatory network where *C. albicans* HSF-type regulators Sfl1, Sfl2 and Skn7 coordinate morphogenesis. This model fits in the wider and more complex morphogenetic transcriptional circuitry, implicating intimate functional interactions with other regulators.

Y3173B Dissecting *CTF4*'s role in DNA replication through a synthetic dosage lethality genetic interaction network. *E. Bryant*[1], R. J. D. Reid[2], R. Rothstein[2]. 1) Columbia University, New York, NY; 2) Columbia University Medical Center, New York, NY.

Chromosome Transmission Fidelity 4 (*CTF4*) plays an important role in maintaining replication fork stability by forming a homo-trimer that tethers the lagging strand DNA polymerase α (Polα) to the CMG helicase (Cdc45/Mcm2-7/GINS). *CTF4* genetically interacts with more than 70 different genes annotated to DNA replication, recombination or repair. *CTF4* deletion is especially sensitive to defects in DNA replication fork progression, and joint molecule resolution. Interestingly, *CTF4* overexpression ($CTF4^{OE}$) and *ctf4Δ* share many genetic interactions, and both of these genetic perturbations result in increased Rad52-YFP foci formation (an indicator of DNA repair centers), and increased a-faker frequency (an indicator of genomic instability). However, $CTF4^{OE}$ is uniquely sensitive to loss of 9-1-1 DNA damage checkpoint signaling (Rad17/Mec3/Ddc1), whereas *ctf4Δ* is uniquely sensitive to loss of the fork protection complex (Mrc1/Tof1/Csm3). Interestingly, mutation of the conserved Ctf4 binding site on either the CMG helicase, or Polα, fails to recapitulate *CTF4*'s genetic interactions, which suggests that *CTF4*'s role at the replication fork may be more complex than the current CMG-Ctf4-Polα tethering model. To elucidate *CTF4*'s other possible roles in DNA replication and repair we have overexpressed an array of *CTF4* mutations in combination with a small collection of 200 *CTF4* genetic interaction network mutants. To improve the resolution of these experiments we have developed a system to measure arrayed colony growth over time in various sensitizing conditions. By comparing the resulting genetic interaction profiles of *CTF4* mutations we have begun to separate the function of *CTF4* domains. Preliminary results suggest that Ctf4 may physically interact with several other replication factors, and may also have a role in signaling the DNA replication checkpoint. These experiments highlight the utility of overexpression as a genetic perturbation that can complement a synthetic lethal network analysis to reveal separation of function and biological insight.

Y3174C Using genetic interactions to dissect the cellular response to cisplatin. *E. Bryant*[1], R. J. D. Reid[2], I. Sunjevaric[2], A. Canat[2], E. Rizk[1], L. Crowley[2], R. Rothstein[2]. 1) Columbia University, New York, NY; 2) Columbia University Medical Center, New York, NY.

Cisplatin, a frontline chemotherapy agent for ovarian, breast and lung cancers, is in a class of DNA damaging agents that lead to replication fork stalling and collapse, apoptosis and cell death. Cisplatin sensitivity is affected by a number of DNA repair pathways including nucleotide excision repair, the multiple pathways that collectively make up post replication repair, and processes that specifically incise DNA interstrand crosslinks. Although much is known about the genetic control of these DNA repair mechanisms, the interactions and overlapping functions of these pathways are not completely understood. Furthermore, efforts to catalog the genes affecting cellular sensitivity to cisplatin has either defined a few, well studied genes, or has defined a large number of genes that may only be peripherally involved in sensitivity. We therefore reexamined datasets of cisplatin sensitivity in *Saccharomyces cerevisiae* to define a gene set for systematic double mutant analysis. The CLIK

(Cutoff Linked to Interaction Knowledge) algorithm expanded the number of likely cisplatin sensitive genes in individual high throughput studies, and additional genes were identified via growth curve analysis of gene disruption libraries using multiple cisplatin concentrations. Pilot experiments have highlighted the importance of tailoring the drug concentration for each query mutation to optimally identify epistatic versus synergistic genetic interactions. Analysis of a translesion polymerase, Polζ (Rev3-Rev7) and the homologous recombination related SHU complex (Shu1-Shu2-Psy3-Csm2) demonstrates that optimal detection of synergy between these complexes requires a low concentration of cisplatin. On the other hand, detection of epistasis among Polζ complex members requires a much lower concentration of cisplatin than the SHU complex. Interestingly, synergy was detected between SHU complex members Shu1 and Shu2, which suggests a possible redundancy between these two factors. These experiments lay the foundation for a high-fidelity cisplatin dependent epistasis map that will be used to disambiguate relationships between the many gene and pathways involved in managing DNA crosslinks.

Y3175A Functional interaction network of the conserved NDR kinase Orb6. *C. Chen*, I. Nuñez, D. Wiley, G. D'Urso, F. Verde. University of Miami, Miami, FL.

NDR (nuclear dbf2-related) kinases represent an evolutionarily conserved subclass of AGC kinases. NDR kinases control cell morphogenesis in different organisms, ranging from yeast to mammals. Our lab previously found that Orb6 kinase regulates cell polarity by spatial control of Cdc42 GTPase (*Das et al., Curr Biol. 2009* and *Das et al., Science. 2012*).

Our lab used an ordered fission yeast gene deletion library to perform a genome-wide screen for gene functions that display synthetic lethality or suppression interactions with an analog-sensitive Orb6 kinase mutant (orb6-as2). The potential modulators of the NDR kinase Orb6 were further refined by using computational, microscopy, mass spectrometry, and 2-hybrid analysis approaches. By this genome-wide screen, our lab has identified two genetically separable functions of Orb6, cell morphogenesis and P-body formation, mediated by two direct substrates, Gef1 (*Das et al., MBoC 2015*) and Sts5 (*Nuñez et al., under review*), respectively. Also, two other novel functions of Orb6 kinase identified from the same screens are (1) stress response and (2) autophagy regulation. Current work is focusing on the intermediate role of Orb6 kinase in connecting diverse extracellular stress signals and autophagy modulation.

Y3176B Measuring protein-protein assemblies with a molecular ruler in living cells. *A. Chrétien*, I. Gagnon-Arsenault, C. Lamothe, A. K. Dubé, A. Dion-Côté, C. R. Landry. Laval University, Quebec, Quebec, CA.

Protein quaternary assembly is central to many cellular processes. Several methods have been developed to detect and measure protein-protein interactions in model organisms. Some methods allow the identification of members of complexes but do not provide information on their spatial relationships. Other methods allow the detection of binary and direct interactions between physically associated proteins but do not provide direct insights into the larger quaternary architecture. In order to dissect the organisation of protein complexes both in terms of composition and spatial relationship among the subunits, it would be optimal to have a method that combines the two approaches described above. Here, we show that Protein-fragment Complementation Assay (PCA) can meet these needs. PCA is based on the association of complementary reporter fragments that reveals protein-protein interactions upon complementation. The reporter fragments are fused to the proteins of interest by a short peptide linker that determines the maximal physical distance at which fragments can complement. We found that we can modulate the length of the linkers to detect novel protein-protein interactions on a proteome-wide scale and more distant protein-protein interactions within large protein complexes. Overall, we show that this modified PCA can act as a molecular ruler for measuring protein-protein interactions and proximity in living cells.

Y3177C A network of correlated phenotypes contributes to pleiotropy in yeast single-cell morphology. *Kerry Geiler-Samerotte*[1], Austin Taylor[2], Chelsea Ramjeawan[2], Harris Lazaris[2], Annalise Paaby[3], Mark Siegal[2]. 1) Stanford University, Palo Alto, CA; 2) New York University, NY, NY; 3) Georgia Institute of Technology, Atlanta, Georgia.

Introduction: Pleiotropy (i.e. when one gene influences multiple phenotypes) is central to major problems in biology. It contributes to difficulty predicting the fitness effect of mutations and also can lead to development of drugs with undesired side effects. Despite the importance of pleiotropy, there are fundamental disagreements about its prevalence, mechanism, and definition. One particularly intractable issue when studying pleiotropy has been the definition of independent phenotypes, especially in high-dimensional studies in which many related and potentially correlated phenotypes are surveyed. To achieve a fuller understanding of pleiotropy's extent and molecular underpinnings, we develop a novel approach to describe the network of correlated phenotypes that contribute to pleiotropy in yeast single-cell morphology.

Methods: We used high-throughput microscopy and image analysis to quantify hundreds of single-cell morphological features in 374 lines from a cross between two genetically diverged yeast strains. We identified 12 pleiotropic loci (QTL) that each contribute to variation in 2 or more traits. But does each QTL influence multiple unrelated traits or does some fraction of pleiotropy result because genetic effects cascade through a network of phenotypes that exert influence on one another? To determine which phenotypes are correlated in the absence of genetic effects, we leveraged hundreds of single cell measurements from within each of the 374 clonal yeast populations. We used advanced statistical methods that tease apart phenotypic correlations present within strains from those that arise between strains.

Results: *Within* clonal yeast populations, over 80% of phenotype pairs are more correlated than after random permutation, suggesting that a connected network of phenotypes underlies cell morphology. Correlations increase *between* genetically distinct yeast strains for ~35% of phenotype pairs, suggesting that genetic effects contribute additional pleiotropy beyond what would occur due to the underlying structure of the phenotype-phenotype network. As for QTL effects, pleiotropy is achieved through indirect effects cascading through the phenotype-phenotype network roughly 2/3 of the time. A QTL on chromosome 13 is the exception. It affects the most phenotypes in this study (43);

experiments confirm these effects are due to a single gene, CYK2. Our analysis suggests that CYK2 influences 22 phenotypes directly and 21 indirectly through the phenotype-phenotype network. In sum, our novel approach can enhance knowledge of (1) phenotype-phenotype networks, and (2) the extent and nature of pleiotropy. Both types of knowledge further our understanding of the relationship between genotype and phenotype.

Y3178A Expanding the yeast genetic toolkit: developing a pooled assay for genetic interactions. *M. Jaffe*[1], J. D. Smith[1], R. P. St. Onge[1], G. Sherlock[1], S. F. Levy[2]. 1) Stanford Univ., Stanford, CA; 2) Stony Brook Univ., Stony Brook, NY.

Two genes are said to interact when the fitness of a double mutant deviates from the multiplicative fitness of the two corresponding single mutants. *Saccharomyces cerevisiae* is an ideal system to measure these interactions quantitatively and in high-throughput because of its compact genome and its wealth of genetic tools. In order to improve current screening methods, we developed, and present here, two iterations of a pooled assay of genetic interactions named iSeq. These pool-based methods increase the scalability of measurements across growth conditions, because, in contrast to prior methods, a pool of mutants must only be generated once before assaying multiple conditions. In the first iteration of iSeq, we generated ~400 mutant strains representing 45 possible single or double gene deletions, with multiple strains per genotype. Starting with deletions from the yeast deletion collection, we introduced a novel DNA double-barcoding technology to each double deletion strain to use as its molecular identifier during pooled growth. iSeq fitness and interaction score measurements for each strain in the pool were reproducible across three independent cultures for three growth conditions tested (ρ = 0.91-0.99). These measurements also correlated with an independent OD-based growth assay (ρ = 0.68-0.69). However, we observed high variability in estimates across strains carrying the same gene deletion(s), but unique barcodes (N = 4—16 per genotype). Whole-genome sequencing of 73 double mutant and parental strains revealed segregating and *de novo* mutations were common and accumulated over the two rounds of mating and selection used to generate strains. This genetic variability likely led to the observed fitness differences, and observations of aneuploidy were often associated with lower fitness estimates. To reduce this genetic variability for future screens, we are developing a second iteration of iSeq that relies on an inducible CRISPR/Cas9 gene repression system to generate single and double mutants without any mating or selection steps. As validation, we are using this system to perform a preliminary screen for genetic interactions of 9x459 genes, also in a pooled format. Next, we aim to apply this technology to discover novel gene functions and further understand the topology of the genetic interaction network and its dynamics across growth conditions.

Y3179B A Gene Network Model of Cellular Aging and its Applications. *H. Qin*. Spelman College, Atlanta, GA.

Why would a genotypically homogeneous population of cells live to different ages? We propose a mathematical model of cellular aging based on gene interaction network. This model network is made of only non-aging components, and interactions among genes are inherently stochastic. Death of a cell occurs in the model when an essential gene loses all of its interactions. The key characteristic of aging, the exponential increase of mortality rate over time, can arise from this model network with non-aging components. Hence, cellular aging is an emergent property of this model network. The model predicts that the rate of aging, defined by the Gompertz coefficient, is proportional to the number of active interactions per gene and that stochastic heterogeneity is an important factor in shaping the dynamics of the aging process. Hence, the Gompertz parameter is a proxy of network robustness. Preliminary studies on how aging is influenced by power-law configuration, synthetic lethal interaction, and allelic interactions can be modeled. A general framework to study network aging as a quantitative trait has also been found, and the results has implication on missing heritability.

Y3180C Identifying novel factors underlying stress resistance in the pathogenic yeast *Candida glabrata*. *L. C. Ames*[1], A. Cook[1], G. Cromie[2], E. Jeffery[2], A. Dudley[2], K. Haynes[1]. 1) University of Exeter, Exeter, Devon, GB; 2) Pacific Northwest Diabetes Research Institute, Seattle, W.A., USA.

The ability of pathogens, such as *Candida* species, to adapt to stresses encountered in the host environment is vital for survival and the establishment of infection. In particular, they must mount a robust response to reactive oxygen species in the phagosome. Despite highly homologous stress response pathways, *C. glabrata* is intrinsically more stress resistant than its close relative, the non-pathogenic yeast *Saccharomyces cerevisiae*. To identify novel factors contributing to such stress resistance in *C. glabrata*, mutants were generated for characterisation using two methods. Firstly, 96 *C. glabrata* mutants resistant to tBOOH, an oxidative stress-inducing chemical, were produced by EMS mutagenesis. Secondly, *in vitro* passaging experiments were used to force evolution of tBOOH- and H_2O_2-resistant phenotypes in *C. glabrata*.

Characterisation of EMS mutants revealed that the acquisition tBOOH resistance was accompanied by a fitness trade-off where mutants either became less fit under non-stress conditions or became more susceptible to another type of stress. Most notably, 70 % of tBOOH-resistant EMS mutants became more susceptible to the antifungal drug fluconazole. Surprisingly, *C. glabrata* strains passaged in H_2O_2 showed no fitness defect under stress-free conditions. The virulence of stress-resistant mutants is currently being investigated in a newly-optimised *Galleria mellonella* model of *C. glabrata* infection.

Whole genome sequencing was performed on all stress-resistant EMS and passaged mutants, revealing over 4000 polymorphism calls and 14 aneuploidy events. Recreation of selected polymorphisms into the parental strain background, by site directed mutagenesis, will identify mutations contributing to stress resistance in *C. glabrata*.

Y3181A Perseverance and hetero-resistance, the epigenetic ability of a subpopulation of pathogenic yeasts to survive and grow in drug, contributes to the appearance of drug resistance via different genomic mechanisms. *Judith Berman*[1], Alex Rosenberg[1], Noa Wirthheimer[1],

Esther Weindling[1], Noam Shahar[1], Alon Dahan[1], Aleeza Gerstein[1,2], Inbal Hecht[1], Ronen BenAmi[1]. 1) Tel Aviv University, Ramat Aviv, IL; 2) University of Minnesota, Mpls, MN.

The terms resistance, tolerance, persistence and heteroresistance have been used very generally in the current literature to describe the ability of an organism to survive and grow in the presence of an antimicrobial drug. Furthermore, clinical failures are often due to non-resistant (susceptible) strains that persist *in vivo* and likely seed recurrent infections. Resistance is heritable, with growth of ~ all cells in the population up to a given drug concentration. Studies in bacteria have started to define tolerance and persistence much more precisely. By contrast, the use of these terms remains very vague in studies of fungal pathogens such as Candida species. Within different *Candida albicans* isolates we detect different degrees of subpopulations of cells that grow slowly but consistently in drug. We developed and adapted assays to measure this subpopulation and, based on its growth dynamics, we call it "Perseverance". Perseverence is slow, steady growth in drug that is seen for >10% of the population, is concentration-independent, but time-dependent. Furthermore, and in contrast to tolerance in bacteria, these subpopulations exhibit shorter lag times in drug relative to sensitive strains. The degree to which high perseverence is connected to the rate of appearance of frank resistance will be presented.

By contrast, in *Candida glabrata,* we find that clinical strains exhibit hetero-resistance, in which very small subpopulations (<0.1%) survive in drug. Hetero-resistance is also heritable and it allows subpopulations of a clinical strain to persist in the host. Furthermore, genomic analysis indicates that different subpopulations exhibit different gene expression profiles.

Importantly, clinical assays currently measure neither persistance or hetero-resistance and thus these properties of strains are not considered in clinical decisions. We suggest that perseverance and hetero-resistance are important parameters contributing to the evolution of resistance and thus the persistence and recurrence of and infection, which must be considered in the clinical setting. .

Y3182B Structure/Function Analysis of the Hif1 Histone Chaperone in *Saccharomyces cerevisiae*. *Nora S. Dannah*, Jeffrey Fillingham. Ryerson University , Toronto, ON, CA.

Understanding how eukaryotic cells assemble their chromatin is a significant research subject in part because several human pathologies including cancer are associated with defects in chromatin assembly. Transporting of newly synthesized histones H3/H4 occurs in a stepwise fashion and is regulated by a variety of protein factors including histone chaperons. In the budding yeast *Saccharomyces cerevisiae*, the Hif1 protein is an evolutionarily conserved H3/H4-specific histone chaperone and a member of the nuclear Hat1 complex that catalyzes the deposition-related acetylation of newly synthesized histones H4. Hif1 as well as its human homolog NASP have been implicated in an array of chromatin-related processes including histone H3/H4 transport, chromatin assembly, DNA repair and telomeric silencing. In this study, we elucidate structural and functional aspects of Hif1. Through targeted mutational analysis, we demonstrate that the acidic region of yeast Hif1 which interrupts the TPR2 is essential for physical interaction with the Hat1-complex. We also demonstrate that Hif1 requires its C-terminal basic patch for nuclear localization. Furthermore, we provide evidence for the involvement of Hif1 in regulation of histone metabolism by showing that cells lacking *HIF1* are both hypersensitive to histone H3 overexpression. Finally, we describe a functional link with a transcriptional regulatory protein Spt2 possibly linking Hif1 to transcription-associated chromatin reassembly. Taken together, our results provide novel mechanistic insights into Hif1 functions and establish it as a key player in various chromatin-associated processes.

Y3183C Hsp90 perturbations affect genome integrity in *Candida albicans*. *K. Dong*[1*], A. Forche[2], S. Milne[1], L. Alaalm[1], J. Berman[3], S. Diezmann[1]. 1) University of Bath, Bath, GB; 2) Bowdoin College, Brunswick, USA; 3) Tel Aviv University, Tel Aviv, Israel.

One of the leading fungal pathogen of humans, *Candida albicans*, does not appear to engage in canonical sexual recombination. This is surprising given *C. albicans*' proclivity to effectively switch between being a commensal and an opportunistic pathogen and rapidly evolve drug resistances. The molecular chaperone Hsp90, a central regulator of protein homeostasis, governs virulence and drug resistance in *C. albicans*. This then raises the question: how does an 'obligate' diploid generate genetic variations? Here, we address this question by identifying if and how Hsp90 regulates genome integrity in *C. albicans*. Forche *et al*. (2011) demonstrated that different stresses elevated Loss-of-Heterozygosity (LoH) rates across the *C. albicans* genome. We hypothesize that alterations of either Hsp90 level or function result in LoH and thus promote genome diversification. In line with this hypothesis, we conducted fluctuation assay showing that multiple modes of Hsp90 perturbation increase LoH rate, suggesting that Hsp90 is required for the maintenance of a diploid, heterozygous genome but compromised Hsp90 function promotes the genomic rearrangement. More importantly, our SNP-RFLP analyses revealed that the types of LoH events are contingent on the mechanisms used to abrogate Hsp90 function. Pharmacological inhibition increased frequency of local recombination events such as gene conversion or break-induced recombination, whereas high temperature stress caused whole-chromosome homozygosis. This very novel observation suggests that *C. albicans* may utilize distinct forms of LoH to deal with disparate stressors. This concept is supported by our *in vitro* fungal drug resistance test which showing a biological relevant pattern. Hence, our work provides evidence that Hsp90 governing LoH rates and types is one of principles underpinning *C. albicans* genome plasticity, which aids in the generation of mosaic karyotypes with novel phenotypes. This indicates that Hsp90 affects a pathogen's virulence through genome modulations, eventually imparting both theoretical and clinic novel knowledge.

Y3184A Rme1 controls chlamydospore formation in the human pathogenic yeast *Candida albicans*. *A. Hernandez Cervantes*[1,2], S. Znaidi[1,2], V. Basso[1,2], F. Vincent[3], F. Dalle[3], M. E. Bougnoux[1,2], N. Sertour[1,2], S. Bachellier-Bassi[1,2], C. d'Enfert[1,2]. 1) Pasteur Institute, Paris, France; 2) INRA, USC2019, F-75015 Paris, France; 3) UMR 1347, Agroécologie AgroSup/INRA/uB 21065 Dijon, France.

Candida albicans is the most common pathogenic fungus of humans, normally found as a harmless commensal colonizing skin and mucosal epithelium of 30-70% healthy individuals. This yeast causes systemic infections in the absence of a proper immune system, by gaining access to

the bloodstream mainly through translocation across the intestinal barrier. A characteristic of this organism is its capability to react to variations of the environment by growing either as unicellular yeasts or in filamentous forms (true hyphae or pseudohyphae). The ability to switch between yeast and filaments is a virulence trait, important for the success of *C. albicans* both as a commensal and as a pathogen. Upon specific growth conditions, *C. albicans* can produce chlamydospores, which are large refractile cells with thick cell walls, often forming on suspensor cells attached to hyphae, neither dead nor long-term survival cells, likely to be a specialized and alternative form of growth of *C. albicans.* Previous studies in our laboratory suggested that the *C. albicans* transcription factor Rme1, ortholog of *Saccharomyces cerevisiae* regulator of meiosis, was involved in the yeast-hyphae transition. In order to determine the *in vivo* function of Rme1, we performed ChIP-on-chip and transcriptomics analyses on an inducible overexpression (OE) strain, showing that Rme1 binds to 724 promoter regions, upregulating 622 genes and downregulating 357 genes. The most strongly upregulated genes are markers of chlamydospore development. To explore the role of Rme1 in this morphogenetic program, *RME1* OE and knock-out (KO) mutant strains were grown on Potato Carrot Bile Agar medium under microaerophilic conditions in the dark for 7 days. The OE strain formed masses of chlamydospores as compared to the SC5314 wild type strain, whereas the KO strain was unable to form these structures. Moreover, we observed that the expression levels of *RME1* and its targets were increased in *C. albicans* clinical isolates that overproduced chlamydospores. In addition, we observed that *RME1* OE could restore the defect in chlamydospore development displayed by the *hog1*ΔΔ and *efg1*ΔΔ KO strains, suggesting that Rme1 acts as a bottleneck regulator in the chlamydospore formation pathway. Taken together, our results confirm that the function of ScRme1 in the regulation of meiosis has been lost in *C. albicans* and has been rewired towards the control of a complex regulatory network necessary for chlamydospore formation.

Y3185B Isolation and characterization of a manganese tolerant mutant of *Saccharomyces cerevisiae*. *M. Kishida*, T. A. Do, T. Sakai, Y. Tanaka, H. Iwata, M. Furuta. Osaka Prefecture Univ, Sakai, Osaka, JP.

Manganese contamination in water is one of the most serious problems in southeastern countries, including Vietnam, because the large amount of manganese provides the toxicity in cells. Bioremediation using microorganisms is expected to be a useful technique to remove manganese from contaminated water. We employed to breed a yeast strain having the manganese accumulation ability from the brewing yeast *Saccharomyces cerevisiae*. In this study, we indicate that the growth and the manganese accumulation of the isolated yeast strains cultured in manganese ion-containing media.

Strains used were *S. cerevisiae* BY4741 as the wild-type strain and some manganese accumulation mutants bred from BY4741. The used medium was YPD (2% glucose, 1% yeast extract, and 1% peptone) with various concentrations of manganese chloride, if necessary. To test the toxicity of the manganese ion, the growth profile of yeast was determined by turbidity measurement at 660 nm. The concentration of manganese in cells was measured by atomic absorption spectrophotometry after the digestion of yeast cells by the concentrated nitric acid and then an adequate dilution.

Manganese accumulation mutants were screened from the growing strains on YPD with the high concentration of manganese ion (Mn^{2+}) in which BY4741 could not grow, as follows. Overnight cultured BY4741 was inoculated into YPD containing various concentrations of Mn^{2+} and tested for the growth. BY4741 could not grow more than 10 mM of Mn^{2+}. To select manganese tolerant mutants, BY4741 was inoculated in YPD with 10 mM of Mn^{2+} and cultured at 30°C for 24 h. Survival strains were inoculated again in the same medium and cultured at the same condition. Then, the variants that accumulated more manganese than BY4741 were isolated by repeat screening of survivors in 10mM Mn^{2+}-containing YPD media. Finally, nine mutants which accumulated manganese were isolated and named IM1 to IM9. One variant showing the highest manganese accumulation, IM3, accumulated over 4-fold more manganese than its parent strain BY4741, and could grow under 25 mM Mn^{2+}. Effects of culture temperature and pH on manganese accumulation were analyzed in IM3. The maximum accumulation was shown at 30°C while the maximum growth was shown at 37°C. The manganese accumulation was recognized from pH 4.0-9.0 and was highest at pH 6.0. Interestingly, IM3 could grow a little at pH 9.0 when manganese was added to the culture media, while IM3 could not grow without manganese addition. This reason is unclear but it may show the possibility that Mn^{2+} uptake affects the intracellular pH in IM3. We try to analyze the effect of the other stress on manganese accumulation in IM3.

Y3186C Phylogenetic profiling for the elucidation of heme-iron acquisition in pathogenic yeasts. *D. Kornitzer*[1], S. Yaish[1], L. Nasser[1], Z. Weissman[1], G. Horev[2], H. Dvir[3]. 1) Faculty of Medicine, Technion-I.I.T., Haifa, IL; 2) Bioinformatics Knowledge Unit, Technion-I.I.T., Haifa, IL; 3) Technion Center for Structural Biology, Technion-I.I.T., Haifa, IL.

Iron acquisition represents a particular challenge for pathogenic microorganisms, because of the iron withholding mechanisms deployed by the host. Many microbial pathogens, including fungi such as *Candida albicans*, have therefore evolved mechanisms for extracting iron from hemoglobin, the largest iron store in the host, by removing the heme cofactor from the globins, and transferring it to the microbe's cytoplasm. Elucidation of this pathway in *C. albicans* by genetic means was however hampered by the fact that this organism is not suited for forward genetic screening, and that the pathway is absent from the model yeast *S. cerevisiae*. Screening of a *C. albicans* library introduced in yeast enabled the initial identification of a family of extracellular heme-binding proteins involved in heme-iron utilization. These proteins all include a CFEM sequence signature, consisting of 8 cysteines with conserved spacing. We solved the structure of the hemophore Csa2, revealing that the CFEM domain adopts a novel protein fold, held together by 4 disulfide bonds generated by the 8 conserved cysteines, and that it displays a unique heme-iron coordination mechanism. CFEM proteins involved in heme utilization are either secreted, or are GPI-anchored at different locations in the cell envelope. These proteins all are able to capture heme from hemoglobin and to transfer it between themselves, consistent with a pathway in which heme is extracted from hemoglobin outside the cell and is then transferred from one CFEM protein to the next until it reaches the plasma membrane - whereupon it is endocytosed by a mechanism previously shown to involve the ESCRT pathway. A missing link was the putative transmembrane heme receptor that connects the extracellular CFEM network with the endocytic pathway. To identify candidates for such a receptor, we resorted to phylogenetic profiling: taking advantage of the hundreds of fungal genomes available, we

screened for genes jointly present with the CFEM heme transfer cascade genes across fungi. This enabled us to identify a new class of plasma membrane proteins that are essential for heme uptake. The hemoglobin-iron utilization pathway that emerges from these studies, which is distinct from bacterial systems, indicates that fungi have evolved a unique solution to the heme-iron acquisition problem. Phylogenetic profiling is shown here to represent a powerful method for unraveling cellular pathways in organisms that are recalcitrant to conventional genetic screening.

Y3187A Assembling whole eukaryotic genomes from mixed microbial communities using Hi-C. *I. Liachko*[1], J. Burton[1], L. Sycuro[2], A. Wiser[2], D. Fredricks[2], J. Shendure[1], M. Dunham[1]. 1) University of Washington, Seattle, WA; 2) Fred Hutchinson Cancer Research Center, Seattle, WA.

De novo assembly of whole genomes from next-generation sequencing is inhibited by the lack of contiguity information in short-read shotgun sequencing. This limitation also impedes metagenome assembly, since one cannot tell which sequences originate from the same species within a population. We have overcome these bottlenecks by adapting a chromosome conformation capture technique (Hi-C) for the deconvolution of metagenomes and the scaffolding of *de novo* assemblies of complex genomes.

In modeling the 3D structure of a genome, chromosome conformation capture techniques such as Hi-C are used to measure long-range interactions of DNA molecules in physical space. These tools employ crosslinking of chromatin in intact cells followed by intra-molecular ligation, joining DNA fragments that were physically nearby at the time of crosslink. Subsequent deep sequencing of these DNA junctions generates a genome-wide contact probability map that allows the 3D modeling of genomic conformation within a cell. The strong enrichment in Hi-C signal between genetically neighboring loci allows the scaffolding of entire chromosomes from fragmented draft assemblies. Hi-C signal also preserves the cellular origin of each DNA fragment and its interacting partner, allowing for deconvolution and assembly of multi-chromosome genomes from a mixed population of organisms.

We have used Hi-C to scaffold high-quality genomes of animals, plants, fungi, as well as prokaryotes and archaea from very fragmented *de novo* assemblies. We have also been able to use this data to annotate functional features of microbial genomes, such as centromeres in many fungal species including over a dozen yeasts. Additionally, we have applied our technology to diverse metagenomic populations such as craft beer, bacterial vaginosis infections, soil, and tree endophyte samples to discover and assemble the genomes of novel strains of known species as well as novel prokaryotes and eukaryotes. This method's ability to reconstruct multi-chromosome genomes has led to discovery of novel yeast hybrids directly from mixed communities.

The high quality of Hi-C-based assemblies allows the simultaneous assembly and scaffolding of numerous unculturable genomes, placement of plasmids within host genomes, and microbial strain deconvolution in a way not possible with other methods.

- Varoquaux N, Liachko I, Ay F, Burton JN, Shendure J, Dunham MJ, Vert JP, Noble WS. Accurate identification of centromere locations in yeast genomes using Hi-C. Nucleic Acids Res. 2015, Jun 23;43(11):5331-9.

Y3188B Phylogenetic and phenotypic characterization of yeasts from detritivorous beetles. *D. J. Wohlbach*, K. A. Mueller, K. Muirhead. Dickinson College, Carlisle, PA.

Detritivorous beetles of the temperate deciduous forest biome thrive in low-nutrient environments with an abundance of cellulosic material, and it is speculated that yeast endosymbionts aid in the metabolism of such materials within the gut of these beetles. To investigate the biodiversity of microbes in this niche, we isolated over 200 yeast strains from different beetles living in the Pennsylvania area. Isolates contained representatives from both Ascomycete and Basidiomycete fungi, including several putatively novel species. Phylogenetic analysis characterized the evolutionary relationship of isolated yeasts; physiological and morphological growth tests helped to characterize the phenotypes of novel species. Interestingly, we found that the majority of yeast endosymbionts were able to metabolize xylose, a five carbon 'woody sugar,' faster than glucose. This research contributes to the study of yeast biodiversity in a particular niche and future characterized strains could improve methods used for lignocellulosic biofuel production.

Y3189C Convergent evolution of phosphate- and thiamine-regulated phosphatases: The *PMU* gene family in *C. glabrata* is analogous to the *PHO5* gene family in *S. cerevisiae*. *D. D. Wykoff*, C. L. Iosue, N. F. Shaik, S. G. Leone, M. T. Peel, P. Toubia, A. Brower, J. Glowala. Villanova Univ, Villanova, PA.

Acid phosphatase genes are present in most Ascomycete genomes and are related based on sequence similarity to the *PHO5* gene in *Saccharomyces cerevisiae*. In *S. cerevisiae, PHO5* is regulated by inorganic phosphate starvation, and *PHO3* (a *PHO5* homolog) is regulated by thiamine starvation. *Candida glabrata* does not have *PHO5* homologs. Previously, we determined that *PHO5* was functionally replaced in *C. glabrata* with the *PMU2* gene, which is part of a three gene family tandemly duplicated on chromosome 11. Using RNA-seq, we now determine that *PMU3* is highly induced during thiamine starvation, that induction is dependent on the thiamine starvation regulators, *THI3* and *PDC2*, and that *PMU3* encodes a thiamine pyrophosphatase (TPPase). We determined that only Pmu3p (and not Pmu2p or Pmu1p) is a TPPase using a functional assay with thiamine pyrophosphate (TPP) as a sole source of thiamine that can only be accessed by TPPase activity. The RNA-seq data demonstrate that ten genes are highly induced during thiamine starvation and are *THI3* dependent in *C. glabrata*. Unlike *S. cerevisiae*, the regulator *THI3* is not induced during starvation, and additionally, *C. glabrata* does not have a *THI2* homolog. We have characterized the highly inducible thiamine-regulated promoters using promoter-YFP fusions and flow cytometry and identified a minimal region that confers thiamine regulation. We expect that this promoter region binds *Cg*Pdc2 during thiamine starvation. The induction of both phosphate- and thiamine-regulated genes require chromatin remodeling/modification complexes for full induction of gene expression because mutants in *Cgsnf2*Δ,

*Cggcn5*Δ, and *Cgasf1*Δ are aberrant in the regulation of phosphate- and thiamine-regulated promoters. We observe that *C. glabrata* has *de novo* sub-functionalized phosphatase expression into two tandem genes and because this system has analogous behaviors and characteristics to *PHO5* & *PHO3* in *S. cerevisiae*, there might be selective reasons for this sub-functionalized phosphatase architecture.

Y3190A Strategies to produce high levels of extracellular cAMP based on cAMP-PKA and purine synthesis pathway regulation in *Saccharomyces cerevisiae*. *S. Zou*[1], P. Ma[2]. 1) Tianjin University, Tianjin, Tianjin, CN; 2) Tianjin University, Tianjin, Tianjin, CN.

Strategies to produce high levels of extracellular cAMP based on cAMP-PKA and purine synthesis pathway regulation in *Saccharomyces cerevisiae*

Shaolan Zou, Pingsheng Ma.

School of Chemical Engineering and Technology, Tianjin University, Tianjin 300072, China

cAMP, an important compound involved in various biochemical reactions and a key second messenger, is widely used in animal food additives and pharmaceutical research. In yeast, cAMP concentration is tightly regulated because of the important role of the cAMP-PKA pathway in controlling a broad array of cellular processes. Up to now, lots of research has been focused on the cAMP-mediated regulatory pathway and the regulation of intracellular cAMP levels in *Saccharomyces cerevisiae*. In this study, the extracellular cAMP level and its regulation was investigated in detail and *Saccharomyces cerevisiae* was shown to be an excellent candidate for fermentative production of cAMP after manipulating the cAMP-PKA and purine synthesis pathways and optimizing the media. First, the cAMP dependent protein kinase (PKA)-encoding genes were deleted to remove the powerful feedback inhibition of PKA on cAMP synthesis and the lack of viability of *tpk*1 *tpk*2 *tpk*3 triple mutants was further suppressed by mutations such as *yak*1 or *msn*2/*msn*4. Second, the low-affinity cAMP phosphodiesterase Pde1 was inactivated to decrease the breakdown of cAMP. Third, Bas1p and Bas2p were fused and over-expressed by co-integrating into the genome to reinforce their cooperative interaction in purine synthesis pathway and thus the production of the cAMP precursors ADP and ATP. Bas1p is a Myb-related transcription factor. It acts together with the homeodomain-related Bas2p (Pho2p) to regulate purine and histidine biosynthesis genes in response to extracellular purine limitation. Fourth, the content of yeast extract and peptone in fermentation media were increased and the ratio of carbon to nitrogen source was optimized. As a result, the extracellular cAMP level could reach 6414.3 μmol/L.

Y3191B Integrating Post-Translational Modification Data into the *Saccharomyces* Genome Database. *Sage T. Hellerstedt*, Stacia R. Engel, Shuai Weng, J. Michael Cherry, The SGD Project. Stanford University, Stanford, CA.

After translation by a ribosome, a protein can undergo modifications known as post-translational modifications (PTMs). By the covalent addition or removal of various functional groups, PTMs increase the functional diversity of the proteome. At the *Saccharomyces* Genome Database (SGD; www.yeastgenome.org), we have been actively expanding our protein data to include manually curated post-translational modification information for the model organism *Saccharomyces cerevisiae.* Examples of PTM types we are currently curating from the literature include, but are not limited to: phosphorylation, acetylation, methylation, ubiquitination, and sumoylation. These data are displayed in the amino acid sequence section of SGD Protein pages as highlighted residues, including the protein modifier when available. Post-translational modification information is often critical to understanding mature protein function and regulation, thus we include the PTM data in SGD as part of our continuing mission to educate students, enable bench research, and facilitate scientific discovery. This work is supported by a grant from the NHGRI (U41 HG001315).

Y3192C Multi-omic analysis of yeast strains evolved for xylose fermentation reveals a new connection between sugar sensing and oxygen response. *Kevin S. Myers*, Nicholas M. Riley, Trey K. Sato, Joshua J. Coon, Audrey P. Gasch. Great Lakes Bioenergy Research Center, University of Wisconsin - Madison, Madison, WI.

Biofuels produced by microbes, including *Saccharomyces cerevisiae*, have promise as a non-petroleum based energy system. Biofuel production from agricultural waste, such as corn stover, would provide an important advance because it would not compete with food sources. However, corn stover contains high concentrations of xylose, which *S. cerevisiae* cannot naturally ferment, for reasons that are not understood. This defect renders nearly a third of the potential carbon in corn stover biomass unutilized. To address this, an engineered *S. cerevisiae* strain containing bacterial xylose isomerase was subjected to directed evolution for over 200 generations. Strain Y127 was evolved from a stress-tolerant wild yeast strain (Y22-3) for aerobic xylose fermentation; strain Y128 was further evolved from Y127 to ferment xylose anaerobically. Whole-genome sequencing identified responsible mutations in the evolved strains, but the physiological effect of these mutations remains unclear. To better understand the physiology of these strains, we performed genome-scale analyses to study differences in gene expression (RNA-seq), protein levels (label-free quantitative mass-spec proteomics), and phosphorylation abundance (mass-spec phosphoproteomics) on the parental strain and the two evolved strains, in the presence of glucose or xylose and under aerobic or anaerobic growth conditions. Remarkably, comparison of the mRNA and protein changes revealed a disconnect between mRNA and protein abundance in the unevolved strain growing anaerobically on xylose, and a defect in mounting the hypoxic response when cells are grown anaerobically on xylose. Over-expression of AZF1 significantly improved anaerobic xylose fermentation in the evolved Y128 strain, but only during anaerobic growth on xylose. Comparative analysis across the multi-omic datasets implicates downstream targets of Azf1 and upstream regulatory pathways that enable anaerobic xylose fermentation. These results present important new insights into how anaerobic xylose fermentation can be engineered in yeast and reveal new connections between sugar and oxygen responses.

Y3193A Quantitative phosphoproteomics identifies regulatory feedback between inositol polyphosphate signaling and yeast pseudohyphal growth. *Kaitlyn Norman*, Christian Shively, Anuj Kumar. University of Michigan, Ann Arbor, MI.

Inositol polyphosphates are important eukaryotic second messengers with diverse roles in chromatin remodeling, telomere maintenance, mRNA export, and regulation of the phosphate starvation response. Despite strong research interest, relatively little is known regarding the regulation of inositol polyphosphate signaling in yeast or metazoans. Through studies incorporating quantitative phosphoproteomic analysis of kinase signaling pathways required for yeast pseudohyphal growth, we report here an unexpected regulatory interrelationship between inositol polyphosphate signaling and the cellular response to nitrogen stress. *S. cerevisiae* exhibits a dramatic growth response to nitrogen limitation, characterized by the transition from a vegetative yeast-like form to a filamentous form with chains of elongated pseudohyphal cells. Pseudohyphal growth is regulated through signaling networks encompassing MAPK and Snf1p pathways. We find that kinase-dead mutants of Ste11p, Ste7p, Kss1p, and Snf1p exhibit differential phosphorylation of the inositol polyphosphate kinases Arg82p, Vip1, and Kcs1p. Homozygous mutants deleted for *IPK1*, *VIP1*, and *KCS1* display distinct pseudohyphal growth phenotypes under conditions of nitrogen limitation. Profiling of inositol polyphosphates upon growth in media with limited nitrogen reveals striking increases in the abundance of numerous inositol polyphosphate species, including IP_3, IP_7, and IP_8. Further, deletion mutants of the pseudohyphal growth MAPK *KSS1* and *SNF1* exhibit altered profiles of IP_7 isomers by HPLC analysis. In sum, we present data indicating regulatory control of inositol polyphosphates by Kss1p and Snf1p pathways, as well as results identifying regulatory control of pseudohyphal growth through inositol polyphosphate signaling. These findings are consistent with a role for inositol polyphosphate second messengers during the pseudohyphal growth transition, particularly with respect to downstream inositol polyphosphates and pyrophosphates that may function in a complex feedback control system with pseudohyphal growth regulators.

Y3194B Omics approaches for discovery of aging-delaying and anti-tumor compounds and defining mechanisms of their action. *V. Titorenko*, A. Leonov, A. Arlia-Ciommo, Y. Medkour, V. Svistkova. Concordia Univ, Montreal, PQ, CA.

Caloric restriction (CR) and dietary restriction (DR) extend lifespan across species and improve health by delaying the onset of age-related diseases. All currently known aging-delaying chemical compounds 1) mimic lifespan-extending and health-improving effects of CR and DR without restricting caloric and nutrient intake; and 2) target signaling pathways that are under the stringent control of calorie and/or nutrient availability. It was believed therefore that all longevity pathways are “adaptable” by nature because they modulate longevity only in response to certain changes in the extracellular and intracellular nutrient and energy status of an organism. However, it is possible that that some longevity pathways could be “constitutive” or “housekeeping” because they control longevity irrespective of calorie and/or nutrient availability. We designed a high-throughput chemical genetic screen for compounds that increase the chronological lifespan of yeast under CR by modulating such housekeeping pathways. Our screen identified lithocholic bile acid (LCA) as a geroprotector which significantly delays the onset and reduces the rate of yeast chronological aging. Using proteomics, lipidomics, metabolomics, and cell biological approaches, we found that LCA delays yeast chronological aging by: 1) remodeling lipid metabolism in the endoplasmic reticulum, lipid droplets, and peroxisomes - thereby preventing liponecrotic programmed cell death caused by the age-related accumulation of fatty acids; 2) remodeling the repertoire of mitochondrial membrane lipids - thereby reducing the number of mitochondria, increasing their size, expanding their cristae, elevating the abundance of respiratory supercomplexes in the inner mitochondrial membrane, and altering the age-related dynamics of changes in mitochondrial respiration, membrane potential, and reactive oxygen species; 3) attenuating age-related mitochondrial fragmentation - thereby suppressing mitochondria-controlled apoptosis; and 4) promoting “mitohormesis” through the activation of several stress response-related processes in mitochondria. Our findings also imply that, in addition to its robust aging-delaying effect, LCA exhibits a potent and selective anti-tumor effect in cultured human neuroblastoma, glioma, breast cancer, and prostate cancer cells by activating both the intrinsic and extrinsic pathways of apoptotic death.

Y3195C Quantitative proteomics of the yeast Hsp70/Hsp90 interactomes during DNA damage reveals chaperone-dependent regulation of ribonucleotide reductase. *Andrew Truman*[1], Laura Knighton[1], Isaac Sluder[1], Donald Wolfgeher[2], Stephen Kron[2]. 1) University of North Carolina at Charlotte, Charlotte, NC; 2) University of Chicago, Chicago, IL 60637.

The highly conserved molecular chaperones Hsp90 and Hsp70 are indispensible for folding and maturation of a significant fraction of the proteome, including many proteins involved in signal transduction and stress response. To examine the dynamics of chaperone-client interactions after DNA damage, we applied quantitative affinity-purification mass spectrometry (AP-MS) proteomics to characterize interactomes of the yeast Hsp70 isoform Ssa1 and Hsp90 isoform Hsp82 before and after exposure to methyl methanesulfonate (MMS). Of 256 proteins identified and quantified via 16O/18O labeling and LC-MS/MS, 142 are novel Hsp70/90 interactors. Nearly all interactions remained unchanged or decreased after DNA damage, but 5 proteins increased interactions with Ssa1 and/or Hsp82, including the ribonucleotide reductase (RNR) subunit Rnr4. Inhibiting Hsp70 or 90 chaperone activity destabilized Rnr4 in yeast and its vertebrate homolog hRRM2 in breast cancer cells. In turn, pre-treatment of cancer cells with chaperone inhibitors sensitized cells to the RNR inhibitor gemcitabine, suggesting a novel chemotherapy strategy.

Y3196A Humanization of entire yeast pathways via CRISPR/Cas9. *A. Akhmetov*[1], A. Kachroo[1], E. Marcotte[1,2,3]. 1) University of Texas at Austin, Austin, TX; 2) Center for Computational Biology and Bioinformatics, University of Texas at Austin, Austin, TX; 3) Department of Molecular Biosciences, University of Texas at Austin, Austin, TX.

We have recently found that a large number of S. cerevisiae genes can be "humanized", i.e. the yeast gene is deleted and replaced with its human ortholog to generate viable strains. We have also observed several gene modules (pathways or complexes) which are comprised mostly of genes that can be humanized (Kachroo et al. (2015) Science, 348:921-925). The sterol biosynthesis pathway, which is common between yeast and humans (producing the precursors of ergosterol and cholesterol in them respectively) is one such pathway; 17 of the genes in it

(many of them essential) can be individually humanized.

We have sought to investigate the possibility of higher order humanizations of an entire gene module (simultaneous humanization of multiple genes), using the sterol biosynthesis pathway as a starting point. We have developed a rapid, high-throughput approach based on CRISPR/Cas9 technology which allows us to easily and efficiently perform genetic engineering at several yeast loci. We have also investigated the utility of methods for combining modifications at several different loci in one strain. We expect that module-scale humanization will yield valuable insights into the evolution of species. In addition to this, this system is a promising platform for systematically investigating interactions between human genes, both in their wild-type as well as mutant forms or allelic variants. Since experiments with humanized yeast are much less labor and cost intensive than alternatives such as cultured human cells, they offer the possibility of probing human allelic variation on a greater scale than has been possible before.

Y3197B Program number not assigned

Y3198C Long-term real-time imaging of budding yeast with on-demand perturbation via a microfluidic examination trap. *J. T. Helton*, P. J. Hung. EMD Millipore, Hayward, CA.

The budding yeast Saccharomyces cerevisiae has been commonly used to study the biology of aging and growth rate. Yet it is difficult to image cells long-term due to their mobility to escape the focal plane as well as the rapid growth nature to overcrowd the imaging area. To address this we have developed a microfluidic device that is capable of mechanically restraining cells in a 72 × 72 × 4 µm (L x W x H) elastic trap area for long-term, real-time observation with 6 programmable on-demand flow switches. The design provides continuous dissection of excess daughter cells outside the well-defined trap site to prevent cell congestion in the 3mm x 3mm x 10 µm chamber. In addition, cells can be held for several days in a focused monolayer and continue to replicate throughout their entire lifespan during imaging. Specifically in the 72 hour experiment, we monitored growth of single budding yeast cells at a fixed xyz position under high magnification to form a monolayer culture without overcrowding the chamber. Image analysis tool was used to track and quantify the number of daughter cells a yeast mother cell produced. Software-driven perturbation provided precise media flow to the thriving colony which was verified by introducing two-color fluorescent to measure viability. Together, the resulting dynamic cell dissection in tightly controlled focused area with long-term real-time imaging offers considerable potential for cell analysis.

Y3199A A tandem-integration interaction sequencing platform. *Xianan Liu*[1,2], Sasha Levy[1,2]. 1) Laufer Center for Physical and Quantitative Biology, Stony Brook University, Stony Brook, NY; 2) Department of Biochemistry and Cell Biology, Stony Brook University, Stony Brook, NY.

Combinatorial biological screens, such as those that assay genetic interactions between mutations or gene deletions, or that assay physical interactions between proteins, have historically been limited in throughput by the requirement to test for interactions one-at-a-time. A potentially higher-throughput alternative would be to provide each combination with a unique barcode and measure the interaction score of each barcoded genotype *en masse* in cell pools via barcode sequencing (bar-seq). However, construction and storage of a uniquely barcoded strain for each combination is impractical for genome-scale interaction screens. Here, we introduce a pair of novel double barcoding systems that allow us to easily construct and assay extremely large combinatorial libraries. The key innovation is a tandem “landing pad” in the yeast genome that allows two barcoded plasmid libraries to be brought to the same genetic location. Pooled growth of double barcode libraries and paired-end amplicon sequencing can be used infer the relative fitness of each pairwise interaction in a population. We show that this system can easily scale up to yeast pools containing 10^7 or 10^9 double barcodes, depending on whether barcode pairs are brought together by sequential integration or mating. As a proof-of-principle, we generated a library of ~3000 double barcoded haploid and diploid yeast strains, each with a different pair of auxotrophic rescue plasmids. We are currently assaying these pools across several environments to determine the fitness error rates of the assay. Additionally, we are porting our tandem integration platform to mammalian cell systems. This platform will be useful for a variety of applications including assays of interactome dynamics, as well as mammalian protein-protein interaction and CRISPR/Cas9-based genetic interaction assays.

12th International Conference on
Zebrafish Development and Genetics

Poster Session Abstracts

Z6001A Investigating the role of tetraploid intermediates in melanoma progression. *R. Darp*[1,2], S. Gujja[1], Y. Edwards[1], D. Pellman[3], L. Zon[4], N. Ganem[5], C. Ceol[1,2]. 1) University of Massachusetts Medical School, Program in Molecular Medicine, Worcester, MA, USA; 2) University of Massachusetts Medical School, Department of Molecular, Cellular and Cancer Biology, Worcester, MA, USA; 3) Howard Hughes Medical Institute, Department of Pediatric Oncology, Dana-Farber Cancer Institute, Children's Hospital and Department of Cell Biology, Harvard Medical School, Boston, MA, USA; 4) Howard Hughes Medical Institute, Stem Cell Program and Division of Hematology/Oncology of Boston Children's Hospital and Dana Farber Cancer Institute, Harvard Stem Cell Institute, Harvard Medical School, Boston, MA, USA; 5) Departments of Pharmacology and Experimental Therapeutics and Medicine, Division of Hematology and Oncology, Boston University School of Medicine, Boston, MA, USA.

Tetraploid cells and their aneuploidy progeny have been proposed as intermediates in tumor development. Support for this hypothesis comes from deep sequencing studies that suggest at least one third of solid tumors have undergone a genome doubling event during their progression and additional studies that have implicated genome doubling as an important step early in tumor progression. These studies propose that nascent tetraploid tumor cells can more easily sample genetic configurations that are advantageous for growth because they, as compared to diploid cells, are buffered against deleterious effects of mutations and changes in gene dosage. Studies using a melanoma-prone *Tg(mitfa:BRAFV600E);p53(lf)* strain suggest a role for tetraploidy and genome doubling in the genesis of tumors in these fish. We have found that, unlike wild-type melanocytes, melanocytes in *Tg(mitfa:BRAFV600E)* animals are binucleate and tetraploid. In tissue culture, newly-formed tetraploid cells undergo a *p53*-dependent G1 cell cycle arrest. A similar arrest likely occurs in zebrafish melanocytes, as melanocytes in *Tg(mitfa:BRAFV600E); p53(lf)* animals exhibit 8N and greater DNA content, suggesting bypass of an arrest that halts progression of tetraploid *Tg(mitfa:BRAFV600E)* melanocytes. These data implicate tetraploids generated by increased BRAF pathway activity as a contributor to melanoma initiation. To gain insight into the mechanism by which *BRAFV600E* generates binucleate cells, we have established a lentiviral-based doxycycline inducible *in vitro* model system to induce *BRAFV600E* expression. We are currently using live-cell imaging approaches to determine the mechanism by which these binucleates arise in culture. We are also conducting retrospective bioinformatic analyses to determine whether melanomas in *Tg(mitfa:BRAFV600E);p53(lf)* zebrafish progress through tetraploid intermediates, supporting the notion that the combination of oncogenic *BRAFV600E* and mutated *p53* causes the generation and progression of nascent tetraploid melanoma cells.

Z6002B Optical Control of Cancer Initiation in Zebrafish. *Zhiping Feng*[1], Vriz Sophie[2], Michel Volovitch[2,3], Ludovic Jullien[4], Shuo Lin[5], Shimon Weiss[1,6], David Bensimon[6,7]. 1) Department of Molecular, Cellular and Integrative Physiology, UCLA, USA; 2) Collège de France, Center for Interdisciplinary Research in Biology, France; 3) Department of Biology, ENS, France; 4) Department of Chemistry, ENS, France; 5) Department of Molecular, Cell and Developmental Biology, UCLA, USA; 6) Department of Chemistry and Biochemistry, UCLA, USA; 7) Laboratoire de Physique Statistique, ENS, France.

Although cancer initiation and evolution have been extensively studied, they are not, as of yet, fully understood. In particular, two outstanding questions, the effectiveness of oncogenic transformation and the role of the local microenvironment on cancer initiation, require the investigation into early events of cancer initiation and the study of the fates of individual cells and their progenies. Several models have attempted to answer how cancer arises from individual transformed cells. However, current probes of cancer development are restricted to the collective properties of many thousands of cells. Recently, we developed a technology that allows for the control of protein activity and gene expression in single cells through light activation. In this work, we utilize this method to activate in a small number of cells in a live zebrafish a typical oncogene, K-RasG12V, and investigate effects of these changes on tumorigenesis under varied genetic backgrounds. We successfully demonstrated the spatiotemporal control of oncogene expression in live zebrafish. Furthermore, we investigated different tumorigenic phenotypes by transiently or permanently activating K-Ras at varied developmental stages. We believe that our studies could shed new light on cancer initiation and growth and provide new tools for target validation and testing of novel anti-cancer drugs.

Z6003C Synergy between Loss of *NF1* and Overexpression of *MYCN* in Neuroblastoma Is Mediated by the GAP-related Domain. *Shuning He*[1], Marc R. Mansour[1,2], Mark W. Zimmerman[1], Dong Hyuk Ki[1], Hillary M. Layden[1], Koshi Akahane[1], Eric D. de Groh[3], Antonio R. Perez-Atayde[4], Shizhen Zhu[5], Jonathan A. Epstein[3], A. Thomas Look[1]. 1) Dana-Farber Cancer Institute, Boston, MA; 2) University College London, London, UK; 3) Perelman School of Medicine at the University of Pennsylvania, Philadelphia, PA; 4) Children's Hospital Boston, Boston, MA; 5) Mayo Clinic, Rochester MN.

Earlier reports have shown that hyperplasia of sympathoadrenal cell precursors during embryogenesis in *Nf1*-deficient mice is independent of Nf1's role in down-modulating RAS-MAPK signaling. By contrast, loss of *nf1* leads to aberrant activation of RAS signaling in *MYCN*-induced neuroblastomas that arise in these precursors, and the activity of the GTPase-activating protein (GAP)-related domain (GRD) is sufficient to suppress the accelerated onset of neuroblastoma in *nf1*-deficient zebrafish. Thus, even though neuroblastoma is a classical "developmental tumor" of childhood, NF1 uses a very different mechanism to suppress malignant transformation than it does to modulate normal neural crest cell growth. We also show marked synergy in tumor cell killing between the MEK inhibitor trametinib and the retinoid isotretinoin *in vivo* in primary neuroblastomas. Thus, our model system has considerable translational potential for investigating new strategies to improve the treatment of very high risk neuroblastomas with aberrant RAS-MAPK activation.

Z6004A Somatic deficiency of DNA polymerase α causes tissue-specific nuclear atypia and apoptosis in Zebrafish. *A. Y. lin*, K. C. Cheng. Penn State Hershey College of Medicine, Hershey, PA.

Nuclear atypia is a morphological abnormality noted by histology that is common and diagnostically important in cancer diagnosis, but its mechanisms are not understood. A zebrafish genetic screen for mutations that cause nuclear atypia yielded a mutant, *huli hutu* (*hht*) with a

pleiotropic phenotype that included nuclear atypia in gastrointestinal cells, apoptotic nuclear fragmentation in neurons of the brain and eye, reduced head and eye size, and body curvature. The causative mutation was a frameshift in *pola2*, which encodes subunit B of DNA polymerase α (Pol α), that results in a premature stop codon at the 38th amino acid position of the 600 amino acid protein. Loss of function mutations of *pola2* in other model organisms such as *S. cerevisiae* and *Arabidopsis* are known to cause rapid growth arrest, delay in S phase progression, and cell division defects. In contrast, *hht* can live up to 7dpf as a result of wild-type maternal *pola2* mRNA detected in mutant eggs by allele-specific PCR. Subsequent somatic loss of wild-type mRNA results in atypical cellular morphology, abnormal mitoses, and tissue deformation in homozygous mutant larvae. This *hht* phenotype is strikingly similar to that observed in zebrafish with CRISPR/Cas9-mediated loss of function mutations in *pola2* and other DNA polymerase α subunits, *pola1, prim1, and prim2,* indicating an effect that is not subunit-specific, but rather due to deficiencies in DNA polymerase activity. In support of this idea, inhibition of DNA synthesis associated with aphidicolin or hydroxyurea treatment also yielded tissue-specific *hht*-like phenotypes. Prolonged survival and development allows *hht* to demonstrate tissue-specific changes in cellular and nuclear morphology, suggesting that different tissues may have different requirements for DNA polymerase α activity during development.

Z6005B PHF6 keeps hematopoietic lineage development in check. *S. Loontiens*[1], K. Durinck[1], I. van de Walle[2], E. Janssens[1], S. Vanhauwaert[1], F. Moore[3], P. Rondou[1], G. Dewyn[1], C. De Bock[4], J. Cools[4], D. Langenau[3], P. Van Vlierberghe[1], T. Taghon *[2], F. Speleman *[1], * shared last authorship. 1) Center for Medical Genetics, Ghent Univeristy, Gent, BE; 2) Departement of Clinical Chemistry, Microbiology and Immunology, Ghent University, Ghent, BE; 3) Harvard Stem Cell Institute, Boston, Massachusetts, USA; 4) Laboratory for the Molecular Biology of Leukemia, Center for Human Genetics, University of Leuven and Center for the Biology of Disease, Vlaams Instituut voor Biotechnologie, Leuven, BE.

T-cell acute lymphoblastic leukemia (T-ALL) is a genetically heterogeneous disease. The *PHF6* gene is frequently targeted by loss-of-function mutations or deletions, with the highest prevalence in *TLX1* or *TLX3* rearranged T-ALLs. We aim to gain insights into the role of PHF6 during normal thymocyte development and malignant transformation. To this end, transcriptome wide perturbation effects were measured following PHF6 knock down in the *PHF6* wild-type T-ALL cell lines Jurkat and ALL-SIL. In parallel, gene expression profiles were established from cord blood CD34^{+} progenitor T-cells, cultured for short-term on an OP9-DL1 feeder layer, with stable knockdown of PHF6. Modulation of *PHF6* expression induced robust and broad transcriptional regulatory effects of PHF6 including on *IL7R* expression. *IL7R* encodes a cytokine receptor critically involved in normal T-cell development and acts as a *bona fide* oncogene in subsets of T-ALLs. Using the *in vitro* differentiation assay for all lineages starting from CD34+ cells we also identified a broader role for PHF6 beyond thymocyte differentiation acting as a master regulator of early hematopoietic differentiation along the T-cell, B-cell, myeloid and NK-cell lineages (Durinck et al., in preparation). To further test this *in vivo*, we performed *phf6* gene inactivation by injection of gRNAs and Cas9 protein into the one-cell stage zebrafish embryos yielding varying out-of-frame in/dels. In addition, we used a TALEN based PHF6 knock out zebrafish line (Moore et al., Plos One, 2012).
Upon *phf6* knockdown accelerated T-cell maturation was seen in support of our *in vitro* data in human cells. Interestingly, transcriptional changes in the *phf6* knock out lines were noted for *lmo2* and *notch1*, both key players in zebrafish hematopoiesis. Using optimized of RT-qPCR and RNA sequencing on sorted lymphocytes we are currently evaluating the transcriptional effects of *phf6* down regulation during lymphocyte development. We will present findings on whole kidney marrow tissue for changes in hematopoietic population distribution in wild type versus *phf6* knock out zebrafish. In conclusion, we were able to show for the first time a conclusive role for PHF6 in hematopoiesis using *in vitro* and in vivo modeling in human and zebrafish respectively.

Z6006C Investigating Colorectal Cancer Metastasis to Liver in Zebrafish. *S. Mukhopadhyay*[1], M. Mesmar[1], J. Gustafsson[1,2], C. Williams[2], M. Bondesson[1]. 1) University of Houston, Houston, TX; 2) Karolinska Institutet, Solna, Sweden.

Chemokines are known to play a role in cancer. C-C chemokine Receptor type 6 (CCR6) and its sole ligand, CCL20 have been reported to be up-regulated in colorectal cancer (CRC) cells. We are studying the chemotaxis of CCR6-expressing CRC cells to CCL20, whose expression is highest in the liver. It has been suggested that it is due to this chemoattraction that 75% of the CRCs metastasize to the liver. Hence, disruption of the CCR6-CCL20 interaction is one strategy for inhibiting CRC liver metastasis. This hypothesis is being tested using a variety of *in vitro* assays and *in vivo* in zebrafish. We investigated CCR6 RNA and protein expression in different CRC cell lines, and selected the highest expressing cell lines for microinjection into zebrafish embryos, following tracking of the fluorescence-labeled migrating cells. When injected to the perivitelline space, SW480 and HT29 cells micro-metastasize to the vasculature. We are now injecting CRC cells into the zebrafish intestine following imaging of cancer cell migration to evaluate whether zebrafish xenografting is a viable model for studies of liver metastasis.

Z6007A aMOTIV microscopy: mechanical characterization of the *in vivo* tissue microenvironment, a step towards living mechanical histology. *K. Tanner*. National Cancer Institute, Bethesda, MD.

Microscale heterogeneities in tissue rheological properties such as stiffness and viscosity strongly influence cell fate and malignancy. However, outstanding questions about the timescales of interactions (measured as a range of frequencies), length scales and type of interactions sensed by cells within tissues that are physiologically relevant remain unanswered. What is needed is the ability to resolve and quantitate minute forces that cells sense in the local environment (on the order of microns) within thick tissue (~mm) and 3D culture models, that approximate clinically relevant *in vivo* architecture and signaling cues, allowing for real time characterization of cell-ECM dynamics. We performed active Microrheology using an Optical Trap In Vivo (aMOTIV) microscopy using an *in situ* calibration method to obtain exact trap stiffness at each probe to quantify local applied forces with high spatial and temporal resolutions. This allowed us to determine tissue mechanics at length scales (nm-mm) and frequencies (1-10,000's Hz) unobtainable by bulk rheology, which misses the cell-scale

heterogeneities, or with passive microrheology, which misses the interesting non-linear stress/strain curves seen with active probing then apply defined strains, Applicable to thick tissue, this technique allowed us to distinguish mechanical heterogeneities with micrometer spatial resolution at penetration depths up to 500 μm. After initial characterization of 3D cell culture gels, we applied our technique in zebrafish, Danio rerio; the first time in situ calibration and microrheology has been applied to a living model vertebrate organism. Our initial data indicates a broad range of elastic moduli, with measurements in the tail ranging ~ 10s to 1000s of Pascals, while the brain is significantly softer (10's to 100's Pa). We show here an advanced technique for micro-rheological characterization *in vitro* and *in vivo*, to accurately quantify physical determinants of the local microenvironment. This allows for accurate measurements mechanical properties in living organisms and in tissue models to definitively account for microenvironmental impact on individual cells and organogenesis.

Z6008B Studying the functionality of the homologous repair pathway in zebrafish embryos: heading for an in vivo functional test to evaluate the pathogenicity of BRCA2 variants identified in breast/ovarian cancer patients. *Jeroen Vierstraete*[1,2], Andy Willaert[1], Kris Vleminckx[1], Petra Vermassen[1], Paul Coucke[1], Leen Pieters[2], Anne Vral[2], Kathleen Claes[1]. 1) Center for Medical genetics Ghent, Ghent University Hospital, Belgium; 2) Department of Basic Medical Sciences, Ghent University, Belgium.

Aims:

Since the introduction of next generation sequencing, the challenge for genetic testing moved from developping mutation detection methodologies towards adequate variant interpretation. We propose a novel in vivo approach to study the functionality of BRCA2 missense variants in zebrafish. We aim to develop an in vivo functional assay to measure in zebrafish embryos the capacity of homologous recombination (HR) for human BRCA2 mRNA containing variants of unknown clinical significance (VUS).

Methods:

To evaluate the efficiency of HR repair we induce DNA double strand breaks (DSB) in zebrafish embryos by irradiation. We use yH2AX and RAD51 foci assays as markers for DSB and HR repair respectively. We generated zebrafish brca2 knockdown models by morpholino injection and Crispr-Cas9 mutagenesis, and obtained a mutant line from the European Zebrafish Resource Center (EZRC). Rescue experiments will be performed with wild type human BRCA2 mRNA and mRNA containing the VUS of interest.

Results:

We developed a protocol for visualising and quantifying RAD51 foci in zebrafish embryonic tissue. Brca2 knockdown by morpholino results in an almost complete absence of RAD51 foci. Similar results have been generated in the EZRC line, and are currently being generated in the Crispr-Cas9 knockout model. In a next step we will rescue the phenotype by microinjection of wild type human BRCA2 mRNA and mRNA containing VUS to study the effect of these VUS on HR capacity.

Conclusions:

The zebrafish genome contains nearly all genes involved in different DNA repair pathways in eukaryotes, including HR, in which BRCA2 plays a major role. Therefore, zebrafish provides an ideal in vivo model for studying variants in genes involved in DNA damage and repair.

Z6009C Probing cancer genomes using tissue-specific genome editing. *R. Vyas*, A. M. Venkatesan, M. Kasheta, C. J. Ceol. University of Massachusetts Medical School, Worcester, MA.

Site-directed nucleases have recently emerged as potent tools for gene disruptions in various model organisms, including disruptions of tumor suppressor genes. However, whole organism tumor suppressor gene disruption is time-consuming and often causes deleterious effects such as lethality. To mitigate these problems, we have developed somatic cell gene-targeting approaches. Our strategy is to target candidate tumor suppressor genes specifically in melanocytes. Using the miniCoopR system, in which transgene-expressing melanocytes are reconstituted in a *mitfa(lf)* background, we have expressed TALENS in melanocytes and validated targeted knockdown of *p53* in melanomas. In order to achieve greater targeting efficiency, we are using CRISPR-Cas system. With our improved genome-editing system we aim to target candidate tumor suppressors that are recurrently deleted in human and zebrafish melanomas. Additionally, we are assessing the function of these candidate tumor suppressors in human melanoma cell lines using down-regulation and over-expression studies and will present our progress. Combining the throughput afforded by genetics in zebrafish with functional in vitro studies has enabled our identification of novel melanoma oncogenes. We now extend that approach to tumor suppressor genes.

Z6010A Understanding the mechanistic roles of Integrin Alpha 6 in tumor development using humanized zebrafish model system. *Ashley B. Williams*, Shauntell N. Luke, Andy Diamanduros, Vinoth Sittaramane. Georgia Southern, Statesboro , GA.

Present day cancer incidence and mortality rates indicate the need for effective cancer diagnostic tools and targeted cancer therapeutic strategies. Recent studies have focused on the biological pathways of cells and tumor microenvironments to identify putative biomarkers and potential drug targets as diagnostic and therapeutic tools. Human integrins, transmembrane adhesion receptors, have become the focal points in these studies, specifically Integrin Alpha 6 (*ITGA6*) which has been implicated in major tumor progression roles. Several human tumors like pancreatic, prostate, breast and ovarian cancers exhibit increased levels of ITGA6 expression (Marthick JR et al., 2012; Lathia JD et al., 2010; Hirozumi S et al., 2006; Johnatty S et al., 2010). *ITGA6* has been implicated in tumor angiogenesis, metastasis and cancer stem cell maintenance (Primo L et al., 2010; Wang J et al., 2013; Carrion B et al., 2013). These characteristics make *ITGA6* an excellent candidate for potential drug or diagnostic target, however the mechanism by which *ITGA6* imparts tumor progression is unclear. Cell culture studies have indicated ITGA6 could be cleaved extracellularly to increase metastasis (King TE et al., 2008; Cress AE et al., 2014). But, zebrafish with organismal structures and vascular network, presents a complete *in vivo* model to track metastasis and angiogenesis. In the present study we aim to identify the specific role of *ITGA6* in tumor development by using a humanized zebrafish model, where Di-I labeled human prostate cancer cells (PC3) are

transplanted into *Tg*(*Fli1a:gfp*) zebrafish embryos that is overexpressed with various forms of human ITGA6. To test the domain specific role of *ITGA6*, Human full length or Truncated extracellular or Mutated non-cleavable ITGA6 RNA is injected to the zebrafish PCs tumor xenograft. Our studies indicate that truncated *ITGA6* overexpression significantly upregulate tumor metastasis compared to full-length *ITGA6* overexpression. Similarly, mutated *ITGA6* significantly decreased the tumor metastasis. The results suggest that cleaved *ITGA6* increases tumor metastasis potentially aiding in extracellular matrix remodeling. The cellular role of *ITGA6* will be evaluated by transplanting *ITGA6* siRNA transfected PC3 cells for zebrafish tumor xenografts. We anticipate these experiments will help establish the cell and non-cell autonomous roles of *ITGA6* during tumor development. Further, we expect to use high resolution imaging techniques to track the migration of single cancer cells an *in vivo* system to understand the dynamics of tumor metastasis.

Z6011B Identification of melanoma progenitor cells remaining after regression in zebrafish models. *S. Wojciechowska*[1], A. Capper[1], Z. Zeng[1], J. Lister[2], E. E. Patton[1]. 1) MRC Institute of Genetics and Molecular Medicine, MRC Human Genetics Unit & Edinburgh Cancer Research Centre, University of Edinburgh, Western General Hospital, Crewe Road South, EH4 2XR, UK; 2) Department of Human and Molecular Genetics and Massey Cancer Center, Virginia Commonwealth University, School of Medicine, Sanger Hall 11-014 1101 E. Marshall Street Richmond, VA 23298-0033, USA.

Melanoma is the most deadly form of skin cancer that kills over 20,000 Europeans each year and incidence continues to rise rapidly. $BRAF^{V600E}$ inhibitors have led to clinically significant improvements in outcomes for melanoma patients, yet many patients with metastatic melanoma rapidly succumb to the disease due to eventual chemoresistance, or insensitivity to the drug. Thus, it is critical to identify new therapies that can act alone, or be combined with available treatments for enhanced efficacy and/or to overcome drug resistance.

Evidence from human melanoma indicates that the melanocyte lineage is critical for melanoma survival and contributes to therapeutic resistance. MITF is a highly conserved "master melanocyte regulator" with a complex role in melanoma. Our lab has developed two temperature sensitive zebrafish melanoma models (earlier published $BRAF^{V600E}$ *mitf* and a new BRAF-independent model *p53 mitf*), both carrying the $mitf^{v7}$ splice site mutation that enables us to conditionally control its endogenous activity by adjusting the water temperature. We showed that the MITF activity is crucial for melanocyte survival and that both mutated BRAF and p53 deficiency are oncogenic with low levels of MITF, and result in fish nevi and melanoma resembling the pathology of human disease. Complete inhibition of MITF activity leads to rapid tumor regression, but once its activity is restored the melanomas recur at the same site as the original tumor. This suggests that a subpopulation of cancer initiating cells remains following melanoma regression and is capable of repopulating the tumor. We have been able to show that some cells remaining at the sites of regression express $BRAF^{V600E}$ and we are currently searching for other markers. Our goal is to identify the molecular signatures of these proposed melanoma stem cells and to develop approaches to visualize and target these subpopulations. We are using histopathology studies, molecular and lineage tracing imaging methods and melanocyte lineage transgenes in our genetic zebrafish models, as well as zebrafish melanoma cell culture to study the nature of the cell of origin for the tumor recurrence.

Z6012C Assessing the Lineage Fate of First Vs. Second Heart Field Derived Cells in Cardiac Development and Regeneration. *J. Choubey*[1,2], I. Scott[1,2,3]. 1) University of Toronto, Toronto, Ontario, CA; 2) The Hospital for Sick Children, Toronto, Ontario, CA; 3) Heart & Stroke/ Richard Lewar Center of Excellence, Toronto, Ontario, CA.

Surgical intervention for patients with some forms of congenital heart diseases (CHD) has increased patient survival to adulthood; however post surgical stress contributes to a high incidence of heart failure, with the right ventricle being more susceptible to ventricular failure. Developing novel therapies for CHDs requires an understanding of the underlying biological mechanisms driving cardiac progenitor cell specification and differentiation. Two distinct progenitor populations, termed the first heart field (FHF) and the second heart field (SHF), have been shown to drive cardiac development . Whereas the FHF contributes to the left ventricle (LV) , the SHF derived cells contribute to the right ventricle (RV), inflow and outflow tracts in the mammalian heart. Unsurprisingly, SHF defects are a major contributor of CHDs. Recently, second heart field progenitors in zebrafish have been shown to give rise to three cardiovascular lineages in the OFT and myocardium in the distal ventricle; thus displaying a multipotent characteristic.

My project focuses on studying the underlying biological mechanisms and the intrinsic competence of cardiac progenitor cells to differentiate into multiple lineages within the heart. There are currently no studies that have assessed the lineage specification of FHF and SHF progenitors in the zebrafish adult heart. This will help us to understand how the two distinct progenitor populations give rise to the adult heart and its structures; thus allowing us to model CHDs in zebrafish. I'm employing a Cre recombinase-mediated lineage-tracing of cells expressing *cmlc2* in order to assess the lineage specification of FHF and SHF progenitors in the zebrafish heart. The *cmlc2* gene product is found in the sarcomere of cardiomyocytes undergoing differentiation. I am using a tamoxifen-inducible Cre driven by *cmlc2* regulatory sequences, Tg(*cmlc2*:ERCreER).This line, when crossed with Tg(*cmlc2*:loxP-GFP-STOP-loxP-mCherry) will allow visualization of cardiomyocytes with mCherry fluorescence after tamoxifen induced excision of loxp-flanked STOP sequences . The SHF population begins differentiation later, and adds onto the linear heart tube gradually; expressing the differentiation marker later. Thus, administering tamoxifen to the double transgenic embryos prior to SHF differentiation will lead to the labelling of FHF specific cells with mCherry fluorescence. The late differentiating progenitor population will not undergo excision of the loxp-flanked STOP sequences, and will be marked with GFP fluorescence.

Z6013A Sensory cilia functions in zebrafish. *Judith Bergboer*[1], Cameron Wyatt[2], Christina Austin-Tse[1], Jonathan Raper[3], Emre Yaksi[4], Iain Drummond[1]. 1) MGH/HMS, Charlestown, MA; 2) Neuroelectronics Research Flanders, Leuven, Belgium; 3) University of Pennsylvania, Philadelphia, PA; 4) Kavli Institute for Systems Neuroscience, Trodheim, Norway.

Primary cilia mediate signal transduction by acting as an organizing scaffold for cell membrane receptors, signaling proteins, and ion channels.

Ciliated olfactory sensory neurons (OSNs) organize olfactory G-protein coupled receptors and ion channels on dendritic cilia and generate a cAMP-coupled influx of calcium ions as a primary signal in odorant detection. In the zebrafish olfactory placode, ciliated OSNs and microvillus OSNs constitute the major OSN cell types with reported distinct odorant sensitivity. Here we report single cell analysis of transgenic zebrafish expressing the calcium indicator GCaMP5 in OSNs to directly image cilia-dependent OSN responses to odorants in live zebrafish larvae. *Oval/ift88* mutant (*ift88 -/-*) and *ift172* knock-down zebrafish showed fewer and severely shortened OSN cilia without a reduction in total OSN number. OSN response amplitude to bile acids, and food odor were significantly reduced in *ift88* mutants and *ift172*-deficient embryos while the responses to amino acids were not significantly changed. We have also generated CRISPR/Cas9 mutants of the syndromic ciliopathy genes Cep290 and BBS4 which show delayed defects specifically in sensory cilia structures. Combining ciliopathy gene mutations with biosensor transgenes provides a quantitative model for studying sensory ciliogenesis in zebrafish and a platform for therapeutic screening. Our results also implicate *ift172*-deficiency as a novel cause of anosmia.

Z6014B Positional cues within the nucleus underlie the dynamic chromosome events of meiosis in zebrafish. *S. M. Burgess*, Y. P. Blokhina, A. Nguyen, D. B. Chu, H. Roberts, T. A. Newman, B. W. Draper. Univ California, Davis, Davis, CA.

Chromosome aneuploidy is a leading cause of birth defects and miscarriages in humans. The majority of aneuploidies are generated by errors in segregating homologous chromosomes at the first meiotic division. The incidence of chromosome segregation errors is higher in female mammals than males. Nonetheless, meiosis is largely understudied in females since the events of meiotic prophase I occur in the fetal ovary. The zebrafish model overcomes many of the limitations of using mice because gametogenesis occurs throughout adulthood in both sexes, the progeny number in the hundreds and embryos develop outside of the body. We will describe a comprehensive toolkit we have developed to study the chromosome events of meiotic prophase in zebrafish at the molecular, genetic and cellular levels. We found that both male and female zebrafish follows the canonical pathway of meiotic progression seen for fungi, plants, and mammals; that is, SPO11-induced double-strand breaks (DSB) are required for pairing and synapsis of homologous chromosomes. As seen for human males, synapsis (SYCP1 loading) initiates near telomeres and zippers inward until chromosomes are fully synapsed at pachytene. In zebrafish, the extension of the chromosome axis (SYCP3) also initiates near telomeres and extends just ahead synapsis. There is a dramatic localization of DSBs (RAD51 foci) to the sites of clustered telomeres in the bouquet stage. Synapsed telomere regions are not always associated with RAD51 foci and many RAD51 foci are not associated with telomeres. These data suggest that multiple chromosomal loci undergoing DSB repair may coalesce to a single region of the nucleus during the earliest stages of pairing and synapsis and bring into question the mechanism of pairing. Further analysis of the *spo11* mutant shows that females are fertile, however, embryos are largely deformed due to high levels of aneuploidy; by contrast, *spo11* males fail to make sperm. While the meiotic program occurs until chromosome axes have formed, synapsis is absent. Together these findings point to zebrafish as an excellent model to study the dynamic events of meiotic prophase. Similarities and differences between multiple model organisms point to a conserved relationship between telomere clustering, DSB repair and synapsis initiation as contributing to the successful execution of the meiotic program.

Z6015C *marsyas:* a zebrafish mutant in GBF1 showing defects in epithelial integrity. *Thomas A. Hawkins*[1], Liana Goodings[1], Patrick Toolan-Kerr[1], Richard J. Poole[1], Rodrigo M. Young[1], Heather L. Stickney[1], Florencia Cavodeassi[2], Quenten P. Schwartz[3], Stephen W. Wilson[1]. 1) Div. Biosciences, UCL, London, UK; 2) Centro de Biologia Molecular Severo Ochoa, Universidad Autonoma de Madrid, Madrid, Spain; 3) Center for Cancer Biology, University of South Australia, Adelaide, Australia.

The zebrafish mutant *marsyas* (*mrys)* was identified through a screen for skin defects using the vital dye R18 at 3dpf. *mrys* mutants display skin defects from 36hpf with the outer layer of skin cells sloughing off from the basal layer and ineffective formation of all fins. *mrys* mutants also have defective blood vessel formation, displaying bleeds across their circulatory system concurrent with defects in the skin. Apico-basal polarity of epidermal cells appears unaffected.

Initial bulked-segregant mapping indicated a lesion on chromosome 13 and subsequent whole genome sequencing identified a premature stop codon in GBF1 (golgi brefeldin-A resistance factor 1). This lesion was confirmed by high-resolution mapping. We are currently attempting phenocopy and rescue of the phenotype to confirm the mutation as causative.

GBF1 is an ArfGEF implicated in the entry of vesicles to the *cis*-golgi, feeding primarily the exocytosis pathway of vesicle trafficking although it is also implicated in endocytosis by some studies. The drosophila GBF1 mutant *gartenzwerg* has defects in tracheal and other tubular structure formation, suggesting a comparable phenotype.

We are currently carrying out further phenotypic analysis, including cell-autonomy tests, electron microscopy and GFP tagging of golgi and other organelles to closely examine the phenotype. Our primary question concerns whether the phenotypes we observe originate from a failure of the vesicular delivery of protein(s) important for epithelial integrity or whether the phenotype is caused by defective balance between membrane compartments of epithelial cells.

Z6016A Differential Lectin Binding and Coronary Angiography in Zebrafish and Giant danio. *O. Shifatu*, A. May, J. Quinn, D. Lafontant, W. He, P. Lafontant. DePauw University, Greencastle, IN.

Lectins are carbohydrate-binding proteins commonly used in the study of glycoprotein expression in mammalian hearts. However lectins have received little use in fish models and non-models species. We hypothesize that lectin binding may reveal specific and differential patterns of glycoprotein expression in fish hearts. Here, we determine the binding patterns of commonly used lectins, including wheat germ agglutinin (WGA), Ulex europaeus agglutinin (UEA lectin), Bandeiraea simplicifolia lectin (BS lectin), Concanavalin A (Con A), Ricinus communis (RCA), and Lycopersicon esculentum lectin (tomato lectin) in zebrafish and giant danio hearts. Our results show that WGA stained fish cardiac myocyte

borders in patterns similar to that seen in mammalian hearts, with staining markedly stronger in the fish compact hearts. Con A showed broad and strong staining in fish ventricles. Interestingly, BS lectin reacted poorly to a number of fish species including zebrafish, pearl danio, common koi, goldfish, and Buenos Aires tetra. By contrast BS lectin strongly stained coronary vessels of giant danio, and several pleco and gourami species. Importantly, enhanced BS lectin biding to vascular endothelium compared to endocardium allowed for 3D coronary angiography in the giant danio, and for quantitation of vascular reconstruction during regeneration. Differential lectin reactivity was further observed in developing zebrafish hearts. In conclusion, our study demonstrates that lectins are simple but important tools for studies in model fish species, and in adult and regenerating giant danio heart.

Z6017B Type-Specific Cells Differentiate into Neurons in Spinal Cord of Zebrafish Embryos after Hypoxic Stress or Injury. *Chih-Wei Zeng*[1], Yasuhiro Kamei[2], Yun Yu[1], Chih-Tien Wang[1], Huai-Jen Tsai[3]. 1) Institute of Molecular and Cellular Biology, National Taiwan University, Taipei, Taiwan; 2) National Institute for Basic Biology, Okazaki, Japan; 3) Institute of Biomedical Science, Mackay Medical College, New Taipei City, Taiwan.

Neuron stem/progenitor cells (NSPCs) of zebrafish central nervous system (CNS) are known to thrive during recovery after hypoxia, but not all cells have been fully characterized. To address this, zebrafish transgenic *huORFZ* embryos were exposed to hypoxia, followed by oxygen recovery (OR), and GFP was exclusively expressed in some CNS cells. Among these GFP-expressing cells, most were NSPCs and radial glia cells (RGs), along with a few oligodendrocyte progenitor cells (OLPs) and oligodendrocytes (OLs), all termed as hypoxia-responsive recovering cells (HrRCs). After hypoxia, HrRCs did not undergo apoptosis, but GFP(-) neurons did. Among HrRCs, only GFP(+)-NSPCs and GFP(+)-RGs proliferated, migrated, and differentiated into functional neurons during OR. When some HrRCs were ablated in the spinal cord of hypoxia-exposed *huORFZ* embryos, swimming performance was impaired, suggesting that HrRCs are involved in neuronal regeneration. In *huORFZ* embryos treated with spinal cord injury, GFP-expressing cells displayed characteristics similar to HrRCs. These results imply that type-specific cell populations in zebrafish spinal cord can respond sensitively to hypoxia and play a role in neural regeneration.

Z6018C The neurosteroids alfaxalone and allopregnanolone protect larval zebrafish against PTZ-induced deficits. *P. R. Lundegaard*[1], T. Dyhring[2]. 1) University of Copenhagen, Copenhagen, DK; 2) Saniona A/S, Ballerup, DK.

The zebrafish has emerged as a vertebrate model system amenable to study human disease states. Zebrafish models of human neurobiological disorders offer the opportunity to identify novel therapeutic treatments through phenotype-based chemical modifier screens and larval zebrafish have previously been suggested as an experimental model of epilepsy-related pathogenic states.
Using alternating light and dark conditions, combined with a sub-convulsive concentration of pentylenetetrazole (PTZ) we show that the most pronounced effects were obtained with the neurosteroids alfaxalone and allopregnanolone. In addition, neurosteroid and benzodiazepine drug combinations were found to significantly improve phenotypic rescue in larval zebrafish, as reflected by a reduction in the minimal effective drug concentrations needed to reverse locomotion in the alternating light/dark assay.

Z6019A Optogenetic Control of Cell Ablation for Regeneration Studies of Spinal Cord Injuries. *K. Mruk*, J. Chen. Stanford University, Stanford, CA.

Spinal cord injuries (SCIs) affect multiple cell types. After the initial injury, additional tissue loss occurs by a self-propagating cascade of cellular and biochemical mechanisms that exacerbate the SCI. Animal models capable of regeneration are likely our best resource for understanding and ultimately treating SCIs. The zebrafish central nervous system (CNS) shares many organizational, cellular and molecular pathways with humans, yet it is capable of functional regeneration even after complete spinal cord transection. Zebrafish models of SCI are unique, valuable tools for studying spinal cord regeneration, particularly because the optical transparency of larvae permits real time observation of the CNS and optogenetic manipulations. To better understand how the CNS responds to SCI, we are developing optogenetic approaches to selectively ablate cells in the zebrafish spinal cord and monitor regeneration in real time. Applications of our optogenetic technologies and characterization of the SCIs they cause in zebrafish larvae will be discussed.

Z6020B Discovery of novel psychotrophic agents using zebrafish larval behavioral assays. *Ashley B. Williams*, Danielle Lott, Abid Shaikh, Vinoth Sittaramane. Georgia Southern, Statesboro, GA.

Psychotropic agents are a loosely defined group of drugs which affect consciousness through pharmacological action on the nervous system. Current psychotropic agents act as anxiolytics, antidepressants, hallucinogens and anesthetics. These compounds may reduce anxiety, relieve pain, and compensate for mental irregularities, but are also responsible for serious complications, including paralysis and death. The discovery of novel psychotropic agents which exhibit high potency and low toxicity remain in high demand. The present study aims to identify the psychotropic potential of novel organic compounds such as quinolone derived trifluoromethyl alcohols and 4-Methylcyclohexanemethanol (MCHM). The behavioral screening of MCHM and quinolone compounds revealed specific defects in motor activity of zebrafish larvae (5 dpf). Our data show that zebrafish larvae treated with MCHM and quinolone derivatives exhibit a reduction in motor activity in lower concentration (1-10uM) exposure. However, at higher concentrations (25uM) it results in loss of balance and failure to respond to touch. The reduction in motor activity is reversible and specific without any toxicity. Simple pharmacokinetic studies reveal that the effects were very rapid, sustained for the entire duration of exposure and reversible up to 72 hours without any toxicity. Further studies with ionic indicators such as CoroNa Green (labels Na^+) and DiH-MEQ (labels Cl^-) on larvae indicate that these compounds specifically block sodium channels on the mitochondria rich cells at 72 hpf. Therefore, our studies have identified some specific and novel organic compounds with profound and specific

pharmacological activity. We are currently characterizing other neuroactivity mechanisms of these compounds such as their ability to modulate other ionic transport channels.

Z6021C Vanderbilt Phenotypic Discovery Resource:Screening, Discovery, Crowdsourcing. *C. H. Williams*[1], C. C. Hong[1,2]. 1) Vanderbilt University, Nashville, TN; 2) Vanderbilt Univ. Med. Ctr., Nashville, TN.

Phenotypic changes are the ultimate cause of disease, whether the molecular pathology is multigenic, congenital, acquired or multifactorial. The result is that there are likely multiple modes to any given "treatment". Viability is the first phenotype observed in any organism, and arises from a complex interplay of signaling molecules across multiple cell and tissue types. Defects in these functional units form the basis of the phenotypic changes that result in disease. Phenotypic screening in zebrafish presents numerous advantages, including low cost, genetic tractability, aqueous drug delivery, and the biological in vivo features that preselect for favorable properties such as selectivity, target engagement and bioavailability. Here we describe a resource of compounds being screened that modulate critical nodes during embryonic development. These compounds will be associated into a chemotype-phenotype database that is publically available in an effort to crowd source discovery through the various stages of early drug development.

Z6022A Melanophore-iridophore interactions during adult pigment pattern maintenance in zebrafish. *E. J. Bain*, L. M. Saunders, D. M. Parichy. University of Washington, Seattle, WA.

Boundary formation and maintenance are critical aspects of multicellular development. These processes have been well studied in the embryo; however, boundaries must be maintained beyond embryonic stages into adulthood. The pigment pattern of adult zebrafish offers a tractable system in which to study post-embryonic boundaries. It consists of four to five dark stripes of black melanophores separated by lighter interstripes of yellow xanthophores and iridescent iridophores. Positive and negative interactions between pigment cell types are required to initiate and reiterate this pattern, but homeostatic roles of these interactions are not well understood. While iridophores help position and terminate melanophore stripes, melanophores prevent iridophore expansion into the stripe region. Using a temperature-sensitive allele, we experimentally manipulated melanophore numbers during boundary maintenance to query effects on iridophore patterning. We find that iridophores accumulate ectopically in stripe regions when melanophores die, and disperse when melanophores differentiate. These observations suggest that melanophores prevent iridophores from trespassing into stripe regions and signal their presence via some molecular cue. We have identified candidate genes for such signaling by RNA-Seq, and we are using conditional CRISPR/Cas9 mutagenesis to test roles for these candidates during stripe maintenance. These data will further our understanding of the molecular bases for post-embryonic boundary maintenance which can then be used to explore how defects in these mechanisms lead to boundary failure in the context of human disease.

Z6023B Using zebrafish to probe how Cdx transcription factors specify the posterior spinal cord. *Alana V. Beadell*, Robert K. Ho. University of Chicago, Chicago, IL.

Vertebrate *cdx* genes are members of the parahox gene cluster and are homologs of *Drosophila* Caudal. They are expressed in the posterior tissues of every major group of bilaterians, where they control growth and development of the posterior embryo. In zebrafish, and likely all vertebrates, Cdx homologs have acquired an additional role, namely, specification of the spinal cord: *cdx* genes are among the earliest expressed in the spinal cord territory during development and are necessary and sufficient for spinal cord fate within the zebrafish posterior neural plate. Additionally, unlike the brain and anterior spinal cord, cells of the posterior spinal cord are not specified by the end of gastrulation and instead must be continually generated and patterned from precursor cells within the tailbud as the embryo elongates. Work from our lab and others indicates that Cdx plays a key role in specifying/committing posterior cells to the posterior spinal cord fate, as well as maintaining the posterior growth zone itself from which the caudal tissues of the embryo emerge.

In this work, we ask: how does zebrafish Cdx4 specify/commit posterior cells to the spinal cord fate? Currently, we do not know at what step or steps, from precursor specification to neural differentiation, Cdx acts in this process. To understand the role of Cdx in posterior neural cell fate, we developed a scalable loss-of-function assay that takes advantage of the CRISPR/Cas9 system to generate F0, genetically mosaic loss-of-function zebrafish embryos. We use this assay, a powerful and efficient alternative to morpholino knockdown and akin to RNAi-based screens in other systems, to query a candidate gene list of Cdx4 direct and indirect effectors compiled from multiple high-throughput experiments. We have confirmed several candidates as expressed in the spinal cord, responsive to Cdx4 levels, and whose loss-of-function causes ectopic expression of hindbrain marker genes within the spinal cord territory as loss of Cdx4 does. Some of these candidates, like the helix-loop-helix protein Id1, are known regulators of neural differentiation; others, like the metalloproteinase Adamts18, are poorly characterized. In particular, we have found that mosaic knockdown of multiple components of the BMP signaling pathway also produce ectopic marker gene expression in our assay.

Creating mutant lines for some of these Cdx4 effector loci, we are further characterizing their role in posterior neural development. This work should shed light on the generation of posterior neural tissue from the multipotent stem cell-like niche within the vertebrate tailbud.

Z6024C A transcriptomics analysis of *tbx5a* and *tbx5b* during early fin and heart development. *Erin Boyle Anderson*, Robert Ho. University of Chicago, Chicago, IL.

Holt-Oram syndrome is a human condition that occurs in 1 in 100,000 births resulting in developmental defects in both heart and hand/arm. It is a result of haploinsufficiency due to a mutated copy of *TBX5*. Unlike humans, zebrafish have two copies of *tbx5*: *tbx5a* and *tbx5b*. Both Tbx5a and Tbx5b-deficient embryos display defects in heart and pectoral fin development. Although the role of Tbx5a in zebrafish fin development and the role of Tbx5 in heart and limb development in other animals has been well studied, much less is known about the roles

Tbx5b plays during zebrafish development.

From expression data and morpholino data, it appears that Tbx5a and Tbx5b have overlapping but distinct roles in the development of the fin and heart. The role of Tbx5b in the lateral plate mesoderm was investigated and compared to the previously characterized functions of Tbx5a. RNA-sequencing identified targets of Tbx5a and Tbx5b and allowed for an unbiased comparison and approach towards identifying differences between Tbx5a and Tbx5b function at multiple time points during lateral plate mesoderm migration. These transcriptomics methods reveal similarities and differences between Tbx5a and Tbx5b function that may be reflected in their transcriptional networks.

Z6025A Vegf signaling promotes vasculogenesis and arterial specification by upregulating Etv2 / Etsrp expression. *D. Satish Casie Chetty*[1,2], Megan S. Rost[1,2], Jacob Enriquez[1], Jennifer A. Schumacher[1], Kristina Baltrunaite[1], Andrea Rossi[3], Didier Y. R. Stainier[3], Saulius Sumanas[1]. 1) Cincinnati Children's Hospital, Cincinnati, OH; 2) University of Cincinnati College of Medicine, Cincinnati, OH; 3) Max Planck Institute for Heart and Lung Research, Bad Nauheim Germany.

Vasculogenesis involves the differentiation of vascular endothelial progenitors de novo from undifferentiated mesoderm, their migration and coalescence to form the major embryonic vessels and the acquisition of arterial or venous identity. Vascular Endothelial Growth Factor (Vegf) signaling has been implicated in regulating arteriovenous specification and overall vascular endothelial differentiation during embryonic vasculogenesis. However, it is not known how Vegf signaling results in different functional outcomes. Here we examined the role and mechanisms of Vegf signaling during vascular endothelial differentiation and arteriovenous specification in zebrafish embryos. Chemical inhibition of Vegf receptor (VegfR) signaling resulted in a loss of arterial specification and downregulation of overall vascular endothelial marker expression. Conversely, Vegfaa overexpression resulted in the expansion of arterial markers and increase in the overall vascular endothelial differentiation. Our results further suggest that Vegf signaling affects arterial differentiation by modulating the expression of the ETS transcription factor Etv2/Etsrp. *Etv2* expression was downregulated in VegfR inhibited embryos, while endothelial specific Etv2 overexpression was sufficient to rescue arterial marker expression in Vegf inhibited embryos. *vegfaa* genetic mutants, similar to VegfR inhibited embryos, displayed absent arterial differentiation and reduced numbers of vascular endothelial cells. These results argue that Vegf signaling plays two distinct roles during vasculogenesis, by promoting arterial specification and proliferation of vascular endothelial cells, and Vegf promotes arterial specification by upregulating Etv2 expression.

Z6026B Roles of RyR-mediated intracellular calcium mobilization in muscle development and function. *A. A. Chagovetz*, E. Ritchie, D. Gunther, M. Jurynec, D. Grunwald. University of Utah, Salt Lake City, UT.

The Ryanodine Receptor (RyR) intracellular calcium release channels (CRC) regulate release of calcium from intracellular stores in the ER/SR. Though expressed in many cell types, they are best known for their roles in muscle contraction; indeed loss-of-function mutations are associated with myopathy in humans. We propose this narrow view of the RyR function fails to account for the full range of phenotypes observed in humans carrying RYR1 mutations, which include slow muscle cell defects. Here we elucidate unexpected functions of RyR in the zebrafish embryo. Our lab has previously demonstrated multiple Hedgehog-dependent cell specification events, including generation of somite muscle cells and dorsal root ganglia, require RyR-mediated calcium mobilization. We report the results of our efforts to identify the specific combinations of *ryr* genes that support these developmental functions. We have i) reinvestigated the expression of *ryr* genes, ii) generated null *ryr* alleles, and iii) characterized phenotypes for single and compound mutants using a combination of histology, live imaging and behavioral assessments.

Z6027C Zebrafish *GCaMP6s* transgenic lines for imaging calcium activities *in vivo*. *J. Chen*, J. Li-Villarreal, L. Solnica-Krezel. Washington University School of Medicine, St. Louis, MO.

Intracellular calcium signaling plays important roles to regulate cell activity during embryogenesis and in adult organisms. In this study, we generate stable transgenic lines, *Tg[ßactin2:GCaMP6s]*^{stl351}to leverage the ultra-sensitive calcium indicator GCaMP6s together with the transparent characteristics of zebrafish embryos**,** for improved *in vivo* calcium imaging during early embryogenesis. During the cleavage stages, calcium signaling is associated with the cleavage furrow progression in zebrafish. We recently discovered that embryos lacking maternal and zygotic function of atypical cadherin *dachsous1b* (MZ*dchs1b)* display abnormal cleavages (Li-Villarreal et al., Development, 2015). Using the *Tg[bactin:GCaMP6s]*, we observed that MZ*dchs1b* embryos displayed various furrow positioning, propagation, and deepening defects at cleavage stages.

During the blastula stages, we detected higher frequency of calcium transients in the enveloping layer (EVL) cells, and a longer dorsal-biased calcium signaling window (3-5hpf) in the WT blastomeres compared with earlier studies. We further report the direct visualization of calcium signaling in the gastrula dorsal forerunner cells (DFCs), which are formed by ingression of dorsal surface epithelium cells at the margin in a Nodal signaling dependent manner. Interestingly, we found that excess Nodal signaling not only leads to the increased number of calcium transients, but also an increase of calcium transient duration specifically in the DFCs. Current studies are addressing whether embryos dorsalized by inhibition of BMP activity show altered pattern of calcium signaling in the EVL. We anticipate that the *GCaMP6s* transgenic lines described here offer a valuable addition to the zebrafish toolbox that will enable to visualize many more dynamic calcium events at embryonic and larval stages as well as in adult animals.

Z6028A Zebrafish *dyrk1aa*, an orthologue of human Down syndrome gene *DYRK1A*, plays a role in cerebrovascular development. *Hyun-Ju Cho*[1,2*], Se-yeol Yang[2], Kweon Yu[1,2,3], Jeong-Soo Lee[1,2,3]. 1) Korea Research Institute of Bioscience and Biotechnology (KRIBB), Daejeon, South Korea; 2) Korea University of Science and Technology (UST), Daejeon, South Korea; 3) Korea Institute of Science and Technology (KIST), Seoul,

South Korea.

Human *DYRK1A* is one of the crucial genes within the Down's syndrome critical region of human chromosome 21. DYRK1A has been implicated in neuronal development and neurodegenerative disorders, but its roles in the brain vascular development is not clear. Here we generated a zebrafish knockout mutant for *dyrk1aa* gene (*dyrk1aa*^{kbr1}), one of the two zebrafish orthologues of mammalian *DYRK1A,* using the TAL endonuclease technique. Approximately 30% of the length and branching points of the central arteries (CtAs) situated in the hindbrain were reduced in *dyrk1aa*^{kbr1} at 52hpf compared to the wild type (wt) control. Consistently, similar vascular defects were observed in a dose-dependent manner upon the treatment of harmine, a well-characterized DYRK1A inhibitor, while forced expression of *dyrk1aa* mRNA rescued CtA defects of *dyrk1aa*^{kbr1}. Overexpression of *dyrk1aa* mRNA in the wt background led to the increased length and branching points of CtAs, corroborating the role of *dyrk1aa* in promoting vascular formation in the developing brain. Currently we investigate the involvement of signaling pathways important for the *dyrk1aa*-regulated cerebrovascular development by examining expression patterns of candidate target genes and exploiting reporter transgenic lines. This study will reveal underappreciated roles of *dyrk1aa* in the vascular formation during cerebral development, and shed light on the vascular pathology in DYRK1A-related diseases including Down syndrome and Alzheimer's disease. .

Z6029B A morphogenetic role for FGF signaling in zebrafish cardiac looping and ballooning. *B. Christophers*, M. Grant, R. Burdine. Princeton University, Princeton, NJ.

Three of the most common forms of human congenital heart defects result from aberrant asymmetric cardiac morphogenesis. Using zebrafish as a model, we aim to better understand the links between cellular aberrations during heart morphogenesis and the resulting cardiac defects. To that end, we have investigated the role of Fibroblast Growth Factor (FGF) signaling, which is known to couple morphogenesis to cell migration events in zebrafish, in asymmetric heart development. We have uncovered a role for FGF signaling in dextral looping that is independent of its early role in establishing left-right asymmetry. We find that treatment of embryos with the FGFR inhibitor SU5402 during different time windows results in defective cardiac looping and ballooning. Treatment from 24-30hpf affects both the position of the heart chambers as well as their morphology; however, treatment from 30-36hpf affects chamber morphology without significantly impacting chamber positioning. We thus propose that FGF signaling plays two different roles during late cardiac development: the promotion of dextral looping and of chamber expansion. We will present data that define the role of the pathway during event. .

Z6030C Maturation of Photoreceptor Cells during Zebrafish Retinal Development. *Cátia Crespo*[1], Satu Kujawski[1], Daniele Soroldoni[2], Elisabeth Knust[1]. 1) Max Planck Institute-CBG, Dresden, Dresden, DE; 2) Department of Cell and Developmental Biology, UCL, London, UK.

Photoreceptor cells (PRCs) are a highly specialized type of neurons present in the retina, which are responsible for phototransduction. Vertebrate PRCs can be divided into rods, specialized for night vision, and cones, responsible for daylight and colour vision. In zebrafish, there are 4 different types of cones: green, red, blue and UV. Mature PRCs are polarized cells, with the apical surface subdivided into the outer and the inner segment and they arise from columnar epithelial progenitor cells.

PRCs have a highly specialized structure, which is essential for their function. Several studies have focused on the role of different proteins in PRC development and phototransduction. However, a detailed characterization of the morphological changes from the precursor stage to its functional form is lacking.

In this study, we aim to characterize the maturation of the apical surface of PRCs in zebrafish. We are performing a time course of the formation of the inner and outer segments and the connecting cilium using protein markers expressed in specific regions. We are also measuring cell volumes and cell lengths every four hours from the appearance of the PRC precursors to the matured stages using reporter lines specific for the *red* and UV sensitive *PRCs*.

We used Crb2a and Crb2b for labeling the inner segment. We found that in PRC precursors Crb2a localizes in the apical membrane of the cells, changing it's location to the sub-apical region of the incipient inner segment during the maturation process. Crb2b is also present in the sub-apical region of PRCs but it only starts being expressed when the inner segment is forming.

With this detailed characterization we aim to have a better understanding of the maturation process of the apical surface of PRCs. As a next step, we intend to use these methods to investigate the role of candidate proteins in PRC maturation.

Z6031A Regulation of canonical Wnt signaling activity by zebrafish Nup62l. *Zongbin Cui*, Xiaojie Yang. Institute of Hydrobiology, CAS, Wuhan, Hubei, CN.

Canonical Wnt signaling is one of intracellular signaling pathways that play crucial roles in vertebrate embryonic development, cell fate determination and maintenance of adult tissue functions. Activation of this pathway is closely associated with cytoplasmic degradation and nuclear accumulation of beta-catenin. Once transported into the nucleus, beta-catenin forms a complex with transcription factor LEF/TCF to drive the transcription of target genes. Currently, many proteins within the membrane, the cytoplasm and the nucleus are known to affect the intracellular localization of beta-catenin and thus control the activity of canonical Wnt signaling.

Nucleoporin p62 (Nup62)localizes in the central channel of nuclear pore complexes (NPCs) and regulates nuclear pore permeability and nucleocytoplasmic transport. Zebrafish Nup62-like protein (Nup62l) is a homolog of mammalian Nup62. The *nup62l* gene is maternally expressed, but its transcripts are ubiquitously distributed during early embryogenesis and enriched in the head, pharynx, and intestine of developing embryos. Activation of the Wnt/beta-catenin pathway positively modulates *nup62l* transcription, while Bmp signaling acts downstream of Wnt/beta-catenin signaling to negatively regulate *nup62l* expression. Overexpression of *nup62l* dorsalized embryos and enhanced gastrula convergence and extension (CE) movements. In contrast, knockdown of Nup62l led to ventralized embryos, an impediment

to CE movements, and defects in specification of midline organ progenitors. Mechanistically, Nup62l acts as an activator of Wnt/beta-catenin signaling through interaction with and facilitation of nuclear import of beta-catenin-1/2 in zebrafish. Thus, Nup62l regulates dorsoventral patterning, gastrula CE movements, and proper specification of midline organ precursors through mediating the nuclear import of beta-catenins in zebrafish.

Obviously, in-depth studies of mechanisms underlying the regulation of Wnt/beta-catenin signaling activity would reveal the asymmetric and tissue-specific activation of canonical Wnt signaling during early development in zebrafish and the activity of intracellular beta-catenin in pathological contexts.

Z6032B Opto-CRISPR : a new tool for genome editing at the single cell level. *B. Ducos*, W. Zhang, D. Bensimon. LPS-ENS, CNRS, Paris, FR.

The CRISPR-Cas9 system has recently emerged as an essential tool for genome editing, acting like genetic scissors to precisely abrogate or restore gene function, or transcribe specific targets. An important issue in deciphering gene regulation in time and space is to develop strategies for conditional gene expression. Usually this approach is based on transgenic lines where the expression of the genes of interest is under the control of tissue-specific promoters that can be switched on or off using drugs or heat. While much qualitative information on genetic networks have been obtained by that method, the lack of precise control of the concentration, location and timing of the gene products impair a quantitative analysis of the physiological response to such perturbations.

To overcome this gaps our lab has developed an optical method combining the use of conditional protein release via a protein-ERT fusion and a caged ligand, namely caged-cyclofen. Upon illumination with UV light (at 370nm) or with a two-photon laser beam, active cyclofen is released in the illuminated cell(s). It binds to the hormone binding domain of a truncated estrogen receptor (ERT) fused to the protein of interest which it releases from the complex it forms with cytoplasmic chaperones. If the protein of interest is a Gal4 transcription factor, it then diffuses to the nucleus, binds to its UAS promoter and turns on the gene of interest (in particular a Cas9 gene) and a fluorescent protein (CFP) reporter expressed as a bi-cistronic gene. This method allows us to specifically express Cas9 in live zebrafish in a controlled manner at given time and spatial location and to visualize the photoactivated cells.

We shall present results where we co-injected UAS:Cas9-T2A-CFP-Ubi:EosFP and gRNA for EosFP gene at one cell stage. Caged-cyclofen was UV activated at 256 cells and the embryos imaged at 24 hpf. CFP (blue) fluorescence was observed in the photoactivated cells and was negatively correlated with EosFP green fluorescence suggesting that in these cells Cas9 was active as indeed confirmed by T7 endonuclease analysis.

We have also developed a direct photo-switchable Cas9 by fusing its gene with ERT. In this context while Cas9 is continuously expressed, it is sequestered by cytoplasmic chaperones and quickly released at the single cell level upon cyclofen uncaging.

These new tools are currently developed as zebrafish transgenic lines offering the zebrafish community a powerful tool to investigate gene functions and networks (by crossing with relevant gRNA lines or by injections of appropriate gRNAs).

Z6033C Reverse genetics screening for uveal coloboma in zebrafish using CRISPR-Cas9 mediated genome editing. *S. Dutta*, B. P. Brooks. NEI/NIH, Bethesda, MD.

The vertebrate eye development begins with the symmetric, bilateral evagination of the diencephalon to form optic vesicle (OV). As development continues the OV invaginates to form bilayer optic cup, the invagination of OV is asymmetric and creates a gap in the ventral region of the developing eye, known as the optic fissure. To continue normal development, the two edges of this fissure must fuse. Any abnormality in the optic fissure closure results in a potentially blinding congenital ocular malformation known as uveal coloboma, account for 10% of childhood blindness. Several modes of inheritance have been documented, yet, most cases are sporadic, impeding effective genetic counseling for families affected by the disease. Although the embryology has long been understood, the genetic and developmental mechanisms behind optic fissure closure defects are still largely unknown.

CRISPR/Cas9 mediated genome engineering technology made it possible to perform targeted mutagenesis in a fast and economical way in zebrafish that facilitate large-scale phenotyping efforts in mutant embryos. We have used CRISPRs to generate knock out (KO) lines for previously described *nlz1* and *nlz2* gene that are necessary for normal optic fissure closure (1) and *nlz1* and *nlz2* CRISPRs KO embryos exhibited ocular coloboma (2). Genes that are dynamically regulated at the edges of the optic fissure during the process of closure are likely to be important for proper execution of this developmental process. Our lab identified 164 annotated genes dynamically regulated during optic fissure closure in the mouse using laser capture microdissection (LCM) and microarray (1), and the function of 90% of the genes during eye development are unknown. To understand the function of the genes expressed during optic fissure closure, we are generating CRISPRs KO zebrafish lines and screen for ocular coloboma, and other eye abnormalities in the KO embryos. In future our research will shed light into genes and genetic network that are crucial for optic fissure closure and eye abnormalities as well as to move forward in the genetic research of uveal coloboma.

Z6034A Tbx5a functions in migration of cardiac and forelimb precursors of the anterior lateral plate mesoderm in zebrafish. *L. Fong*, E. Boyle Anderson, H. K. Stinnett, R. K. Ho. University of Chicago, Chicago, IL.

The *tbx5a* mutant, *heartstrings*, has a lethal phenotype where the primary heart tube fails to loop during development and a pectoral fin is not formed. Our lab group has previously shown that cells within the anterior lateral plate mesoderm fail to converge in Tbx5a knockdown

conditions during limb initiation. We have hypothesized that during limb initiation, Tbx5a may play an early role in the ability of lateral plate mesoderm to migrate towards a localized signaling source of an Fgf molecule, namely Fgf24.

We have further elucidated a fate map for the Tbx5a-positive cells of the lateral plate mesoderm to include the heart tissues and have studied the dynamics of cardiac precursor migration using timelapse imaging. One interesting facet of this study is that the formation of the heart occurs asymmetrically, with looping of the heart tube towards the left side. We will report upon the specification and migration of the lateral plate mesoderm on the right versus left sides of the wild-type embryo during heart formation. Here we will also address whether cardiac precursors migrate topologically in a manner similar to limb bud precursors, or if the migration dynamics of the heart precursors are significantly different to those of the limb bud precursors.

Studying the dynamics of the migration in this process has generated several questions: Does Tbx5a have a similar early migration function in other systems such as cardiac precursors? Do similar ligand-receptor interactions found to play important roles during limb bud development also occur during the migration of heart precursors? Alternatively, could Tbx5a be affecting cell fate decisions within the anterior lateral plate mesoderm? To address these issues, we will also report upon the specification and migration of the lateral plate mesoderm precursors in Tbx5a knockdown embryos compared to wild-type embryos.

Z6035B Investigating role of breast tumor kinase/protein tyrosine kinase 6 (Brk/PTK6) during zebrafish development using TALEN-generated knockout alleles. *S. Foster*[1], S. Glover[1], A. Challa[1], K. Chatti[2]. 1) University of Alabama at Birmingham, AL; 2) University of Hyderabad Campus, Hyderabad, India.

Breast tumor kinase/protein tyrosine kinase 6 (Brk/PTK6) was initially discovered in a screen of tyrosine kinases overexpressed in metastatic breast cancer tissue. It is currently known to be expressed in several cancer types, and cell culture studies indicate a pro-oncogenic role for PTK6. PTK6-null mice are viable, but show hyperproliferation of colonic villi and hyperactivation of AKT. Contrasting evidence supporting a pro-apoptotic role of PTK6 has also been reported. In cultured non-cancer cells, PTK6 appears to sensitize the cells to inducers of apoptosis. The contrasting functions of PTK6 are likely to be a result of cell-type specific genetic interactions, biochemical regulation and environmental effects during oncogenesis. In order to gain a comprehensive understanding of the developmental role of PTK6 genes and to potentially explain their contrasting effects on cell growth and differentiation in vertebrates, we generated several indel alleles of the two zebrafish genes *ptk6a* and *6b* using TALENs. Our current findings suggest that homozygous mutant animals are viable presumably because these two genes complement each other, or because of maternal expression of the genes that can rescue the zygotic loss-of-function. Further characterization is underway to generate and analyze double mutants as well as maternal-zygotic mutant animals for each of these genes to identify any developmental roles.

Z6036C Temporal and spatial requirements for Nodal-induced anterior mesendoderm and mesoderm in anterior neurulation. *N. Gonsar*[1,2], A. Coughlin[1], J. A. Clay-Wright[1], B. R. Borg[1], L. M. Kindt[1], J. O. Liang[1]. 1) University of Minnesota, Duluth, MN; 2) Gustavus Adolphus College, St Peter, MN.

Zebrafish with defective Nodal signaling have a phenotype analogous to the fatal human birth defect anencephaly, which is caused by an open anterior neural tube. Previous work in our laboratory found that anterior open neural tube phenotypes in Nodal signaling mutants were caused by lack of mesendodermal/mesodermal tissues. Defects in these mutants are already apparent at neural plate stage, before the neuroepithelium starts to fold into a tube. Consistent with this, we found that the requirement for Nodal signaling maps to mid-late blastula stages. This timing correlates with the timing of prechordal plate mesendoderm and anterior mesoderm induction, suggesting these tissues act to promote neurulation. To further identify tissues important for neurulation, we took advantage of the variable phenotypes in Nodal signaling-deficient *sqt* mutant and Lefty1-overexpressing embryos. Statistical analysis indicated a strong, positive correlation between a closed neural tube and presence of several mesendoderm/mesoderm-derived tissues (hatching glands, cephalic paraxial mesoderm, notochord, and head muscles). However, the neural tube was closed in a subset of embryos that lacked any one of these tissues. This suggests that several types of Nodal-induced mesendodermal/mesodermal precursors are competent to promote neurulation.

Z6037A The Effect of Timing on Wnt Induced Neural Posteriorization. *D. Green*, A. Lekven. Texas A&M, College Station, TX.

During embryonic development morphogenic signaling gradients inform cells of their relative positions so that they may take on specific fates. There has been controversy in many models whether these signaling gradients are generated spatially, temporally or a combination of these. We have used the neural ectoderm of the zebrafish as a model to study the interface between spatial and temporal morphogen gradient signaling and its effect on cell fate in anterior posterior (AP) neural patterning.

In vertebrates, all neural ectoderm cells initially have an anterior fate. Through morphogenic signals, including Wnt's and Fgf's, the cells within the neural ectoderm are informed of their spatial position and take on specific fates along the (AP) axis. The primary morphogen of early neural posteriorization, *wnt8a,* is expressed in the blastoderm margin during epiboly. *wnt8a* generates a signaling gradient and posteriorizes the neural ectoderm in a dose dependent manner, with high doses inducing a more posterior fate. This signaling event occurs over roughly 4 $^{1/2}$-hour period that includes a large degree of dynamic cell movement as the cells of the blastoderm migrate towards the vegetal pole. How the timing and duration of the Wnt8a signal affects its ability to posteriorize the neural ectoderm is poorly understood. Of particular interest is how the different regions of the neural ectoderm change in response to the Wnt8a signaling gradient at different times during neural posteriorization.

To better understand the temporal aspect of Wnt8a's signaling gradient we have used heat shock inducible lines to analyze the response of the neural ectoderm to Wnt8a signaling during early neural posteriorization. Through comprehensive analysis of the temporal response to Wnt signaling we will determine how spatial and temporal factors can integrate to establish a morphogenic signaling gradient in development.

Z6038B Zebrafish Zic2a and Zic2b play redundant roles in brain, retinal and craniofacial morphogenesis. *Y. Grinblat*, L. Roberson, I. Sedykh. Univ Wisconsin, Madison, WI.

Human Zic2, a zinc-finger transcription factor, is strongly associated with holoprosencephaly (HPE), a malformation of the forebrain, and with a unique set of dysmorphic facial features. We have previously used knockdown assays to demonstrate critical roles for zebrafish Zic2 orthologs, Zic2a and Zic2b, in the developing retina, forebrain and craniofacial cartilages. To examine the mechanism of Zic2 function in more depth, we have generated compound *zic2a;zic2b* mutants and determined that embryos homozygous for mutant alleles at both *zic2a* and *zic2b* loci develop with retinal coloboma, aberrantly shaped ventricles and greatly reduced and disorganized craniofacial cartilage. In addition, mutant embryos present with periocular hemorrhages and edema suggestive of vascular malformations. To characterize the molecular consequences of Zic2 loss-of-function, we examined transcriptomes of *zic2a;zic2b* mutant embryos vs siblings using RNAseq. The resulting gene set identified several neural crest lineages, including but not limited to chondrogenic neural crest, as strongly dependent on Zic2 function. Among the candidate zic2 targets is a homeobox gene Alx1, which is expressed in neural crest and is required for both craniofacial and retinal morphogenesis in zebrafish. Moreover, human Alx1 has been linked to a severe form of frontonasal dysplasia. Based on these data, we hypothesize that Zic2 functions in neural crest lineages that contribute to craniofacial structures and regulate formation of adjacent structures, including the ventral retina. In-depth functional analysis of Alx1 and other candidate targets of Zic2 identified by RNA-seq will test this hypothesis, clarifying the mechanism of conserved Zic2 functions during vertebrate embryogenesis.

Z6039C Using diapause as a platform to dissect and understand various signaling pathways and regulatory mechanisms during early embryo development. *CHI-KUO HU*, Anne Brunet. Stanford University, Stanford, CA.

Many organisms encounter and overcome extreme condition which is not ideal for embryo development by diapause, a unique surviving approach by which embryos put all developmental processes in temporary arrest to live through an adverse environment. Although similar dormancies are widely observed among species, still little is understood about the underlying mechanical principles of diapause. It is especially intriguing that how distinct tissues and cells in different developmental programs can altogether be suspended at the same time, and if their developmental status/identity are maintained or modified during the 'suspended state' of diapause. Zebrafish is known to suspend its early embryo development when oxygen is deprived, but only for a short period of time (up to 24 hours). A similar but more significant case of diapause can be found in turquoise killifish *Nothobranchius furzeri*, which possess an ability to suspend embryonic development at the end of somitogenesis. Living in ephemeral ponds where water presents only during the brief annual rain seasons, newly laid killifish embryos prepare the coming drought by entering diapause for months, sometimes even years, until the ponds are refilled with water again in another rain season**.** This lengthy diapause in killifish is obligatory and can still occurs in lab conditions, providing a unique opportunity to study early embryo development and their crosstalk with diapause**.** Our transcriptome profiling revealed a dramatic shift of gene expression patterns at the transition between embryogenesis and diapause. Immediately after diapause entry, more than 35% of genes changed their expression levels for over 2 folds, indicating that diapause embryos were switching into a phase distinct to embryogenesis. With many antagonistic mechanisms upregulated, various embryonic developmental programs were either put on hold or erased in diapause. Key regulators of cell differentiation such as NeuroD1, and MyoD1 were heavily downregulated, and critical morphogens of embryogenesis such as Wnt and Fgf were mostly depleted. Interestingly, with developmental processes suspended in diapause, many general or tissue-specific genes related to stress tolerance, protection and homeostasis were highly expressed for already developed tissues, especially neural tube/crest and muscles. Overall, diapause provides a unique pausing point to further dissect and understand the developmental programs and their signaling pathways in early embryo development. The research in embryonic diapause not only provides insights of tissue and cell homeostasis during embryo development, but also a complementary platform for various known or ongoing zebrafish studies in early embryo developments.

Z6040A Immune cell-independent elimination of signaling-perturbed cells support robustness of early vertebrate embryogenesis. *T. Ishitani*, Y. Akieda. Kyushu University, Fukuoka, Fukuoka, JP.

Developmental systems possess robustness, which is the ability to maintain phenotypic stability in the face of diverse perturbations arising from environmental changes, stochastic events, and genetic variation. But molecular signaling systems that control embryonic development are sensitive to these perturbations. Therefore, developing embryos should equip the mechanisms for overcoming the signaling perturbation during development. However, such mechanisms have been well understood. Here we show that early vertebrate embryonic tissues have an ability to eliminate signaling-perturbed cells. To investigate how embryonic tissues overcome the signaling perturbation, we mosaically induced Wnt signaling-hyperactivated cells in early zebrafish embryos. Interestingly, these mosaically-induced abnormal cells underwent apoptosis in wild-type embryos, but not in APC- or GSK3-inhibited embryos in which Wnt signaling is hyperactivated in entire tissues, indicating that signaling-perturbed cells are eliminated from normal embryonic tissues and this elimination requires the existence of normal cells. These results also suggest the possibility that embryonic cells may sense the difference of signaling activity in neighboring cells and make decision whether the neighboring cells should be eliminated. This cell elimination must be immune cell-independent event because early embryos don't have immune cells. Importantly, Wnt signaling-hyperactivated cells-introduced normal embryos grew up almost normally, while inhibition of abnormal cell elimination severely disturbed embryonic development. It is suggesting that the signaling-perturbed cell elimination supports robustness of early vertebrate embryogenesis. Now we are exploring the detailed mechanisms that regulate the signaling-perturbed cell elimination. We'd like to show our recent progress of these studies.

Z6041B *unc119* genes are required for cilia function in zebrafish. *F. Jean*, D. Pilgrim. University of Alberta, Edmonton, Alberta, CA.

Unc119 proteins form a structurally distinct family composed of proteins that are strikingly conserved among all metazoans. Intriguingly, this

small family is implicated in diverse activities, including initiating the cellular immune response, promoting neural development in *C. elegans*, and coordinating signal transduction in mice. Despite these seemingly distinct roles, orthologues appear to be functionally interchangeable, suggesting that a common biochemical mechanism underlies each of these cellular processes and that redundancies may arise where paralogues exist.

A compelling unifying mechanism is intraflagellar transport (IFT), which is a protein trafficking system initially described in cilia. Cilia are microtubule-based protrusions from the cell body and are critically important for vertebrate organ function, body patterning and signalling pathways. IFT factors are additionally required for cellular processes unrelated to cilia, like those that involve Unc119 proteins. Since Unc119 proteins appear to be required for all cellular processes that rely upon IFT and have been shown to be required for trafficking, I propose that they are novel IFT factors. I hypothesize that the highly conserved Unc119 family proteins are previously unrecognized ciliary factors that promote proper cellular trafficking via the IFT machinery. To test this hypothesis, I am studying the cellular and phenotypic consequences of a loss of *unc119* genes using zebrafish.

Zebrafish have four paralogues of *unc119*, none of which have previously been studied in great detail in terms of cilia function. To begin, I wanted to determine whether any of the paralogues have a potential role in cilia by performing *in situ* hybridization. I found that each paralogue has a distinct expression pattern, although there is a large degree of overlap particularly in ciliated organs. To assay for ciliary phenotypes, I have been using CRISPR-Cas9 technology to create deletion mutations in each of the zebrafish paralogues. My preliminary results using morpholinos to target one of the paralogues (*unc119b*) have revealed that there are ciliary phenotypes (hydrocephaly, kidney cysts, l-r asymmetry defects), but these are milder and less penetrant than expected, which is consistent with redundancy between paralogues. Given the conserved nature of these genes and the overlap in expression between paralogues, it's possible that there is functional redundancy, which we will be testing using rescue assays. Thus far, we have shown that at least one of the paralogues is involved in cilia but it is likely that the other paralogues act similarly molecularly to affect cilia function.

Z6043A Cartilage development requires the function of Estrogen-related receptor alpha that directly regulates sox9 expression in zebrafish. *Y. Kim*, S. Bhandari, I. Nam, K. Yoo, R. Park, S. Choe. center for metabolic function regulation, Wonkwang Univ, Iksan, Jeonbuk, KR.

Estrogen related receptor alpha (ESRRa) regulates a number of cellular processes including development of bone and muscles. However, direct evidence regarding its involvement in cartilage development remains elusive. In this report, we establish an *in vivo* role of ESRRa in cartilage development during embryogenesis in zebrafish. Gene expression analysis indicates that *esrra* is expressed in developing pharyngeal arches where genes necessary for cartilage development are also expressed. Loss of function analysis shows that knockdown of *esrra* impairs expression of both *sox9* and *col2a1* and thus induces abnormally formed cartilage in pharyngeal arches. Importantly, we identify putative ESRRa binding elements in upstream regions of *sox9* to which ESRRa can directly bind, indicating that ESRRa may directly regulate *sox9* expression. Accordingly, ectopic expression of *sox9* rescues defective formation of cartilage induced by the knockdown of *esrra*. Taken together, our results indicate for the first time that ESRRa is essential for cartilage development by regulating *sox9* expression during vertebrate development.

Z6044B Characterisation of tail mutants in the self-fertilising mangrove killifish. *T. Kudo*[1], Hussein Saud[1], Brian Ring[2]. 1) University of Exeter, Exeter, Devon, GB; 2) Valdosta State University, Valdosta, Georgia, USA.

The mangrove killifish, Kryptolebias marmoratus and another related killifish species are only two known self-fertilising vertebrates. By making use of the self-fertilising ability, it is possible to isolate both zygotic and maternal mutant lines from this fish with one generation earlier than zebrafish and medaka allowing, much smaller scale and shorter process of mutant screening and maintenance. We have isolated two mutant lines that shows abnormalities in the tail development, R109 (short-tail/stl) and R228 (ball-tail/btl). At the somitogenesis stage, both mutants show normal length of the tail, but in the stl mutant, gene expression in the tail including sox3 (neural tube), col9a1b (notochord) and hsp90 (muscle) all reduce. The tail stop growing at late somitogenesis and regress. In the btl mutant, sox3 and col9a1b expression is normal but hsp90 is strongly suppressed suggesting the defect is specific to the tail somite muscle. We are currently mapping these mutations in the genome to identify the mutations and will report the progress of the mutation analyses in the meeting.

Z6045C Vitamin D receptor signaling is required to modulate BMP signaling during cranial cartilage development in zebrafish. *H.-J. Kwon*[1], B. B. Riley[2]. 1) Princess Nora University, Riyadh, Kingdom of Saudi Arabia; 2) Texas A&M University, College Station, TX.

Vitamin D, an essential regulator of calcium and phosphate homeostasis, is necessary for skeletal development. The active hormonal form of vitamin D functions through the vitamin D receptor (VDR), a member of the nuclear receptor family of transcription factors. The *vdr* mRNA and VDR protein are present in several cartilages of the skull in zebrafish embryos. To investigate the role of VDR on craniofacial cartilage development, *vdr* depletion experiments were performed. In zebrafish embryos, two distinct VDR genes (*vdra* and *vdrb*) have been identified. Knockdown of *vdra* has little effect on cartilage elements, whereas disrupting *vdrb* gene causes reduction and malformation of head cartilages. Remarkably, depletion of both *vdra* and *vdrb* produces more severe defects including complete loss of cartilage. These results strongly indicate that VDR signaling is essential for cartilage development in zebrafish. Previous studies in zebrafish revealed correct BMP signaling is required for cartilage formation in the skull. Interestingly, we show that knockdown of VDRs lead to increased expression of *fsta*, a BMP antagonist, in pharyngeal region around 36 hours post-fertilization. Taken together, these findings suggest that VDR may control cranial cartilage development by modulating BMP signaling.

Z6046A Development of left-right asymmetries in the vertebrate brain. *I. Lekk*, A. Faro, C. Stern, S. Wilson. University College London, London, GB.

While most of the bilaterian body is symmetrical with respect to the midline, a few functions have evolved to be concentrated on one (left or right) side. Although long thought to be a human-specific characteristic, it is now clear that lateralisation of the brain is an evolutionarily conserved mechanism to add layers of complexity to brain function and enable lateralised behaviour within the population. Here, to shed light on how brain asymmetries arise during vertebrate development and to what extent underlying molecular mechanisms are conserved within different species, zebrafish and chick embryonic epithalamus has been studied. By two-photon laser ablations, cell transplants and high-resolution imaging, we find that the exact timing of regulation by the parapineal – a small left-sided group of cells in the zebrafish epithalamus – is essential for the establishment of overt molecular and anatomical asymmetries described in the the adjacent habenulae. However, whole-mount *in situ* hybridisation, RT-PCR and qPCR experiments show no apparent asymmetries in gene expression patterns of chick epithalamus. Since no region equivalent to parapineal has yet been discovered in birds, it is likely that the anatomical and functional asymmetries found in the epithalamus of vertebrates such as fish, reptiles and amphibians, result from the emergence of a parapineal or a parapineal-like organ during evolution.

Z6047B Roles of PGE2 signaling pathway in ciliogenesis and organ development. *Wenyan Li*[1], Quan Zhao[1], Daqing Jin[1], Tao P. Zhong[1,2]. 1) State Key Laboratory of Genetic Engineering, Department of Genetics, School of Life Sciences, Fudan University, Shanghai, 200438, China; 2) Department of Medicine, Vanderbilt University School of Medicine, Tennessee 37232, USA.

ABSTRACT: Cilium, a microtubule-based organelle protruding from the cell surface, has crucial roles in embryonic development and human physiology. Our lab reveals that Prostaglandin E2 plays a significant role in ciliogenesis and organ development. Based on these results, we hypothesize that key components in PGE2 signaling pathway participate in cilia formation and function. We have generated *ptgs1*, *ptgs2a*, *ptger4a* and *ptger4b* mutants using CRISPR/Cas9 technique in zebrafish. These homozygous mutants can survive into adulthood. We are currently in the process of constructing double mutants to eliminate functional redundancy in ciliogenesis. To understand the conserved ciliary roles of PGE2 signaling in mammalian models, we analyzed cilia-associated phenotypes of *ptger4*-deficient mouse. Our study shows that mouse embryonic fibroblasts (MEF) display deficiency in *ptger4* receptor. Furthermore, *ptger4*-deficient mouse exhibit ciliogenesis defects and abnormal development of lungs, kidneys and tracheas. Together, these findings indicate the conserved regulation of PGE2 in mammalian ciliogenesis.

Key words: Prostaglandin E2 ciliogenesis *ptger4* zebrafish mouse .

Z6048C Probing how cell sorting refines developmental patterning. *Z. Liu*, O. Weiner. University of California, San Francisco, San Francisco, CA.

The final developmental pattern of multicellular organisms is extraordinarily precise, with sharp boundaries between cell types that can be as fine as a single-cell layer. Although morphogen gradients that direct cell fates can be quite defined, development operates on a background of substantial variability due to intrinsic stochasticity in cell fate specification and active migration of cells within the morphogenic field. Cell sorting is thought to enable systems with initially noisy fate specification to generate robust final patterns. In the early zebrafish embryo, an initially mixed mesendodermal population ultimately resolves into distinct mesodermal and endodermal cell layers, but how this precise patterning is achieved is not understood. Previous studies demonstrated that induced endodermal cells transplanted to ectopic locations can still sort into the endogenous endodermal domain. Here, we aim to understand how this sorting behavior is achieved and how cell sorting enables pattern refinement during endodermal morphogenesis.

We experimentally introduced positional errors by first overexpressing the constitutively activate Nodal receptor TARAM-A* to induce endoderm fate and then transplanting these cells to the animal pole of a wild type embryo, which normally gives rise primarily to ectoderm. We then used whole embryo imaging to track the transplanted cells. Consistent with previous reports, we found that these ectopically introduced endodermal cells preferentially migrate to the correct endodermal layer, but surprisingly, these cells did not follow the normal endodermal migration pattern of epiboly and involution. Instead, they appeared to take a short-cut by radially ingressing into the inner layer. We propose that this ingression ensures that cells that may arrive at the margin late can still find a path into the inner layer, thus increasing the precision of the first step of endoderm formation. Currently we are exploring the informational sources of such directionality. By examining contractility based extrusion of the surrounding cells and membrane protrusions of ectopic endodermal cells, we will be able to determine the underlying mechanisms of the ingression based sorting behavior, and thus further our understanding of the largely unexplored frontier of how cell sorting facilitates the robustness of multicellular development.

Z6049A The requirement of cell-matrix interactions for planar cell polarity and convergence and extension. *A. Love*, J. Jessen. Middle Tennessee State University, Murfreesboro, TN.

Integral to convergence and extension movements during development, the planar cell polarity (PCP) pathway is a non-canonical Wnt pathway that regulates the coordinated movement of cells within a tissue plane. During zebrafish gastrulation, defects in core PCP proteins such as Vangl2, encoded by the *trilobite* gene, result in failed convergence and extension cell movements. As a result, *vangl2*/*trilobite* mutant embryos have hallmark phenotypes, including a shortened and broadened dorsal body axis. Previous work from the Solnica-Krezel lab showed that mesodermal cells in *vangl2*/*trilobite* mutant embryos do not follow the intended path of collective migration to the dorsal axis for proper embryonic development, instead these cells lack directionality. In other work, the Jessen lab demonstrated that *vangl2*/*trilobite* mutant embryos also exhibit an increase in matrix metalloproteinase activity and a decrease in the extracellular matrix (ECM) protein fibronectin. Given

that cells in *vangl2/trilobite* mutant embryos are characterized as having inappropriate membrane protrusive activity, we hypothesize that these embryos have defective cell-matrix interactions necessary for proper protrusion formation. Integrins are transmembrane receptors for many ECM proteins, including perhaps the most prevalent ECM protein in the zebrafish gastrula, fibronectin. Integrins control dynamic interactions between the cell's actin cytoskeleton and its surrounding matrix. It is well known that mesenchymal cell migration begins with protrusion at the leading edge, adhesion to ECM, and stabilization; at which time, cell body movement occurs as the rear cell adhesions are released. Using whole-mount in situ hybridization and confocal microscopy, we are characterizing the relationship between cell-matrix interactions and the PCP pathway. We have shown that *vangl2/trilobite* mutant embryos are sensitive to loss of integrins a5, aV, and b1 function. Moreover, we find that loss of fibronectin in *vangl2/trilobite* mutant embryos results in only a subtly enhanced convergence and extension phenotype, indicative of decreased sensitivity to loss of fibronectin. These preliminary results are consistent with the notion that *vangl2/trilobite* mutants have decreased total fibronectin. Ongoing experiments address the effects of disrupted cell-matrix interactions on the establishment of planar cell polarity at the cellular level.

Z6050B Sox2 and canonical Wnt signaling co-regulate multipotent tailbud progenitors. *B. L. Martin*, Yu-Jung Tseng, Richard Row. Stony Brook University, Stony Brook, NY.

Tailbud progenitor cells contribute to multiple tissues of the lengthening post-gastrula vertebrate embryo. Recent evidence shows that these cells continue to make germ layer decisions after gastrulation, contrary to long-held dogma. Wnt signaling and the transcription factor Sox2 are known regulators of these cells, and we have found an unexpected interaction between these two pathways.

The tailbud is a conserved structure in vertebrate embryos, formed at the posterior-most end of the body axis after gastrulation completes. Multiple progenitor cell pools are maintained in the tailbud, and these cells are continuously specified to different germ layer fates. In zebrafish the posterior-most progenitors make an ectoderm/mesoderm fate decision, primarily contributing to the neural tube or somites respectively. Wnt signaling and the transcription factor Sox2 are potent regulators of this fate decision. Undifferentiated progenitors express *sox2* and reside in a region of active Wnt signaling. Cell fate is specified when a cell receives only one of the two signals. Sox2 is considered to have a pro-neural function in this context while Wnt specifies a mesodermal fate. Both signals can antagonize the activity of the other, likely serving to lock in a fate decision when the balance tips to one side within a cell. We use transgenic zebrafish that allow inducible overexpression of *sox2* or manipulation of Wnt signaling to understand the role of these signals in tailbud progenitors.

We found an unexpected role for Sox2 in regulating the behavior of mesoderm-fated cells: Sox2 prevents the maturation program of these cells from progressing. A further surprising result is that Sox2 can respecify some mesoderm-fated cells to a neural fate. Precise regulation of Sox2 and Wnt levels is crucial both for maintenance of tailbud progenitors and for proper maturation of mesoderm-fated cells.

Z6051C Zebrafish *ambra1a* and *ambra1b* silencing affects heart development. *G. Meneghetti*[1], T. Skobo[2], N. Facchinello[1], P. Bonaldo[2], F. Cecconi[3], L. Dalla Valle[1]. 1) Department of Biology, University of Padua, Italy; 2) Department of Molecular medicine, University of Padua, Italy; 3) Department of Biology, University of Rome Tor Vergata, Italy.

In zebrafish two paralogous genes, *ambra1a* and *ambra1b*, both required for the autophagic process and during development, encode the protein Ambra1, a positive regulator of early steps of autophagosome formation. As evidenced by whole mount *in situ* hybridization (WMISH), both transcripts are expressed in the heart-forming region. In this work, we analyse the *ambra1a* and *ambra1b* knockdown effects on heart development by means of morpholino oligonucleotides (MOs). Silencing of the two proteins by ATG-MOs affects heart morphogenesis resulting in a small, string-like heart with pericardial edema, whereas treatment with SPLIC-MOs does not result on clear cardiac phenotypes, indicating the importance of maternally supplied *ambra1* transcripts. Co-injection of both ATG-MOs determines a more severe phenotype with a prominent pericardial edema. Cardiac defects are effectively rescued by co-injection of MOs with human *AMBRA1* mRNA showing the conservation of Ambra1 functions during evolution. WMISH of *myosin light chain 7* (*myl7*) transcripts as well as confocal analysis of *ambra1a* and *ambra1b* morphants of the transgenic line Tg-myl7:egfp reveal, at 24 hpf, defects in the heart jogging process followed by imperfect cardiac looping with a high percentage of 48 hpf embryos in which the heart is organized as a linear tube. Moreover, WMISH of *pitx2* transcripts, which at the 21-somite stage are expressed on the left plate mesoderm, reveals both bilateral or reversed expression of this gene in both *ambra1* morphants indicating that *ambra1* silencing interferes on heart laterality.

3-dpf WT and morphants purified hearts were used for expression analysis of developmental heart markers by means of qPCR. This analysis shows a differential expression not only between WT and morphants hearts but also between *ambra1a* and *ambra1b* morphants. In fact, while *atrial* and *ventricular myosin heavy chain*, as well as *gata5* transcripts present a general down regulation in both types of morphants, the expression of other cardiac markers, such as *nkx2.5* and *hand2,* is up regulated only in *ambra1b* morphants. Although both *ambra1a* and *ambra1b* genes appear to be involved in heart development, the different expression pattern suggests the possible acquisition of specific functions by the two paralogous genes.

Z6052A Eph-ephrin signaling maintains the boundary of the embryonic left-right organizer during laterality development in fish. *A. Meng*, J. F. Zhang, Z. Jiang, X. Liu. Tsinghua University, Beijing, CN.

The kupffer's vesicle (KV) is the so-called left-right organizer in teleost fishes. KV is formed from dorsal forerunner cells (DFCs) and generates asymmetrical signals for breaking symmetry of embryos. It is unclear how DFCs or KV cells are prevented from intermingling with adjacent cells. In this study, we show that the Eph receptor gene *ephb4b* is highly expressed in DFCs while the ephrin ligand genes including *efnb2b* are expressed in cells next to the DFCs cluster during zebrafish gastrulation. *ephb4b* knockdown or mutation and *efnb2b* knockdown cause dispersal of DFCs, a smaller KV and randomization of laterality organs. The DFCs often dynamically form blebs, filopodia and lamellipodia at the

interface, which attempt to invade but are bounced back by adjacent non-DFC cells during gastrulation. Upon inhibition of Eph-ephrin signaling, however, the repulsion between DFCs and non-DFC cells is lost, allowing DFCs to migrate away. Ephb4b/efnb2b signaling by activating RhoA activity mediates contact and repulsion between DFCs and neighboring cells during gastrulation, preventing intermingling of different cell populations. Therefore, our data uncover an important role of Eph/ephrin signaling in maintaining DFCs boundary and KV boundary for normal left-right asymmetrical development.

Z6053B Transcriptional Regulation of Neural Plate Patterning by Wnt Signaling through the Sp1 family of Transcription Factors. *Saurav Mohanty*, Arne Lekven. Texas A & M University, College Station, TX.

Wnt signaling has a conserved role in anterior-posterior (A/P) patterning of the remarkably complex vertebrate brain from a very basic primordium, the neural plate, by differentially expressing downstream target genes to induce distinct neural fates. Wnt proteins originate from the blastoderm margin and diffuse anteriorly to re-pattern the default state of the anterior neural tissue to more posterior fates. How this graded Wnt ligand in the neural plate is translated by responding cells to establish specific cell fate zones along the A/P axis is not well established. In order to understand neural posteriorization by Wnt better, we need to identify the downstream components of this pathway, for instance, the transcriptional targets of wnt signaling and their subsequent roles. We are currently focussing on two direct targets of Wnt/b-catenin signaling in Zebrafish, the *sp5* and *sp5-like* genes. These paralogous genes potentially play an important role in mediating Wnt-dependent posterior neural plate patterning.

The *sp5* genes encode zinc finger transcription factors and transcriptional regulation of *sp5* orthologs by Wnt signaling is conserved in vertebrates. In spite of the compelling evidence of a significant and evolutionarily conserved relation between the *sp5* genes and Wnt signaling in vertebrates, function of these genes and how they induce changes downstream of the Wnt pathway to pattern the vertebrate brain is not understood properly. We are currently studying the in vivo functions of *sp5* genes by mutant analysis, utilizing the CRISPR-Cas9 genome editing tool to generate zebrafish *sp5* and *sp5l* mutant lines. We are examining the regulation of these genes by Wnt signaling and other signaling pathways through analysis of transgenic zebrafish sp5 reporter lines developed in our lab. Finally, we want to understand how Wnt signaling regulates the transcription of several target genes downstream through the sp5 transcription factors, to pattern the neural plate during embryogenesis.

Z6054C Biomechanics of zebrafish gastrulation. *A. Mongera*, E. Shelton, D. Kealhofer, A. Lucio, P. Rowghanian, F. Serwane, O. Campas. UCSB, Santa Barbara, CA.

Morphogenesis is traditionally regarded as the implementation of multiple genetic programs regulating cell differentiation rather than a complex biomechanical process involving cell-generated forces and tunable mechanical properties of the tissue. It has been shown that mechanics controls not only massive cellular rearrangements, as observed during gastrulation, but also pathological changes in tissue shapes such as those found in neoplastic transformation. *In vivo* measurements of endogenous forces and local mechanical properties during gastrulation are crucial to understanding how collective cellular movements arise during morphogenesis. Employing novel techniques that use fluorescent oil micro-droplets as *in vivo* force transducers and actuators, we quantify the spatiotemporal patterns of both forces and mechanical properties (tissue elasticity and fluidity) in different cell populations of the zebrafish embryo. Furthermore, we show that cell adhesion, cortical tension, and extracellular matrix composition affect different mechanical parameters in the tissue. The quantitative description of the embryonic force fields and the local mechanical properties will enable a better understanding of the interplay between signaling and mechanics, which in turn will facilitate the development of treatments for diseases, such as cancer, by restoring normal mechanical conditions within the tissues of interest.

Z6055A Role of Snail1b in migration of Posterior Lateral Line primodium. *U. M. Neelathi*[1], A. B. Chitnis[2]. 1) NIH, Bethesda, MD; 2) NIH, Bethesda, MD.

Authors Uma M Neelathi and Ajay B Chitnis

Collective cell migration, is an important event in embryonic development, wound healing and cancer metastasis. Posterior Lateral line primodium (PLLp) presents an excellent model for studying collective cell migration. Its a group of 100 cells, from ectodermal placodes behind the otic vesicle migrates along the horizoantl myoseptum depostiing neuromasts at regular intervals, which constitutes the lateral line sensory system. While the leading PLLp cohort maintain mesenchymal cellualrity thorugh Wnt signaling. The trailing epithelial cell types are conferred via a Wnt dependant Fgf signaling, which are organised into rossettes that are deposited as neuromasts. Factos, which make the pseudo epithelial to mesemchymal transition of the primodium cells during migration, are not known. Expression analysis of various mesenchymal genes by RNA in situ, identified Snail1b in the leading doamin at 22hpf when primodium initiates its migration. Snail1b is positively regualted by Sdf1a in the leading domain and negatively by Fgf singaling in the trailing domain. Morpholino based loss of function of Snail1b cause a delay in initiation and reduced speed of migration of PLLp compared to the controls. The delay in initiation and rate of migration is though imbalance between the Wnt and Fgf signaling systems in the PLLp. Absence or a total loss of migration of PLLp could possibley due to partial knockdwon of Snail1b or by other compensatory complementary genes. Our data suggest that Snail1b is necessary in breaking the symmetry of Wnt signaling and giving in way for Fgf signaling to estbalsih and initiation of the primodium migration.

Z6056B The formation of dorsal axial structures in zebrafish requires the activity of a homolog of the *Drosophila* gene *squid*, which regulates dorsal patterning in flies. *M. L. O'Connell*, L. J. Pasick, N. Maglakelidze, D. M. Ferrer. The College of New Jersey, Ewing, NJ.

In *Drosophila melanogaster* the hnRNA binding protein Squid is required during oogenesis and early embryogenesis for the earliest patterning

events in the embryo. In particular, specific isoforms of the Squid protein bind to and regulate the localization and translation of the *gurken* mRNA, which codes for a TGFa-like growth factor required for proper dorsal/ventral and anterior/posterior patterning of the egg and future embryo (Kelley, R., *Genes & Dev* 7:948, Norvell, A. et al., *Genes & Dev* 13:864). While the orientation of the dorsal/ventral versus anterior/posterior and left/right axes in invertebrate embryos is reversed relative to that of vertebrate embryos, at the molecular level there is clear conservation of many regulatory genes and paradigms. In fact, the expression of key genes required for dorsal/ventral patterning is exactly reversed in the two groups of embryos. In light of the tremendous conservation this demonstrates in the molecular regulation of bilateral symmetry across divergent taxonomic groups, we have analyzed a family of four genes in zebrafish that are the most closely related fish genes to fly *squid*, based on an NCBI BLAST search. In zebrafish, the mRNAs for all four fish genes (zsqdA-zsqdD) are maternally provided, suggesting that – like their fly counterpart – the fish proteins likely play a role in embryogenesis. Furthermore, we provide evidence that the mRNA for zsqdA (gene symbol: hnrnpaba), which shares the greatest sequence homology to fly *squid*, is translationally controlled via cytoplasmic polyadenylation at a particularly interesting stage during embryogenesis. This would result in the zsqdA protein being produced soon after the MBT and just before the formation of the earliest dorsal tissues (the shield). Finally, inhibition of zsdA translation via morpholino injection specifically disrupts early neurogenesis and the formation of axial structures such as the somites. Therefore, it appears that the zsdaA gene in zebrafish is not only homologous in sequence to *Drosophila squid*, but also in function.

Z6057C Development of the second pharyngeal pouch in zebrafish; Interface of discrete developmental systems. *K. Okada*[1,2], S. Takada[1,2,3]. 1) OIIB, Okazaki, Aichi, Japan; 2) NIIB, Okazaki, Aichi, Japan; 3) SOKENDAI, Okazaki, Aichi, Japan.

Pharyngeal Arches (PA) are segmental structures, which are bilaterally arranged in the pharynx of all vertebrate embryos. During the segmentation of PAs, the pharyngeal endoderm plays a prominent role to organize each PA by means of reiterative outpocketings called Pharyngeal Pouches (PPs). In gnathostome (jawed vertebrate), the first and second pouches (PP1 and PP2) are concurrently formed earlier than the posterior PPs. On the other hand, the PPs posterior to PP2 are sequentially formed in an anterior to posterior order. Additionally, previous studies in several vertebrate species have clearly shown the mechanisms controlling PP1-2 and PP3-6 development are different. Thus, distinct segmentation systems for the anterior and posterior PPs appear to cooperate in the generation of the complete set of PPs. However, it remains to be elucidated how these distinct systems are coordinated to integrate properly in PP development. Here, we focus on the development of PP2, which develops near the interface point of the two systems. Time-lapse recording and lineage tracing of endodermal cells in transgenic zebrafish showed that the prospective rostral and caudal halves of PP2 are generated in separate locations in the endoderm and then fused together forming PP2. In concordance with morphological observations, the pattern of gene expression throughout PP development supports the idea that there exists two distinct cell populations in PP2. For example, *nkx2.3*, which is a common PP marker gene, was expressed separately in the rostral and caudal halves before PP2 maturation. We also examined the PP phenotypes of zebrafish mutants for several genes, which were generated using the CRISPR/Cas9 system. Interestingly, we found that in some cases, in PP2, only the rostral- or caudal-half development is impaired. Furthermore, the caudal-half development of PP2 was disrupted by the inhibition of retinoic acid signaling, which is required for the segmentation of PP3-6, in spite of this the rostral half of the PP2 was almost normal. These results suggest that discrete segmentation systems are independently established, and subsequently fused to generate the PP2. This hybrid type of PP organization may have contributed to the evolution of the oropharyngeal system in gnathostomes by segregating the feeding component (mandibular and hyoid arches) from the gill region. Our findings also illustrate the drastic alteration of the developmental mechanisms of the PA, which is the most conserved phylotypic structural characteristic within vertebrates.

Z6058A The role of TGFβ member Gdf3 in left-right patterning. *J. Pelliccia*, R. Burdine. Princeton University, Princeton, NJ.

The proper placement of organs in vertebrates is dependent on the expression of *nodal* in the left lateral plate mesoderm (LPM). For this to occur in zebrafish, the expression of the nodal ortholog *spaw* needs to be activated in the left LPM and inhibited in the right LPM. Bilateral expression of nodal (i.e. expression in both the left and right LPM) or expression in the right LPM leads to aberrant organ placement. We have focused on understanding the role of Gdf3 in the proper expression of *spaw*. Gdf3 is a TGFbeta ligand whose mRNA is present during the stages of mesoderm and endoderm patterning and during the stages of left-right patterning in zebrafish embryonic development. Using morpholinos against *gdf3*, we have identified a dual role of *gdf3* in left-right patterning. Both in the expression of *spaw* and in the proper development of the laterality organ in zebrafish called Kupffer's vesicle (KV). Our data suggest that *gdf3* is required for proper temporal expression of *spaw* in the lateral plate mesoderm and for the proper asymmetric expression of *dand5*, a *spaw* inhibitor needed to prevent *spaw* expression in the right lateral plate mesoderm. The aberrant development of KV in these *gdf3* morphants was likely the cause of the irregular expression of *dand5*. Additionally, our attempts at making mutants using CRISPR/Cas9 technology have been rewarded with potential *gdf3* zebrafish mutants that exhibit defects in mesoderm and endoderm formation. These defects are also attributed to previously identified mutations in two other *nodal* orthologs called *cyclops* and *squint*. Collectively, our initial findings indicate that *gdf3* is important for mesoderm and endoderm patterning in early development and it may then be subsequently required for proper left-right patterning .

Z6059B The zebrafish *specter* mutant: a role for Cyclin B1 in early embryogenesis. *T. Petrachkova*, L. Bakke, A. Bard, J. Singh, R. M. Warga, D. A. Kane. Western Michigan University, Kalamazoo, MI.

Cell division is controlled by genes that regulate the cell cycle. Here we show that the zebrafish mutant *specter* (*spr*) is a mutation in *cyclin B1*, a gene necessary for the G2 to M transition of the cell cycle. The *spr* mutant phenotype becomes visible by the 7-somite stage as subtle differences in the head-to-tail ratio. Initial studies showed that the *spr* mutant arrests with a body shape at roughly midsegmentation and eventually exhibits signs of massive cell death in the nervous system. Investigation of the nervous system reveals that *notch1b* and *deltaA* are

more weakly expressed in neural stem cells that give rise to fewer, but bigger neuronal precursors. Likewise blood markers reveal mutant embryos also have fewer but bigger blood cells.

The *spr* mutation was mapped to the zebrafish *cyclin B1* gene. Sequencing showed a transition (C139T) that causes a nonsense mutation in exon 2 of the *cyclin B1* gene. *In situ* analysis revealed that *cyclin B1* mRNA is absent in the mutant embryo by the end of gastrulation suggesting that *spr* is a loss of *cyclin B1* function. Phospho-histone-3 antibody staining showed that the cell cycle is abnormal in the mutant embryo. The expression of the Dual FUCCI transgene in live *spr* mutant embryos confirmed that cells are delayed in the S/G2/early M phase of the cell cycle. We confirmed that *spr* is a mutation in *cyclin B1* using CRISPR/Cas9 mediated germline mutagenesis. This produced a mutation that failed to complement the original mutant allele confirming that the absence of CyclinB1 causes the mutant phenotype. Interestingly, the CRISPR *cyclin B1* mutation expresses morphological changes that are more severe and can be detected earlier. Phospho-histone-3 antibody staining and the expression of the Dual FUCCI transgene in the live CRISPR *spr* mutant embryos suggested that the cell cycle abnormalities are more severe: very few cells enter mitosis, and a majority of the cells remains in the S and G2 phase of the cell cycle. *In situ* hybridization of *cyclin B1* revealed that mRNA transcripts are still present in the CRISPR mutant and reverse transcriptase/PCR showed variable mRNA sizes. These results suggest that the new mutation is possibly a splicing variant that causes a gain-of function mutation, although we have yet to identify an obvious dominant phenotype.

We conclude that the *spr* mutant phenotype is caused by the mutation in the cell cycle gene *cyclin B1*, an essential regulator of the cell cycle progression from the G2 to M phase of the cell cycle. This leads to mitotic abnormalities, such as delayed cell cycle progression, developmental arrest, and activation of apoptotic pathways.

Z6060C Investigating the role of cadherin-mediated cell adhesion during planar cell polarity. *D. Prince*, J. Jessen. Middle Tennessee State University, Murfreesboro, TN.

Planar cell polarity (PCP) describes the coordinated polarization of cells or cell structures within the plane of a tissue and is an essential process of embryogenesis. For zebrafish gastrula cells engaged in directed cell migration, PCP is defined as the elongation and mediolateral alignment of each cell with respect to the dorsal embryonic axis. Loss of PCP protein function disrupts membrane protrusive activity, cell elongation and orientation resulting in misshapen embryos. Mutations in the Wnt co-receptor *glypican4/knypek* cause embryos to have a pronounced convergence and extension phenotype characterized by a shortened and broadened body axes. For many types of collective or group cell migration events, it has become clear that the movement of polarized cells requires regulation of cell-cell adhesion. Rapid remodeling of cadherin-mediated cell adhesion allows dynamic changes in cell coupling while maintaining coherent movement of cell populations. However, though cadherins are often required for collective cell migration, their molecular relationship with the PCP pathway is not well understood. Previous research by the Jessen laboratory showed that *glypican4/knypek* mutant embryos have increased cell surface expression of cadherin. Moreover, *glypican4/knypek* mutant embryos have increased cell-cell adhesion and increased fibronectin fibrillogenesis. We have now shown that loss of Glypican4 function affects the cell surface level of both E-cadherin (Cdh1) and N-cadherin (Cdh2). We hypothesize that Glypican4 function and Wnt/Frizzled PCP signaling regulate the endocytosis of Cdh1 and Cdh2. Indeed, we find that *glypican4/knypek* mutant embryos are sensitive to *rab5c* knockdown. Current efforts are aimed at further understanding the molecular mechanism connecting Glypican4 function and cell surface cadherin levels and determining the role of cadherin-mediated cell adhesion in establishing planar cell polarity.

Z6061A Tbx20 is an essential regulator of cardiomyocyte proliferation in zebrafish. *L. Raphel*[1], W. Rottbauer[2], S. Just[2]. 1) University of Ulm, Ulm, Baden Wuettemberg, DE; 2) University Clinic Ulm, Clinic for Internal Medicine 2, Albert Einstein Allee 23, Ulm, Germany.

Cardiac diseases continue to be one of the major causes of death worldwide. Ischemic heart disease such as myocardial infarction can result in an irreversible replacement of healthy, contractile heart tissue with a non-contractile, collagen-rich fibrotic scar. As the intrinsic proliferative capacity of adult cardiomyocytes is limited, future therapeutic approaches to mend ischemic heart diseases can hugely benefit from a better understanding of the regulatory mechanisms involved in cardiomyocyte proliferation.

Searching for novel regulators of cardiomyocyte proliferation, we isolated the mutant zebrafish line *weiches herz (whz)* in an ENU mutagenesis screen. *Whz* mutant embryos exhibit a cardiac phenotype, with a thin ventricular myocardial layer. Positional cloning identified a missense mutation in the *tbx20* gene as cause for the *whz* phenotype.

Although, *tbx20* mRNA was not found to be down-regulated in *whz* mutant embryos, we found a severe reduction in Tbx20 protein levels. This suggests that the *whz* mutation leads to destabilization and subsequent degradation of Tbx20 in *whz* zebrafish embryos. Furthermore, injection of a morpholino antisense oligonucleotide against *tbx20* mimicked the *whz* phenotype, confirming that the *whz* mutation causes a loss of Tbx20 function.

Interestingly, counting of cardiomyocytes in *whz* mutant ventricles revealed significantly reduced numbers of cardiomyocytes compared to wild-type littermates at 72 hours post fertilization. To assess whether decreased cardiomyocyte numbers is due to less cardiomyocyte precursors in the Anterior Lateral Plate Mesoderm, we evaluated the cardiac precursor cell population by *cmlc2*-specific *In situ* hybridization at 14 and 20 somite stages. We found no reduction of cardiomyocyte precursors in *whz* mutant embryos, suggesting that impaired cardiomyocyte proliferation later during cardiogenesis might account for reduced cardiomyocyte numbers in *whz* mutants. To address this question, we performed EdU staining at 72 hours post fertilization to measure proliferating cardiomyocytes in *whz* embryos and found that indeed cardiomyocyte proliferation was severely reduced in the mutant embryos compared to the wild-type littermates. We also performed TUNEL staining to analyze the apoptosis in our *whz* mutants and found no difference in cell death compared to the wild-type littermates.

Taken together, our data indicate that the loss of *tbx20* in zebrafish embryos result in a reduced number of cardiomyocytes caused by impaired proliferation of cardiomyocytes.

Z6062B Cytoskeletal regulation by *racgap1*: required for more than just cytokinesis. *S. E. Richards*, R. M. Warga, D. A. Kane. Western Michigan University, Kalamazoo, MI.

Cytokinesis is tightly regulated by the actions of a key protein complex known as centralspindlin. Composed of two dimers of mitotic kinesin-like protein MLKP1 and the Rho family GTPase-activating protein RacGAP1, centralspindlin positions and assembles the actomyosin ring driving furrow ingression and coordinates abscission. Like in files and worms, cells in the zebrafish *racgap1* mutant*, ogre* (*ogr*), become binucleate and even quadnucleate during early development. Although cytokinesis fails, development proceeds albeit somewhat abnormally. Here we present evidence that RacGAP1 plays significant roles in other cellular processes independent of cytokinesis during development. Using confocal microscopy, we show that cell junctions in the mutant are disorganized; further inspection of the membrane reveals that β-catenin is no longer sequestered at the plasma membrane and instead is mislocalized to the cytoplasm. These results suggest that *racgap1* may have a function in cell adhesion. To investigate this hypothesis further, we created double mutants with *half baked* (*hab*), carrying a mutation in the cell adhesion protein E-cadherin. Previously, we have shown that *hab* mutants have a zygotic maternal dominant effect that is expressed when both zygotic and maternal genomes are heterozygous for the mutant locus. These *hab*(-/+) embryos display an epiboly phenotype that is less severe than that of its homozygous mutant siblings; unlike the homozygous mutants, the heterozygous population is able to recover. Embryos that are *ogr(-/-);hab(-/+)* show a delay in epiboly that is more marked than *hab*(-/+) heterozygotes alone; interestingly, these double mutants display a distinctive, repetitive start and stop pattern that is unlike either the heterozygous or homozygous *hab* mutant. Supporting the idea that like E-cadherin, RacGAP1 regulates cell behavior by maintaining cell adhesion, we analyzed the collective migration of the dorsal forerunner cells (dfc) and found that *ogr*(-/-);*hab*(-/+) embryos have a greater tendency than *hab*(-/+) embryos for the dfc to break apart into three or more clusters. Therefore cells appear to be less adhesive when both *racgap1* and E-cadherin are compromised. Our results also indicate that RacGAP1 may have a role in regulating the cytoskeletal framework surrounding the nucleus for when *ogr*(-/-)*;hab*(-/+) embryos eventually reach somatogenesis, they develop a unique nuclear morphology. We conclude that the effects on cytokinesis have obscured the pleiotropic roles of RacGAP1 in mediating other cellular processes and that in particular it may be required for regulating the cytoskeleton at the cell surface and possibly at the nuclear membrane.

Z6063C Roles of RyR-mediated intracellular calcium mobilization in tissue patterning during development. *Erin Ritchie*, Alex Chagovetz, David Grunwald. University of Utah, Salt Lake City, UT.

The Ryanodine Receptor (RyR) intracellular calcium release channels (CRC) regulate release of calcium from intracellular stores in the ER/SR. Though expressed in many cell types, they are best known for their roles in muscle contraction; indeed loss-of-function mutations are associated with myopathy in humans. We propose this narrow view of the RyR function fails to account for the full range of phenotypes observed in humans carrying *RYR1* mutations, which include slow muscle cell defects. We are interested in understanding how each of the *ryr*s contributes to development and behavior. We have generated null *ryr* mutants in each of the genes that contribute to skeletal muscle function in zebrafish. Our results show *ryr1a* appears to be specific to slow muscle fibers, while *ryr1b* and *3* seem to be fast muscle specific. Surprisingly, both *ryr1a* and *ryr3* are dispensable, and we are interested in how calcium release during muscle contraction and behavior are affected. We have used GCaMP6 to visualize calcium fluctuations in both slow and fast muscle fibers for null *ryr* mutants. Muscle contractions are electrically stimulated and imaged using a SPIM microscope. Behavioral assays have also been used to characterize the phenotypes of single and combinations of *ryr* mutants. Our preliminary results indicate: First, animals lacking the RyR isoform specific to slow muscle fibers have no functional slow muscle, exhibit altered movement behaviors as embryos and adults, and are fully viable in the laboratory. This has given us a probe to investigate the role of this subset of muscle. Second, *ryr* mutants have defects in muscle cell differentiation in addition to defects in muscle contraction. Third, triple mutants that are completely paralyzed have distinct malformations in craniofacial development that are wholly secondary to loss of muscle contractility.

Z6064A Gpr15 Adhesion GPCR is an essential component of the Wnt/Planar cell polarity signaling during zebrafish early development. *I. Roszko*[1], X. Li[2], D. Sepich[1], F. Marlow[2], L. Solnica-Krezel[1]. 1) Washington University School of Medicine, Saint Louis, MO; 2) Albert Einstein college of Medicine, Bronx, NY.

Planar cell polarity (PCP) signaling has been shown to be essential for the polarization of mesenchymal cell behaviors during vertebrate gastrulation. Convergence and extension gastrulation movements narrow the embryonic tissues mediolaterally while extending them in the anteroposterior direction. These movements are driven by polarized directed migration and intercalation of mediolaterally elongated cells. Zebrafish mutants carrying mutations in or overexpressing the core Wnt/PCP proteins present impaired mediolateral cell polarization and movements leading to phenotypically shorter and broader embryos. We have identified the G-protein coupled receptor protein Gpr125/Adgra3 as a novel modulator of the Wnt/PCP pathway. We showed that Gpr125/Adgra3 protein is able to recruit the core Wnt/PCP component Dishevelled (Dvl) to cell membrane subdomains and to promote the localization of Frizzled7 (Fzd7) and Glypican 4 into these subdomains. Molecular analyses demonstrated a direct interaction of Gpr125 intracellular domain with Dvl. Using TALEN technology, we generated *gpr125* mutants. Whereas zygotic indel *gpr125* mutants do not exhibit any visible gastrulation defects, mutants lacking both maternal and zygotic *gpr125/adgra3* function show mild C&E defects and consequently shorter and wider embryonic bodies. *gpr125/adgra3* mutants show a strong genetic interaction with the *vangl2* and *scribble1* mutants. These results indicate an essential role for Gpr125 during early embryogenesis. Gpr125/Adgra3 is a seven pass transmembrane protein with a long N terminal and C-terminal fragment. The specific functional domains of Gpr125/Adgra3 regulating particular morphogenetic behaviors as well as the downstream signaling partners are unknown to date. The results of ongoing analyses of the MZ*gpr125/adgra3* mutants and the Gpr125/Adgra3 protein's functional domains will be presented.

Z6065B Loss of SET- and MYND-domain-containing protein 1a (SMYD1a) leads to sarcomeric disorganization in zebrafish. *S. Rudeck*, W. Rottbauer, S. Just. University Hospital, Ulm, Baden-Württemberg, DE.

Assembly, maintenance and renewal of sarcomeric units require highly organized and balanced folding, transport, modification and degradation of sarcomeric proteins. However, mechanisms that regulate these fundamental processes are only poorly understood, but of great clinical importance, since many cardiac and skeletal muscle diseases are associated with defective sarcomerogenesis.
The mutant *flatline* (*fla*) shows disturbed sarcomere assembly exclusively in heart and fast-twitch skeletal muscle. We identified a nonsense mutation within the *SET- and MYND-domain-containing protein 1* gene (*smyd1b*) to be responsible for the *fla* phenotype. Smyd1b localizes to the sarcomeric M-line, where it associates with myosin. Moreover, the zebrafish genome contains a second highly conserved *smyd1*-orthologue, *smyd1a*, which has minor importance for myofiber organization. We found that *smyd1a* mRNA, similar to *smyd1b*, is strongly expressed in skeletal muscle cells and to a weaker extent in the embryonic heart. To characterize the *in vivo* function of *smyd1a*, we performed a morpholino-mediated knock-down of *smyd1a*, which leads to a cardiac defect accompanied by progressive reduction of ventricular contractility. To investigate whether the observed cardiac defects are caused by defective specification of cardiomyocytes, we performed a MF20/S46 immunostaining and found normal specification of atrial and ventricular cardiomyocytes. Furthermore, MF20 staining of *smyd1a* morphants revealed disorganization of skeletal muscle sarcomeres. To assess whether the observed sarcomeric disorganization is caused by impaired skeletal muscle development, we further investigated the expression of myoG and myoD by performing *in situ* hybridization and found no alteration compared to controls, indicating that loss of Smyd1a function does not affect early skeletal muscle development. To compare the localization of the different *smyd1*-orthologues, we generated transgenic lines using a heart and skeletal muscle specific *unc45b*-promoter followed by *smyd1a*- or *smyd1b-gfp* fusion constructs. Interestingly, both orthologues, Smyd1a and Smyd1b localize in an alternating pattern to α-actinin, indicating M-band localization, and implying that both proteins might have redundant functions. To evaluate this hypothesis, we performed rescue experiments by injection of *smyd1a*- or *smyd1b*-mRNA into *fla* mutant oocytes. Remarkably, *smyd1b* deficiency was functionally and structurally rescued by ectopic expression of either *smyd1a*-mRNA or *smyd1b*-mRNA, demonstrating redundant roles for Smyd1a and Smyd1b regarding the control of sarcomere organization in zebrafish.

Z6066C Identification of neuromast disruptor compounds through *in vivo* screening in zebrafish . *Rachna Sachanandani*[1], Savini Thrikawala[1], Cliff Stephan[2], Nghi Nguyen[2], Mary Sobieski[2], Richard Judson[3], Jan-Åke Gustafsson[1], Maria Bondesson[4]. 1) Department of Biology and Biochemistry, CNRCS, UH, Houston, TX; 2) Center for Translational Cancer Research, Texas A&M Health Science Center, IBT, Houston, TX; 3) National Center for Computational Toxicology, Office of Research and Development, US EPA, Research Triangle Park, NC; 4) Department of Pharmacological and Pharmaceutical Sciences, UH, Houston, TX.

Many industrial chemicals, such as pesticides, are released into the environment without a full assessment of their adverse effects on human life and the ecosystem. We aim to understand the developmental toxicity effects of environmental pollutants by using the vertebrate zebrafish (*Danio rerio*) as a model to identify neuromast disruptors. The zebrafish lateral line responds to the flow of water via receptors called neuromasts, which consist of a cluster of hair cell surrounded by a ring of supporting cells and innervated by sensory neurons. Neuromasts are positioned along the zebrafish body through migration of the neuromast primordium formed in the head region. The same family of chemokine receptors that are responsible for neuromast migration also guide metastasis of certain cancer cells (Galardo et al., Disease Models & Mechanisms (2015) 8, 565-576). Transgenic zebrafish embryos expressing fluorescent markers in neuromasts were used to visually monitor neuromast development under normal and perturbed conditions using the control compounds AG1478 and VPA. Next, these embryos were used in a primary high throughput screen (HTS) of 309 (294 unique) compounds of the ToxCast phase I chemical inventory, primarily consisting of pesticides and antimicrobials. This generated a list of 48 hits that altered neuromast development and/or migration. These hits were re-screened with a higher number of replicates to characterize effects and to determine the lowest effect levels (LELs). A univariate analysis was performed to identify ToxCast *in vitro* assays that significantly correlated with the identified *in vivo* neuromast disruptors. In addition, the effect of IT1t, which has been shown to inhibit the metastasis of MDA-MB-231 cells *in vivo* (Tulotta, C. et al. Disease models & mechanisms (2016) 9, 141-153), was tested on neuromast migration. To further investigate the connection between cancer metastasis and neuromast migration, we investigated the effects of neuromast disruptors on the migration of MDA-MB-231 cells. In conclusion, our results identified several environmental pollutants with neuromast disrupting capacity, suggesting that the developing zebrafish embryo is an efficient *in vivo* model that can be used for identification of compounds interfering with cell migration.

Z6067A Intracellular calcium release by Ryanodine Receptors is required for Hh-dependent cell formation and gene expression. *D. K. Shaw*, M. Jurynec, K. Hoshijima, D. Gunther, D. J. Grunwald. University of Utah, Salt Lake City, UT.

The Hedgehog (Hh) pathway has indispensable functions in development and tissue homeostasis. Hh ligand acts as a morphogen, signaling across developmental fields creating a gradient that leads to patterned cell differentiation. Proper differentiation depends on slight differences in ligand concentration; therefore, small fluctuations in ligand or modulations of signaling efficiency have significant impacts on development and homeostasis. This work focuses on characterization of a new and unexpected modulator of this pathway, the intracellular mobilization of calcium via Ryanodine Receptors.

Ryanodine receptors (RyRs) mediate release of calcium from intracellular stores contained in the endoplasmic/sarcoplasmic reticulum and the nuclear envelope. We have found that disruption of RyR function in the zebrafish embryo causes loss or reduction of Hh-dependent muscle, neurons, spinal cord precursors and fins in a manner consistent with reduced Hh signaling. Furthermore, blocking RyR function reduces Hh-dependent gene expression. **My hypothesis is that intracellular calcium release from RyRs is necessary for proper Hh signal transduction.**

In future experiments, we will visualize ciliary and cytoplasmic calcium dynamics during periods of Hh signaling *in vivo* in zebrafish. Additionally, we are currently using novel gene targeting in zebrafish to generate a *Smo-mCherry* targeted knock-in fusion protein that will

allow us to visualize Hh component trafficking in real-time. We will visualize Smo trafficking defects upon depletion of RyR function. Our ultimate goal is to determine where in the Hh pathway RyR function is required.

Z6068B Zebrafish Marcksb regulates dorsoventral axis formation by controlling BMP secretion. *Yonghua Sun*, Xiaosi Wang, Ding Ye, Changyong Wei, Houpeng Wang. Institute of Hydrobiology, CAS, Wuhan, China.

Bone Morphogenetic Proteins (BMPs) plays a pivotal role in dorsoventral (DV) patterning during early embryogenesis. Myristoylated alanine-rich C kinase substrate (MARCKS), a major substrate for protein kinase C, has been shown to regulate cell motility and membrane trafficking. Here, we show the essential role of Marcksb in zebrafish DV patterning. There are 4 MARCKS family genes, *marcksa*, *marcksb*, *marcksl1a* and *marcksl1b* in zebrafish genome, and *marcksb* is the only one showing maternal expression. Knockdown of *marcksb* but not the other 3 MARCKS family members resulted in dorsalization, and the dorsalization defects could be partially rescued by overexpression of each of the 4 genes. The overall BMP signaling activity was strongly reduced in the *marcksb* morphants, as revealed by analysis of BMP targets and phosphorylated Smad1/5/8 levels. Furthermore, Bmp2b-induced ventralization was blocked by knockdown of *marcksb*, indicating that Marcksb is required for proper BMP signaling. Mechanically, we found that the mCherry-fused Bmp2b proteins were largely reduced at ex-cellular space in *marcksb* morphants comparing to wildtype embryos, suggesting that the proper secretion of Bmp2b was disrupted in *marcksb* morphants. We generated maternal-zygotic mutants of *marcksb* (MZ*marcksb*) using TALEN technology. Although *marcksb* is transcriptionally silent in MZ*marcksb*, defects of DV patterning was not observed in those embryos. In contrast to the *marcksb* morphants, the MZ*marcksb* embryos showed strong upregulation of *marcksa*, *marcksl1a* and *marcksl1b*. This suggests that genetic compensation effects occurred when *marcksb* was genetically absent. Therefore, our findings reveal a novel function of *marcksb* in DV patterning possibly by regulating the secretion of BMP ligands.

Z6069C Role of MK2/TTP pathway in early development and innate immunity in zebrafish. *B. Tandon*, GM. Young, SGDLT. Canny, MC. Gustin, DS. Wagner. Rice University, Houston, TX.

The p38 mitogen-activated protein kinase (MAPK) pathway is involved in many important cellular processes, including cell growth, cell survival and immune response. Previous work done in our lab shows that p38 pathway plays an important role in early development in zebrafish. p38 MAP kinase activates MAP-kinase-activated protein kinase (MK2)/*betty boop (bbp)*. Embryos from mutant *mk2a*/*bbp* females undergo dramatic constriction and lysis of yolk cell at 50% epiboly. Preliminary data from this project suggests that *mk2a* negatively regulates the activity of zebrafish homolog of an RNA binding protein Tristetraprolin (TTP), which in turn regulates mRNA degradation and translational repression of target mRNAs by binding to AU-rich elements (AREs) in the 3' untranslated region (UTR). We have identified putative TTP targets expressed in the yolk cell and have developed an in vivo assay to investigate the regulation of gene expression by elements in the 3' UTR.

MK2/TTP pathway is not required for early development in mammals. Instead, it's involved in inflammatory response by regulating production of important immune modulators like TNF- α and GM-CSF. Embryonic zebrafish offers unique advantages over other systems, including the transparency of larvae and the lack of adaptive immune responses for the first few weeks after hatching. Here, we use zebrafish as a model to explore the role of MK2/TTP in regulation of different components of innate immunity in their interaction with the fungus *Candida albicans.*

We hypothesize that the ancestral role of MK2 in innate immunity is conserved and that a novel function in regulating yolk cell gene expression evolved within the actinopterygian linage to regulate gene expression in the newly evolved yolk cell.

Z6070A The regulatory subunits of calcineurin differentially direct zebrafish brain development. *Robert Thorn*, Danielle Clift, Robbert Creton. Brown University, Providence, RI.

Calcineurin, a serine/threonine phosphatase that is integral for immune function has been a target for immunosuppressant drugs for decades. Use of calcineurin inhibition drugs during pregnancy is of particular concern since little is known about the effects of cyclosporine during brain development. We have previously shown that exposing zebrafish embryos to cyclosporine, a calcineurin inhibitor, has led to decreased brain size in larval zebrafish. The current studies have examined the specific role of calcineurin in the developing zebrafish brain. Zebrafish embryos were injected with varying levels of morpholinos against one of the two regulatory subunits of calcineurin (ppp3r1a or ppp3r1b). Brain sizes were assessed at 3 days post fertilization (dpf) and behavioral tests were performed at 5 dpf. At 'medium' injection levels the ppp3r1a morpholino showed a decrease in all measured brain regions, the ppp3r1b morpholino injected embryos showed only a decrease in the midbrain size. In addition, we found a significant decrease in zebrafish brain size when embryos were injected with 'low' levels of both morpholinos together, but separate injections of each morpholino showed no difference at these levels. 'Low' injection embryos underwent behavioral testing and showed abnormal social behavior in the ppp3r1a and ppp3r1b injected larvae. Additionally, ppp3r1b injected larvae were hypoactive compared to controls and ppp3r1a injected, while the ppp3r1a exhibited less thigmotaxis behavior compared to the controls and the ppp3r1b injected larvae. These results suggest an integral role of calcineurin during early brain development in zebrafish. The results also suggest that the calcineurin regulatory subunits have different roles in behavioral development during early zebrafish development.

Z6071B Regulation of cell shape changes during brain morphogenesis. *M. R. Visetsouk*, R. Garde, S. Sahu, C. Kwas, J. H. Gutzman. University of Wisconsin-Milwauke, Milwaukee, WI.

In the developing vertebrate brain, the boundary separating the midbrain from the hindbrain forms through a highly conserved folding of the neuroepithelial tissue, known as the midbrain-hindbrain boundary (MHB) constriction. During MHB formation, cells at the constriction shorten and narrow before basally constricting and apically expanding to form a sharp fold in the tissue. We previously determined that two isoforms of

the actin cytoskeletal motor protein, non-muscle myosin II (NMII), differentially regulate cell shape, with non-muscle myosin IIA specifically regulating cell length and non-muscle myosin IIB specifically regulating cell width. Non-muscle myosin II proteins are tightly regulated via the phosphorylation of their associated myosin regulatory light chains; however, the upstream signaling pathways that initiate differential regulation of NMII-mediated cell shape during midbrain-hindbrain boundary morphogenesis are not known. Our current studies have revealed that calcium signaling is critical for the regulation of cell length, but not cell width, during midbrain-hindbrain boundary formation. In particular, manipulation of cytosolic calcium levels resulted in abnormal midbrain-hindbrain boundary cell length and inhibition of cytosolic calcium rescued the cell length phenotype observed in embryos with over activation of non-muscle myosin II. In addition, we found that calcium signals mediate phosphorylation of myosin light chain in the midbrain-hindbrain boundary region. In addition, we have found that *wnt5b,* which is expressed specifically at the MHB during the time of morphogenesis, is an upstream regulator of cell width. 2D Differential Gel Electrophoresis also revealed that Wnt5b potentially regulates tubulin levels, implicating a novel role for microtubules in this process. Together our findings suggest that modulation of myosin activity by calcium and Wnt5b are critical for proper regulation of cell length and cell width at the MHB to determine embryonic brain shape. We further hypothesize that these mechanisms may be conserved and critical for shaping other epithelial cells and tissues throughout development.

Z6072C Fascin actin-bundling protein 1 is required for trafficking and signaling of TGF-β type I receptors during endoderm formation. *Qiang Wang*[1], Zhaoting liu[1], Guozhu Ning[1], Ranran Xu[1], Yu Cao[1], Anming Meng[2]. 1) Institute of Zoology, Chinese Academy of Siences, Beijing, Beijing, CN; 2) School of Life Sciences, Tsinghua University, Beijing, Beijing, CN.

Microtubules function in TGF-β signaling by facilitating the cytoplasmic trafficking of internalized receptors and the nucleocytoplasmic shuttling of Smads. However, nothing is known about whether actin filaments are required for these processes. Here, we report that zebrafish actin-bundling protein *fscn1a* is highly expressed in mesendodermal precursors and its expression is directly regulated by TGF-β superfamily member Nodal signaling. Knockdown or knockout of *fscn1a* leads to a reduction of Nodal signal transduction and endoderm formation in zebrafish embryos. Fscn1 specifically interacts with TGF-β type I receptors, and its depletion disrupts the association between receptors and actin filaments and sequesters the internalized receptors into clathrin-coated vesicles. Therefore, Fscn1 acts as a molecular linker between TGF-β type I receptors and the actin filaments to promote the trafficking of internalized receptors from clathrin-coated vesicles to early endosomes during zebrafish endoderm formation.Our findings indicate that *fscn1a* and Nodal signaling promote endoderm formation through a positive feedback loop and may allow for a better understanding of how TGF-β signaling is elevated in Fscn1 overexpressed metastatic tumors.

Z6073A Bmp3 is a novel regulator of neural crest cells and ocular fissure closure. *S. A. Widen*, P. Desai, O. J. Lehmann, A. J. Waskiewicz. University of Alberta, Edmonton, AB, Canada.

Proper development of the vertebrate embryo requires fusion of epithelial cell sheets, resulting in closure of the developing neural tube, palate and retina. Within the eye, failure of the ocular fissure to close results in ocular coloboma. Together with the etiologically related disorders microphthalmia (small eyes) and anophthalmia (no eyes), coloboma represents up to 11% of all pediatric blindness. Previous work from our laboratory and others has defined a key role for Bone Morphogenetic Protein (BMP) signaling within the retina in regulating ocular fissure closure. Outside the retina, a population of neural crest cells known as periocular mesenchyme (POM) migrates to the ocular fissure sites and is required for fissure closure, although our understanding of the mechanism remains limited. Here we identify a novel regulator of ocular fissure closure: *bmp3*. Exome and Sanger sequencing of 480 patients with coloboma has identified five with variants in *BMP3*, three of which are in the mature domain and predicted to damage protein function. The high degree of conservation at these residues, and absence of such variants in exome databases and control samples, demonstrates the likely pathogenicity of these mutations. Studies in cultured cells demonstrate that the identified BMP3 variants have altered activity *in vitro*. In zebrafish, morpholino inhibition of Bmp3 results in small eyes and fissure closure defects, implicating this ligand as a key regulator of eye morphogenesis. *bmp3* is an intriguing candidate as it is not expressed within the eye, but in cells immediately anterior to the eye, unlike any previously identified BMP ligand. Intriguingly, knockdown of Bmp3 activity causes defects in cranial neural crest cell development and fewer POM cells surrounding the eye. We hypothesize that *bmp3* is a novel factor that governs neural crest cell development. Consistent with this, *bmp3* has been previously implicated in craniofacial development. To test this hypothesis in a *bmp3* null, we have used the CRISPR-Cas9 system to generate a frameshift mutation that results in a premature stop codon upstream of the mature domain of Bmp3. Current studies are focused on defining neural crest and ocular phenotypes in a *bmp3* mutant background and elucidating the molecular mechanisms underlying Bmp3 function in neural crest development.

Z6074B MiR-145 regulates liver development through Progranulin A signaling in zebrafish. *Jen-Leih Wu*, Ya-Wen Li, Yen-Hsing Li. Academia Sinica, Taipei, TW.

The liver is an essential metabolic organ that maintains numerous vital functions in the body. The regulatory mechanisms of hepatogenesis are complex, involving many growth factors and transcription factors across three stages- hepatic specification, differentiation and outgrowth. miRNAs are known to be important genetic regulators in development. Less is known about which miRNAs participate in embryonic hepatic outgrowth. Dysregulation of miR-145 has been shown to promote pathological liver growth. However, the regulatory mechanism of miR-145 in embryonic liver development remains unclear. In this study, we demonstrated a significant decrease in miR-145 expression during hepatogenesis. We modulated miR-145 expression in zebrafish embryos using a miR-145 mimic or a miR-145 hairpin inhibitor. Impaired embryonic liver morphogenesis was observed in response to altered miR-145 expression. We further confirmed a critical role of miR-145 in hepatic outgrowth, but not in liver specification and differentiation, by whole-mount *in situ* hybridization. Loss of miR-145 expression

promoted hepatic cell proliferation, and vice versa. Our previous studies identified a growth factor, Progranulin A (GrnA), which regulates zebrafish hepatic outgrowth through MET signaling. We further revealed that GrnA is a target of miR-145 and MET signaling is also regulated by miR-145, which was verified by luciferase reporter assay and gene expression analysis. In addition, co-injection of GrnA mRNA with miR-145 mimic or MO-grnA with miR-145 inhibitor could restore the liver defects caused by dysregulation of miR-145 expression. In conclusion, our findings identified a functional role of miR-145 in zebrafish hepatic outgrowth through regulating GrnA signaling. This mechanism may be a new therapeutic target for liver failure and liver cancer.

Z6075C A family of FOX genes determines precise spatial patterns of growth and differentiation within craniofacial skeleton. *P. Xu*, B. Balczerski, A. Ciozda, G. Crump. University of Southern California, Los Angeles, CA.

FOX genes encode a large family of winged helix/forkhead transcription factors that have been shown to play multiple roles during development. While mutations in a number of FOX genes are known to cause craniofacial defects, how members of this large family coordinate development of the craniofacial skeleton remains unclear. In situ analyses in mice have led to the proposal that FOX genes form a complex expression code, much like the Dlx or Hox genes, that pattern the craniofacial primordia, yet this model remains to be tested at the functional level.

In this study, we find that the homologous FOX genes of zebrafish (*foxc1a*, *foxc1b*, *foxd1*, *foxd2*, *foxf1*, *foxf2a, foxf2b*, *foxl1 and foxl2*) are also expressed in distinct patterns within the neural-crest-derived pharyngeal arches that are the precursors to the facial skeleton. By manipulating major signaling pathways, we show that these distinct expression patterns result from differential sensitivity of FOX enhancers to Hh, Fgf, Bmp and Edn1 signaling. This suggests that FOX genes act as integrators of multiple signaling cascades in the cranial preskeletal mesenchyme. Next, we use knockout mutants and conditional transgenic misexpression approaches to show that FOX genes are required in patterning and growth of cartilage in distinct regions of the developing face, suggested that FOX genes act in region-specific manners to regulate the development of craniofacial primordia.

In summary, our evidence in zebrafish supports a model in which different members of the FOX family act very locally to specify cartilage elements of the facial skeleton. Our work indicates that expression and function of FOX genes specify major patterning domains of zebrafish pharyngeal arches.

Z6076A The molecular mechanism for the termination of segmentation clock during zebrafish somitogenesis. *T. Yabe*, S. Takada. National Institute for Basic Biology (NIBB), Okazaki, Aichi, JP.

Somites are metameric structure transiently formed beside the neural tube during vertebrate development and give rise to various tissues including vertebral bone, skeletal muscle and dermis in the adult body. During somitogenesis, somites are sequentially and periodically generated from the anterior end of presomatic mesoderm (PSM). The periodical generation of somite is known to be explained by "Clock and Wavefront" model, in which the spatio-temporal information provided by the cyclic activation of "segmentation clock" and posterior regression of "wave front" are integrated and converted to the morphological pattern of somite at the anterior PSM. In vertebrate somitogenesis, the wave of the activation of segmentation clock propagates from the posterior to anterior PSM and ceases at the anterior end of PSM, in which future segmentation boundary is formed. Previously the termination of segmentation clock was considered to be caused by the gradual decrease of oscillation frequency of segmentation clock, because wave length of segmentation clock became narrow before the termination of segmentation clock. However, recent time-lapse analysis suggested that termination of segmentation clock regulated in the manner independent to the decrease of oscillation frequency. Thus the molecular mechanisms to coordinate the formation of segmentation boundary and the termination of segmentation clock still remains to be elucidated.

In this study, we found Ripply, a groucho interacting protein, negatively regulated expression of the clock genes, *her1* and *her7*, resulting in termination of the oscillatory expression of *her1* and *her7* in the anterior PSM. Conversely, Her1 and Her7 negatively regulate expression of *ripply1* and *ripply2* in the anterior PSM, suggesting that mutual repression between ripply and her is important for segmentation clock termination. Since *ripply1* and *ripply2* are required for the formation of somite boundaries, the mutual repression is important for coupling of the timing of the boundaries formation and the clock termination in zebrafish somitogenesis.

Z6077B Foxc1a plays essential roles in zebrafish cardiogenesis. *Y. Yue*, L. He, Q. Zhang, C. Gu, Q. Zhao. Nanjing University, Nanjing, Jiangsu, CN.

Foxc1 is a highly conserved transcription factor during evolution. It plays dual roles by acting as a transcriptional activator or transcriptional repressor. Foxc1 is involved in regulating mouse out flow tract development. The mutated *FOXC1* is associated with the congenital heart diseases in human. However, its functions and the molecular mechanisms underlying the vertebrate cardiogenesis remain largely unknown. To study the function of Foxc1 in early heart development, we had generated knockout zebrafish mutants of *foxc1a*, an orthologue gene of human *FOXC1*, using TALEN. We found that the *foxc1a* null embryos exhibited severe cardiac edema from 48 hours post fertilization and died at 9-10 days post fertilization. Further analyses revealed that *foxc1a* null mutants displayed serious defects of cardiac structures and heart function. And the data from transcriptomic analysis on the mutated embryos further demonstrated that the expressions of the key genes that control heart development were greatly changed in *foxc1a*$^{-/-}$ zebrafish embryos during cardiogenesis. The roles of the gene in mediating *foxc1a* in zebrafish cardiogenesis are being investigated.

Z6078C Optical control of physiological processes in Zebrafish: the case of fgf8a. *W. Zhang*, B. Ducos, D. Bensimon. ENS PARIS, Paris, FR.

Somitogenesis is a robust mechanism of pattern formation in the development of vertebrates. Although many key factors of somitogenesis

such as fgf8a have been characterized, a quantitative analysis of their action remains poorly documented. Such investigations require the control of the concentration, timing and location of the relevant molecules, which can't be achieved simultaneously by conventional genetic knock-in/out approaches. To fill this gap our lab has developed an optical method combining the use of Gal4-ERT/UAS:fgf8a system and a caged ligand, namely caged-cyclofen. Upon illumination with UV light (at 370nm) or with a two-photon laser beam, cyclofen is released in the illuminated cell(s). It binds to the hormone binding domain of a truncated estrogen receptor (ERT) fused to the Gal4 transcription factor and then releases the Gal4-ERT from the complex it forms with cytoplasmic chaperones. The active Gal4 diffuses to the nucleus, binds to its UAS promoter and turns on the fgf8a gene. This method allows us to over-express fgf8a in live zebrafish in a controlled manner at given time and spatial location.

We have thus analyzed the effect of global over-expression of the fgf8 activated at 70% epiboly and 5 somites stage. The expression of fgf8a was measured using RT-qPCR and its action on somitogenesis was quantitated by time lapse microscopy. While the period of the somitogenetic clock was unaffected by the over-expression of fgf8a, we observed different shortening levels of the somites upon different expression levels and timing of fgf8a over-expression.

Z6079A BATCH-GE: Batch analysis of Next-Generation Sequencing data for genome editing assessment. *A. Boel*, W. Steyaert, N. De Rocker, B. Menten, B. Callewaert, A. De Paepe, P. Coucke, A. Willaert. Ghent University, Ghent, BE.

The CRISPR/Cas9 system recently emerged as the golden standard for targeted genome editing. The simplicity of this technique has enabled the high-throughput set-up of CRISPR/Cas9-based experiments. Analysing these experiments however, is a challenging and time-consuming task. Next-Generation Sequencing (NGS) has been replacing standard techniques such as the T7 Endonuclease I assay, due to its high capacity, sensitivity and ever-decreasing cost. However, the analysis of large amounts of NGS data is a significant hiatus in the otherwise advanced field of CRISPR/Cas9. In this work, we present and evaluate a straightforward tool, BATCH-GE, that performs batch analysis of NGS data for the assessment of knock-out and knock-in genome editing experiments.

BATCH-GE shows a number of important advantages over the current NGS-based genome-editing analysis methods. The tool's most striking asset and improvement, is that it allows for batchwise analysis of a large number of samples. Furthermore, BATCH-GE is implemented as a freely available script, and is therefore available for further optimization by the user. Besides, it can run either within a server environment or on a stand-alone computer, providing an ensured availability. In addition, the user is only required to complete two simple input files, containing easy-to-determine variables that provide the user with the necessary flexibility. Lastly, BATCH-GE enables the assessment of both indel generation as well as HDR-mediated precise genome editing experiments.

BATCH-GE generates four comprehensive text files. The first file lists genomic region, type, length and frequency of every detected indel variant, providing a detailed overview of all sequence alterations. In the second file, a distinctive analysis of full and partial HDR events is carried out. Third, general indel and repair rates are summarized, enabling a quick and straightforward evaluation of the overall mutation efficiency. In the fourth file, URLs are provided to visualize the reads in the UCSC genome browser, offering the possibility to look into the specific sequence alterations.

To evaluate the performance of BATCH-GE, the tool was used for genome editing assessment in two zebrafish experiments, covering sgRNA efficiency testing and precise genome editing via HDR, validating that BATCH-GE is a new and reliable tool for the analysis of NGS-derived genome editing data and contributes to a faster, more informative and flexible analysis of multiple genome editing experiments.

Z6080B Programming the Third Genome Through Mitochondrial DNA Editing. *J. M. Campbell*, E. Perales Clemente, H. Ata, T. J. Nelson, S. C. Ekker. Mayo Clinic, Rochester, MN.

Of the three major genomes that contribute to our health - the nuclear genome, the mitochondrial genome and the bacterial genomes of our microbiome – only the mitochondrial genome has yet to be programmed. The highly conserved mitochondrial DNA (mtDNA) genome consists of 37 genes essential for electron transport chain function, and mutations in mtDNA can cause disease. Much is not known about these diseases because of a lack of sufficient models, and there currently is no long-term treatment for these patients. The ability to edit the mtDNA genome would enable both the interrogation of gene function as well as facilitate the study of mtDNA-based genetic diseases.

Here, we describe to our knowledge the first evidence of mtDNA programming using site-specific mitochondrial DNA enzymes. We use zebrafish as our model system to test these tools. Zebrafish mitochondrial DNA are similar in gene number and order to mammalian models and are readily microinjected to deliver editing tools. We initially deleted a 5kb fragment of DNA between *mt-nd5* and *mt-atp8* by using novel custom enzyme tools. This corresponding deletion is found in humans to cause the disease Kearns-Sayre Syndrome (KSS). Approximately 35% of injected animals carried a detectable deletion, with no deletion detectable in uninjected animals. The resulting deletion was sequence-verified to be mtDNA. To develop mitochondrial DNA carrying a single gene deletion, we then demonstrated that a single 2kb region encoding *mt-nd4* could also be deleted using the same strategy.

We next asked whether we could improve the efficiency of editing by selecting for deleted mtDNA using a site-specific nuclease that targets only the non-deleted genomes. Double-strand breaks are not repaired efficiently in mitochondria, and enzymes that cause DSBs degrade their target rather than inducing NHEJ repair. This represents a major technical challenge in editing mtDNA using standard approaches deployed in the nucleus. By coinjecting the *mt-nd5* and *mt-atp8* custom editors along with a nuclease targeting *mt-nd4,* we were able to detect deletions in over 90% of injected animals, a 2.5-fold improvement. The respiration capacity of these animals were measured, and those injected with custom mitochondrial editors and a nuclease were 4 times lower than uninjected animals and 3 times lower than nuclease-alone injected

animals.

This method of using custom mitochondrial DNA editors combined with nucleases to program the mtDNA genome enable more precise mtDNA disease modeling and single gene function studies.

Z6081C Influences of the gut microbiome on behavioral and stress responses in isogenic mice and zebrafish populations. *D. J. Davis*, H. M. Doerr, A. K. Grzelak, A. C. Ericsson, E. C. Bryda. University of Missouri, Columbia, MO.

The gut microbiota (GM) represents a dynamic microbial community whose collective set of genes encodes a vast array of functions. These microbes play a major role in many physiological processes within the host and are essential for health and well-being. Ongoing research suggests that the GM is not only involved in gut physiology but may also have significant effects on many other aspects of health and disease. However, many researchers are unaware of the impact the GM can have on their animal models, which can hinder reproducibility. Here, we demonstrate the ability of the GM to influence a broad array of behavioral phenotypes in both mice and zebrafish. First, we show that isogenic mice with divergent GM exhibit different, sex-specific neurobehavioral phenotypes. Specifically, male mice with a less diverse GM spent significantly more time in the open arms of an elevated plus maze and displayed less time immobile during a forced swim test. Opposing effects were observed in female mice, wherein a more diverse GM resulted in reduced anxiety- and depression-related behavior. Moreover, we demonstrate that the GM mitigates anxiety-related behavior and is required for characteristic stress responses in zebrafish larvae. Germ-free zebrafish larvae displayed significantly less thigmotactic behavior and exhibited a blunted response to an osmotic stress test compared to conventionally raised larvae. Lastly, we show that alterations of the GM via *Lactobacillus plantarum* supplementation can reduce anxiety-related behavior and protect from stress-induced dysbiosis in adult zebrafish. These findings underscore how changes in GM that can occur during model development may contribute to phenotypic differences of various animal models. Identifying and maintaining a consistent GM will not only facilitate in providing a robust phenotype for particular animal models but also aid in generating reproducible results between experiments.

Z6082A Cdk5-mediated kinase cascade regulates morphogenesis of the intrahepatic biliary network. *M. Dimri*, C. Bilogan, T. Sakaguchi. Cleveland Clinic, Cleveland, OH.

Biliary atresia (BA) is a life threatening liver disorder in infants characterised by the disruption of the biliary system. Various types of BA are associated with the alterations in the intrahepatic biliary network, a complex three dimensional network of conduits lined by biliary epitheilal cells. However, the lack of methodologies for accurately and consistently quantitate the difference in three dimensional branching patterns has impeded the study. We thus designed a computer based algorithm that quantitatively computes the three dimentional structure of the network. We have used the computational algorithm in combination with the systematic screening of small molecule inhibitors and identified that inhibiting cyclin dependent kinase 5 (Cdk5) led to a biliary branching defect. Inhibition of Cdk5 did not alter the total number of biliary epithelial cells; however, decreased the connections of the intrahepatic biliary network. We further identified a downstream kinase cascade regulated by Cdk5, which in turn regulates the activity of Cofilin, an actin severing protein. We showed that chemical manipulations to the kinase cascade changed the activity of Cofilin and hence influenced the actin dynamics in the biliary epithelial cells. Our results provide a new insight into the Cdk5-mediated kinase cascade in actin remodeling and the branching morphogenesis of the intrahepatic biliary network.

Z6083B Optimizing CRISPR/Cas9 rates of mutagenesis and germ-line transmission. *B. Feldman*, C.-H. Tsai-Morris, W.-C. Tseng, F. Porter, G. Trivellin, C. Stratakis, M. Miller, B. Weinstein, D. Martinelli, S. Kaler, S. Krispin. NIH - NICHD, Bethesda, MD.

Adapting published protocols of gRNA synthesis and lesion detection[1-2], we have used CRISPR/Cas9 mutagenesis to target more than 30 genomic loci. Most of the gRNAs we used were taken from the CRISPRscan track[3] and >75% induced a degree of target disruption that we find to be sufficient for the generation of loss-of-function mutations that are germ line transmittable. However, with the exception of the highest-magnitude prediction scores, we observe no strong correlation between the magnitude of CRISPRscan's gRNA-efficiency prediction scores and our quantification of gRNA efficiency outcomes. Thus, most listed CRISPRscan gRNAs are sufficient for mutant allele generation, but if particularly high cutting rates are needed, as may be for F0 phenotyping or homology-directed repair projects, gRNAs with the very highest CRISPRscan prediction scores may be preferable. We will present prediction-outcome correlations for our most up-to-date set of gRNAs, including correlations, where available, with scores from other gRNA design resources that employ distinct prediction algorithms.

Leveraging the ability to multiplex gRNAs in a single injection[2] we are also exploring a strategy of including an extra gRNA, *tyr*-gRNA[4], which targets the *tyrosinase* gene locus, in our microinjections. *tyr*-gRNA causes an observable loss of pigment in embryos and adults >48 hours post-fertilization and accordingly serves as an internal control for injection quality, Cas9 efficiency, and selection of F0 adults with extensive albinism, which presumably indicates they are more likely to transmit germ-line mutations. We have tested this strategy for a limited number of F0 adults, leading to successful egg production in 3 of 4 lines tested. With more *tyr-gRNA*-injected F0s in our pipeline, more definitive data is forthcoming, but we currently hypothesize that inclusion of *tyr*-gRNA facilitates our mutant-generation pipeline with no significantly adverse effects on viability or breeding.

Z6084C Intraspecific susceptibility to environmental toxicant PCB 126 mediated by variation in xenobiotic metabolism gene *cyp1a* in zebrafish. *L. Holden*, P. Vu, K. Brown. Portland State University, Portland, OR.

Understanding the hypervariable effects of environmental toxicant exposure within and between species is vital for ecosystem modeling and remediation. Our aim is to discern the genetic components underlying intraspecific variation in environmental toxicant susceptibility. Zebrafish, *Danio rerio*, exhibit variable susceptibility across lab strains to 3,3',4,4',5-pentachlorobiphenyl (PCB 126), a ubiquitous aromatic hydrocarbon with a high toxic equivalence factor. SNP haplotypes explain 24% of the phenotypic variation in the PCB-susceptibility trait, but the remaining 76% is unknown. Interestingly, 15% of the zebrafish genome is comprised of genomic copy number variants (CNV)—large deletions or duplications—and CNV loads differ between zebrafish strains. We hypothesize that CNV are significant contributors to variation in the PCB 126-susceptibility phenotype.

We assessed CNV across two biomarker genes, aryl hydrocarbon receptor 2 (*ahr2*) and cytochrome P450 1A (*cyp1a*), using publicly available microarray data (GEO: GSE28328) and measured post-exposure mRNA expression levels of the same genes in three strains of zebrafish (AB, TU, WIK). CNV presence was determined using mean log2 ratios over three consecutive probes. Hepatic mRNA expression levels in adults exposed to environmentally relevant levels of PCB 126 for 0, 3, 6, 9, 12, 24, and 48 hours (n=10/timepoint) were compared with time-matched vehicle controls. *ahr2* and *cyp1a* expression levels were assessed in total mRNA via RT-qPCR, normalized to *β-actin*, and quantified using the relative fold change ΔΔCt method.

We found no evidence of CNV across *ahr2*, but found evidence of a deletion across WIK *cyp1a* exons 2-5 of 7 compared to AB and TU strains. PCR confirmation across the identified deletion in *cyp1a* exposed intact gene region frequencies of 0.64 in AB, 1.00 in TU, and 0.40 in WIK (n=25/strain). Post-exposure mRNA levels support increased expression in both *ahr2* (4-fold) and *cyp1a* (14-fold) mRNA in WIK as compared to AB and TU strains. An increase in *cyp1a* expression in WIK may indicate that the identified deletion may be across an intronic repressor region. These results support our hypothesis that CNV are important contributors to interspecific variation in a receptor-mediated xenobiotic metabolism pathway. Alternatively, we may have identified a novel *cyp1a* subtype in zebrafish lacking exons 2 and 3, similar to *cyp1a2* found in some mammals.

Z6085A Zebrafish Genomics Resources – What's There and What's Next? *K. Howe*, J. Loveland. Wellcome Trust Sanger Institute, Cambridge, GB.

For the last decade we have been holding hands-on workshops at the European and International Zebrafish Conferences to introduce zebrafish researchers to web resources for zebrafish genomics data. These workshops provided talks and exercises about the generation, evaluation and improvement of the genome reference sequence assembly, the reference gene set and state-of the art web resources used for data access, analysis and interpretation. In the absence of a framework to provide such a workshop this year, we will present a summary of the usual topics and recent updates.

Both the reference genome assembly, curated by the Genome Reference Consortium, and the gene set, curated by the Havana group, have reached a level of quality that is comparable to that of other model organisms, for instance mouse. This enables us to now embark on sequencing and analysing additional zebrafish strains, and identifying notable variation to be included in future assembly releases.

As always, we welcome community input to alert us to remaining issues and focus on their resolution. Please visit us at the poster and/or write to us at zfish-help@sanger.ac.uk. The latest gene sets can be accessed at vega.sanger.ac.uk and the assembly evaluation browser gEVAL (geval.sanger.ac.uk) allows the assessment of individual genomic regions to support further improvements.

Z6086B Leveraging comparative genomics for zebrafish annotation. *Jane Loveland*, Sarah Donaldson, Deepa Manthravadi, Jen Harrow. Wellcome Trust Sanger Institute, Cambridge, GB.

A high quality reference genome and gene set is essential. In the Human and Vertebrate Analysis and Annotation (HAVANA) team we use our Otter/Zmap annotation tools to manually annotate the zebrafish genome, GRCz10, and collaborate closely with ZFIN to provide an accurate, dynamic and distinct resource for the zebrafish community. We annotate multiple biotypes, so as well as protein coding genes, we annotate pseudogenes and long non-coding RNAs (lncRNAs). Within these main biotypes we also have over 50 controlled vocabulary terms to further categorise and describe our genes. Our annotation tools also allow us annotate multiple species at the same time and unlock the power of comparative genomics, which can tell us a great deal about how genes and genomes evolve.

Gene clusters are a particular target for manual annotation as they are difficult to annotate with automated methods, such as Ensembl. One such cluster is the Olfactory receptors, which consists of protein coding genes and pseudogenes, whose numbers and biotypes vary hugely between organisms, and are the largest multigene family in vertebrates. We are manually annotating these genes and have found them to be greatly expanded in the mouse genome (~1500 genes/pseudogenes) relative to human (~900 genes/pseudogenes), and much fewer in the zebrafish genome (~135 genes, of these only 3 are pseudogenes).

LncRNAs show an absence of sequence homology between different organisms. Despite this many exhibit positional synteny, such as the lncRNA gene *sox2ot,* which suggests functional conservation. The *sox2ot* gene has been manually annotated and shown to be highly conserved between human, mouse and zebrafish and is thought to be important during embryo development and is deregulated in cancer.

Our experience of annotating across several species is proving to be a powerful tool for gene discovery in model organisms.

All of the manual annotation is publicly available from the Vertebrate Genome Annotation database (VEGA), and this is merged with the Ensembl gene set quarterly. Annotation is a continuous process and so between database updates all new annotation is made available for all of our whole genome species in the update track in VEGA: http://vega.sanger.ac.uk/info/data/frequent_update.htm

Our annotation software is freely available via our website: http://www.sanger.ac.uk/resources/software/otterlace/.

Z6087C The Status of Line Rederivation At The Zebrafish International Resource Center (ZIRC). *A. Nasiadka*, J. Hwang-Shum, J. Matthews, K. Core, E. Loucks, D. Marston, J. Murphy, E. Williams, D. Lains, A. Freeman, R. Holland, M. Westerfield, Z. M. Varga. ZIRC, University of Oregon, Eugene, OR.

As the zebrafish research community grows, an increasing number of shared resources are generated. At the ZIRC, adjustments are continually made to accommodate these changes and maintain a balance between efficient resource regeneration and effective distribution. For example, the inventory of mutant and transgenic lines at the ZIRC has increased by over 1000% within the last five years. This increase impacted greatly the strategies undertaken for line identification, regeneration, quality control, and distribution. Previously, most fish lines were mono-allelic. A large number of these lines were maintained as stocks consisting of identified transgene and mutation carriers. The lines were distributed as genotyped adult fish or embryos obtained from natural crosses. Now, most of the ZIRC lines are multi-allelic, and they arrive as frozen sperm. Distribution of these lines involves shipment of embryos generated by in vitro fertilization (IVF) using thawed sperm. We rederive lines to amplify samples in the ZIRC sperm bank. This
process depends strictly on the demand. Lines frequently requested are regenerated more often than lines that are seldom ordered. Regeneration of multi-allelic mutant lines required a significant increase of the genotyping throughput at the ZIRC. We handled this in part by using Kompetitive Allele Specific PCR (KASP) genotyping (LGC Genomics). With this technique, genotypes are determined based on a fluorescence detection system rather than time-consuming restriction enzyme digestion and gel electrophoresis. Due to the immense increase in the number of imported lines, we perform quality control for new imports primarily during line regeneration rather than at the time of importation as previously. Thus, the ZIRC staff no longer confirms all of the distributed genotypes. To reflect the status of ZIRC sperm samples with regard to line identification, we now provide sperm sample
categories. These include a category for samples derived from males whose genotypes were confirmed at the ZIRC as well as a category for samples with genotypes confirmed elsewhere. Only lines with genotypes verified at the ZIRC are distributed without a disclaimer. Lines genotyped elsewhere or whose genotypes have not been confirmed are offered with specific disclaimers.

Z6088A NCBI's Zebrafish Genome Resources. *N. A. O'Leary*, T. D. Murphy, K. D. Pruitt. National Center for Biotechnology Information, National Library of Medicine, National Institutes of Health, Bethesda, MD 20894, MD.

Genomic research on model organisms such as zebrafish (*Danio rerio*) increasingly relies on the availability of high-quality annotated reference genomes to facilitate consistent reporting and mapping of genetic data. The Reference Sequence (RefSeq) project (https://www.ncbi.nlm.nih.gov/refseq/) at the National Center for Biotechnology Information (NCBI) provides a comprehensive annotation of the zebrafish Tuebingen strain reference genome assembly (GRCz10) maintained by the Reference Genome Consortium (GRC). The zebrafish RefSeq dataset is generated by a combination of computational analysis and manual curation that results in an annotation that focuses on representation of all full-length, non-redundant transcripts. The primary sources of data used in this annotation pipeline include mRNAs, expressed sequence tags (ESTs), protein data, RNA-seq data, and protein homology. Zebrafish is one of a select group of vertebrates that are the major focus of RefSeq's manual curation efforts, which involves the in-depth review of sequence data to define new transcript variants, resolve sequence errors, and remove inaccurate information. We also collaborate with expert groups, including the Zebrafish Information Network (ZFIN) and UniProtKB, to provide appropriate annotation and nomenclature for both genes and proteins. In addition to zebrafish, NCBI provides stable reference genome annotation for other fish species with high-quality genome assembly data submitted to NCBI's Assembly resource (https://www.ncbi.nlm.nih.gov/assembly/). To date, 26 other fish species have RefSeq annotated genomes, providing a valuable resource for comparative genomic research. In this poster presentation we will provide an overview of NCBI's zebrafish genome resources and highlight the utility of these resources to the zebrafish research community. We will also provide practical guidance on how to access RefSeq data and tools for analysis of individual genes as well as whole genome datasets.

Z6089B Improving Homology-Directed Repair efficiencies in zebrafish. *Andy Willaert*, Annekatrien Boel, Hanna De Saffel, Anne De Paepe, Paul Coucke. Center for Medical Genetics, Ghent University Hospital, Ghent, Belgium.

The recent emerge of site-directed genome editing technologies such as CRISPR-Cas9 is of great interest for research in medicine. In multiple organisms, it has been shown extensively that the technology can be used to generate knock-out disease models with high efficiencies, enabling the study of gene function. However, to generate disease-relevant models, the introduction of specific base pair alterations (knock-in) is desired, since numerous diseases are caused by specific point mutations, leading to amino acid substitutions or splicing defects. Also in zebrafish, CRISPR-Cas9 has been successfully applied to generate knock-out models. However, results from a limited number of small scale studies, showed that the efficiency of CRISPR-Cas9 mediated knock-in approaches to introduce point mutations, is relatively low. These approaches are based on CRISPR-Cas9 stimulated homology-directed repair (HDR), using either single-stranded oligodeoxynucleotide (ssODN), double stranded DNA (dsDNA) or plasmid templates with varying lengths of homology arms. Because there is no clear consensus concerning the most optimal approach, we assessed the suitability of different types of donor templates (ssODNs, dsDNA and plasmids) to introduce specific point mutations at multiple sgRNA target sites in the zebrafish genome by means of CRISPR-Cas9 stimulated homology-directed repair (HDR). Furthermore, we evaluated the influence of homology arm length of the different templates on mutagenesis efficiency and we tested if there is a difference in mutagenesis efficiency between sense and antisense ssODNs at each of the target sites. Finally, we assessed the influence of several chemical compounds, which either block the non-homologous end joining (NHEJ) pathway or stimulate the HDR pathway, on HDR-based knock-in efficiency.

Z6090C CRISPR-Cas9 based knock-in in zebrafish to facilitate streamlined visual genotyping. *Roland S. Wu*[1], Ian I. Lam[1], Thomas O. Auer[2], Filippo Del Bene[2], Shaun R. Coughlin[1]. 1) Cardiovascular Research Institute and Department of Medicine, University of California San Francisco, San Francisco, CA; 2) Institut Curie, Centre de Recherche, Paris, France.

CRISPR/Cas9-based genome editing has greatly facilitated the ease of generating zebrafish genetic deletions. However, genotyping often requires significant investments in resources and remains a significant bottleneck in maintaining mutant zebrafish lines. Furthermore, there are currently no broadly applicable methods to identify the genotype of a living, unperturbed zebrafish embryo. Here we describe a cloning-free genotyping system to facilitate convenient, high-throughput genotyping of living zebrafish mutant lines. We utilize a knock-in strategy using homology-independent DNA repair to insert a Gal4 reporter into an endogenous locus, allowing live interrogation of gene expression. This knock-in harbors a cassette conferring lens fluorescence, and generation of mutant lines with lens fluorescence in different channels allows unambiguous genotyping of compound heterozygotes by visual examination of living embryos. We use this system to disrupt the *s1pr1* gene locus. Sphingosine-1-phosphate (S1P) has been found to play an important role in vertebrate development and effects of S1P are mediated by a family of five G protein-coupled receptors, sphingosine-1-phosphate receptors 1-5 (S1PR1-5), which confer the diversity of responses to S1P. We have found that disruption of the *s1pr1* gene leads to partial lethality in zebrafish larvae. Analysis of *s1pr1* knock-in embryos reveals *s1pr1* expression in the developing nervous system, caudal hematopoietic tissue, and vasculature. We exploited live embryo genotyping to interrogate the effects of *s1pr1* gene disruption in these tissues. This strategy of gene disruption requires generating two new alleles instead of one per knockout and hence more initial investment than standard CRISPR/Cas9-based gene deletion. However, these knock-in lines allow visual genotyping of live embryos, greatly increasing the efficiency of maintenance and phenotypic evaluation, including identification of null embryos before the onset of phenotype.

Z6091A Determining the functional significance of variant human alleles using zebrafish. *X. Xing*[1], U. Broeckel[2], R. Blank[2], P. Giampietro[3], M. Pickart[1]. 1) Concordia University Wisconsin, Mequon, WI; 2) Medical College of Wisconsin, Milwaukee, WI; 3) University of Wisconsin, School of Medicine and Public Health, Madison, WI.

Assigning function to sequence variants observed in association with clinical studies remains a key priority in the post-genomic era. Numerous reports over the last decade demonstrate that in many instances, overexpression of functional human alleles are sufficient to rescue loss of function (lof) orthologous knockdowns and knockouts in zebrafish. The inability of polymorphic and variant human alleles to rescue lof zebrafish models is thus an efficient platform to assign functional significance to these alleles. To explore this potential further, our collaborative team is investigating known sequence variants in *Tyrosinase* (*Tyr*) and *T* (*Brachyury*) and applying what is learned through this study to inform an ongoing study of sequence variants of unknown significance from patients with underlying vertebral malformations. Human ORFs are cloned into pT3TS or pKTol2BA RNA and DNA expression vectors, respectively. ORFs are modified using pcr mediated overlap extension to create variant alleles and cloned similarly. Both human functional and potential lof variant alleles are then tested for their capacity to rescue zebrafish lof phenotypes. Initial studies of two families with likely inherited vertebral malformations have been examined using whole exome sequencing. Resulting sequences have been processed by applying bioinformatics filters for stop gain/loss and non-synonymous coding changes to ensure high relevance of the 30 variant alleles identified and include genes such as *Polr1d*, *Tle4*, *and Ppib* for example. Functional studies of these alleles are commencing following initial technical progress demonstrating that overexpression of human *Tyr* rescues an orthologous *Tyr* lof zebrafish model. These results support the use of zebrafish for functionally validating pathogenic sequence variants and ultimately improving clinical relevance of association studies for complex disease.

Z6092B A comprehensive map and comparative analysis of cis-regulatory elements in the zebrafish genome. *H. Yang*[1], T. Liu[1], D. Balciunas[2], G. Gerhard[3], F. Yue[1]. 1) Penn State Univ College of Medicine, hershey, PA; 2) Temple University College of Science and Technology; 3) Temple University Lewis Katz School of Medicine.

Zebrafish has been widely used for the study of human diseases, as ~70% of the protein-coding genes are conserved between the two species. Moreover, zebrafish embryos are transparent and thus can serve as an ideal model for genetic studies in animal development. Surprisingly, the functional annotation of zebrafish genome itself has been severely lagging when compared with other model systems such as mouse and drosophila. Here we took a similar approach adopted by the ENCODE and Roadmap Epigenomics projects, and performed RNA-Seq and ChIP-Seq for several histone modifications to generate a comprehensive map of transcriptomes and regulatory elements in a variety of zebrafish tissues, including brain, heart, liver, skeletal muscle, kidney and several embryonic tissues. We predicted over 100,000 cis-regulatory elements in the zebrafish genome, the most comprehensive functional annotation effort in zebrafish so far to our knowledge. We also identified tissue-specific and developmental stage-specific regulatory elements. By comparing the data generated by the ENCODE and Roadmap Epigenomics projects, we also defined a set of functionally conserved and species-specific regulatory sequences among zebrafish, mouse and human. In summary, we generated a great genomics/epigenomics resource for the functional annotation in the vertebrate genomes and further expanded the value of zebrafish as a model of human disease.

Z6093C Establish a Zebrafish genetic mosaic system for single-cell resolution phenotypic analysis of mutant cells. *Guoxin Zhang*, Laura Fontenas, Sarah Kucenas, Hui Zong. University of Virginia, Charlottesville, VA.

Genetic mosaicism is defined by the existence of cell populations with different genotypes in an individual organism. Many human diseases, such as cancer, are caused by genetic mosaicism since cancerous cells harbor genetic mutations that are absent in normal cells within the same person. In research labs, studying mosaic animals reveals **cell-autonomous functions** of a given gene, particularly suitable for polarity, migration, cell-cell interaction problems. Obviously, the unequivocal labeling of rare mutant cells is the prerequisite for one to analyze them in

a genetic mosaic animal. Previously we generated the MADM (mosaic analysis with double markers) system in mice, which generate GFP-labeled mutant cells and RFP-labeled sibling WT cells through site-specific recombinase mediated inter-chromosomal mitotic recombination (Zong 2005 Cell). By comparing green and red cell behaviors in vivo, one can detect even the subtlest phenotypes at the **single cell resolution**. MADM has been broadly adopted in many fields such as neurobiology (Hippenmeyer 2010 Neuron), developmental biology (Packard 2013 Developmental cell), and cancer biology (Liu 2011 Cell). While we have learned a lot of fascinating biology with the mouse MADM system, Zebrafish model carries great advantages in terms of the transparency of its body and the ease to generate a large, genetically identical population. Based on our experience in establishing the mouse MADM system, we are now in the process of establishing the MADM system in Zebrafish. We envision that the system would not only help deepen our understanding of cellular behaviors in normal development and adult functions, but also enable the establishment of disease models and drug-screening platforms.

Z6094A Validation of a cost-effective method to record electrographic activity in larval zebrafish brain. *M. C. Gonsales*, P. G. Barbalho, A. S. Vieira, I. Lopes-Cendes, C. V. Maurer-Morelli. University of Campinas, Brazil.

Purpose: Being able to record zebrafish brain activity is essential to investigate and characterize the abnormal electrical discharges during seizure-like responses in epilepsy studies. The current procedure employed to record extracellular field potentials in the larval zebrafish forebrain is an adaptation of conventional extracellular recording techniques, using a patch clamp amplifier. In the present work, we aim to establish a protocol to obtain electrographic recordings of zebrafish with a simpler and more cost-effective setup for laboratories intending to implement this technique in their routine. **Methods:** Each zebrafish 7 dpf larvae was anesthetized and paralyzed with 400µM tricaine and 10µM d-tubocurarine. After complete loss of movement, the animal was placed in a lid removed from a 1.0 ml eppendorf tube filled with 1% low-melting agarose prepared with aquarium water. Fish was positioned horizontally, with the dorsal side exposed to the surface. Quartz/platinum-tungsten microelectrodes were attached to a pair of connectors and fitted onto a MN-153 Narishige micromanipulator. One electrode was placed slightly in front of the forebrain of the animal, and another in the agarose. Electrical activity was recorded using the RHD2000 Evaluation System (Intan Technologies®). We used a setup that includes an interface board connected to a host computer via standard USB cable, and to a small amplifier board via a 0.9m serial peripheral interface cable. To prevent external electromagnetic interferences, the setup was placed inside a Faraday cage. To validate the system, we performed preliminary recordings of larvae with and without addition of 30 mM pentylenetetrazol (PTZ). **Results:** To date, we have built a setup to record extracellular field potentials in zebrafish brain using a system that transform weak electrode signals directly into a digital data stream. Our pilot study showed high amplitude electrographic discharges in the animal exposed to PTZ compared to the control, starting approximately after 30 minutes of exposition to PTZ, with intervals of 5-10 minutes. **Conclusion:** In the present work, we described a cost-effective protocol for electrographic recordings on immobilized zebrafish larvae, as it does not require a patch clamp amplifier. We have accomplished stable long-term monitoring of brain activity in immobilized zebrafish larvae and we are currently working towards a characterization of the epileptiform discharges in order to study the seizure-like responses evoked by the convulsant agent PTZ. Since studies using zebrafish to elucidate the basis of seizure generation are still scarce, this study provides new tools to study the mechanisms underlying seizures in this model. Supported by Fapesp.

Z6095B Myomesin2 - a potential candidate gene for congenital heart defects. *K.de L. Troelsen*, P. R. Lundegaard, M. Moennich, L. A. Larsen. University of Copenhagen, København N, DK.

Congenital heart defects (CHD) are the most common congenital malformations in newborns and are a major cause of infant morbidity and mortality. Despite many genetic studies, much of the genetic mechanisms behind normal and abnormal heart development remain to be elucidated.

The Myomesin 2 gene (*MYOM2*) encodes a protein located in the M-band of the sarcomere in cardiac and skeletal muscle. A potential role for MYOM2 in the assembly of sarcomeric Titin has been proposed. The assembly of the sarcomere is of tremendous importance for a fully functional skeletal and cardiac muscle and mutations in sarcomere genes like *ACTC1*, *MYH6* and *MYH7* have previously been associated with CHD and rare *MYOM2* variants have been reported in CHD patients. This study focuses on the role of MYOM2 during heart development. The zebrafish genome encodes a *myom2* gene with a 55% homology to the hyman MYOM2. Therefore the zebrafish was used to model the expression of *myom2* during development and to explore the role of gene knockdown in live developing zebrafish hearts.

In situ hybridization showed that *myom2* is expressed specifically in heart and skeletal muscle during zebrafish embryonic development. We also found *myom2* to be duplicated, with similar expression patterns. Two approaches to knock down the gene in zebrafish were used. First zebrafish carrying a nonsense mutation in the *myom2a* gene was obtained from the Zebrafish Mutation Project (Sanger Institute, UK). No obvious cardiac or muscle phenotype was present in homozygous mutants, suggesting that mutants compensate for the loss of myom2 function. Whereas the development of zebrafish embryos injected with morpholinos targeting *myom2*awas delayed and developmental defects were observed. Targeting myom2b with morpholinos did not differ from control injected wild type embryos. Interestingly the *myom2b* morpholino did show developmental changes in *myom2a* mutants.

The preliminary data indicates a possible role of *myom2* in heart development, but further experiments are needed.

Z6096C The zebrafish *prox1a* controls liver development by regulating Wnt signaling pathway. *B. Zhang*, Y. Hu, Z. Luo, M. Wang. Peking University, Beijing, CN.

Prox1, encoding a homeobox transcription factor, has been shown to be essential for liver development in mice, though its molecular mechanism needs further investigation and its function in zebrafish hepatogenesis has not been reported. In this study, we generated *prox1a* knock-out zebrafish by using CRISPR/Cas9 system. *prox1a* homozygous mutants exhibited severe edema around the gut upon 4-5 dpf, with

smaller liver and abnormal intrahepatic structure. The number of mature hepatocytes was reduced, whereas early endoderm development and hepatic bud formation was not affected, as shown by the *in situ* hybridization results of the corrresponding marker genes. *prox1a* ablation resulted in defective hepatocyte proliferation but not apoptosis in the liver outgrowth stage. Moreover, cholangiocyte differentiation was totally blocked in the mutant liver, as shown by using both Notch-reporter transgenic fish and cytokeratin staining. Endothelial cells also failed to invade into the mutant liver to form vascular networks. As a result, the *prox1a* mutants lack intrahepatic biliary ducts and blood vessels. Liver-specific RNA seq was performed to explore downstream effectors of *prox1a*. About 1000 genes were identified as significantly differentially expressed in the mutant liver. Functional clustering analysis on these genes revealed that, majority of the downregulated group was involved in metabolic process, while Wnt signaling was highlighted in the upregultated pathways. Dissecting different components of this pathway uncovered bifurcating outcomes. Upon *prox1a* ablation, excessive expression of Wnt ligands, receptors, as well as inhibitors integrate to activate non-canonical Wnt signaling but suppress canonical Wnt signaling. Reduced expression of canonical Wnt target genes *cmyc* and *ccnd1* led to defective hepatocyte proliferation, rendering smaller liver size. However, enhanced non-canonical Wnt signaling activity interfered with cell polarity, displayed by aberrant subcellular localization of aPKC, an apical membrane protein. Lack of correct cell polarity resulted in loose organization and irregular orientation of hepatoblast/hepatocyte, and may influence interations between different cell types, on which both cholangiocyte differentiation and endothelial cell invasion are dependent. In conclusion, our data illustrated that *prox1a* controls zebrafish liver development at multiple levels, including cell proliferation, polarity and differentiation, through regulating and integrating Wnt signaling pathway.

Z6097A Global identification of the genetic networks and cis-regulatory elements of the cold response in zebrafish. *Liangbiao Chen*, Peng Hu, MingLi Liu, Jinfeng Wang, Hongbo Niu, Yimeng Liu, Zhichao Wu, Bingshe Han, Wangying Zhai, Dong Zhang. Shanghai Ocean University, Shanghai, CN.

The transcriptional programs of ectothermic teleosts are directly influenced by water temperature. However, the cis- and trans-factors governing cold responses are not well characterized. We profiled transcriptional changes in eight zebrafish tissues exposed to mildly and severely cold temperatures using RNA-Seq. A total of 1943 differentially expressed genes (DEGs) were identified, from which 34 clusters representing distinct tissue and temperature response expression patterns were derived using the k-means fuzzy clustering algorithm. The promoter regions of the clustered DEGs that demonstrated strong co-regulation were analysed for enriched cis-regulatory elements with a motif discovery program, DREME. Seventeen motifs, ten known and seven novel, were identified, which covered 23% of the DEGs. Two motifs predicted to be the binding sites for the transcription factors Bcl6 and Jun, respectively, were chosen for experimental verification, and they demonstrated the expected cold-induced and cold-repressed patterns of gene regulation. Protein interaction modeling of the network components followed by experimental validation suggested that Jun physically interacts with Bcl6 and might be a hub factor that orchestrates the cold response in zebrafish. Thus, the methodology used and the regulatory networks uncovered in this study provide a foundation for exploring the mechanisms of cold adaptation in teleosts..

Z6098B Evolutionarily Conserved Functional Compatibility of The Lysosomal Symporter Spin/Spns1 over One-Billion Years across Species. *S. Kishi*[1], S. Lian[1], T. Sasaki[1], A. Khan[1], W. Ja[1], K. Jia[2], M. Gill[1], J. Choe[3]. 1) The Scripps Research Institute, Jupiter, FL; 2) Florida Atlantic University, Jupiter, FL; 3) Rosalind Franklin University of Medicine and Science, North Chicago, IL.

Is phylogenetic distance between worms and humans negated in some cases? If a certain gene function is conserved throughout such organisms, our naïve question would be how often the gene itself can be intactly replaceable between them beyond some 990 million years. As a group, teleost fish are phylogenetically well positioned for comparisons to other vertebrates, having diverged from the amniote lineage (mammals, birds, reptiles) some 400 million years ago. The comparison with human genomes also provides an opportunity to examine the dynamics of fish chromosomal evolution. The genomes of zebrafish (*Danio rerio*) species have been sequenced with annotations and display remarkable structural similarity with the human genome, meaning that findings from zebrafish provide insights into many human conditions and diseases. While many molecules have been considered for their functional conservation among invertebrate and vertebrate species, as far as we know, little has been demonstrated for truly reciprocal compatibility between them. Here, for the first time, utilizing the zebrafish model system, we show that the putative lysosomal sympoter Spinster (Spin)/Spinster homolog 1 (Spns1) is evolutionarily conserved and replaceable across wide variety species from worms through humans beyond approximately one-billion years' evolutionary distance. We demonstrate that human Spns1, *Drosophila* Spin and *C. elegans* Spin-1 are functionally compatible to zebrafish Spns1 and transgenic expressions of any of these Spin/Spns1 can rescue zebrafish *spns1* mutants with successful generations of the stable transgenic lines. Homology-scanning mutagenesis of Spin/Spns1 further confirmed the biologically functional and potential ligand-binding capabilities of the proteins *in vivo* and *in vitro*, respectively. We further demonstrate that a sugar-derived molecule, rather than a conventional sugar, is a common ligand for both human and zebrafish Spns1. Finally, primary and tertiary structure analysis reveal that the Spin/Spns1 proteins have unique substrate- and proton-binding sites as symporters, suggesting that these proteins may represent a novel, as yet unclassified, type of the solute carrier family.

Z6099C Tracing the Evolutionary History of the SLC1 Gene Family. *André Lehnherr*, Lucia Cadetti, Matthias Gessemann, Stephan C. F. Neuhauss. University of Zurich, Zürich, CH.

Efficient removal of glutamate from the synaptic cleft is essential to end synaptic transmission protecting neurons from excitotoxicity. This is achieved by excitatory amino acid transporters (EAAT), which belong to the Solute Carrier Family 1 (SLC1) gene family. Besides glutamate and associated cation transport, EAATs induce a chloride conductance upon glutamate binding.

Phylogenetic analysis of the SLC1 gene family revealed duplication and deletion events during evolution leading to varying number of SLC1

genes in different species. While the zebrafish genome contains thirteen SLC1 genes, amphibians have retained nine and mice and humans only seven SLC1 genes.

In this study, we compare expression and function of selected vertebrate SLC1 genes across species (Zebrafish, *Xenopus*, anole lizard, chicken and mouse) in the retina. Retinal expression of SLC1 RNA provides an ideal system to compare the abundance of SLC1s in different vertebrate species, identifying potential sub-, non or neofunctionalization events. In fact we found striking differences in RNA expression between different species.

For further examination of these differences, we elaborate the biophysical properties of the SLC1 family members by expression of the transporters in Xenopus oocytes and subsequent two electrode voltage clamp recordings. This allows us to correlate expression and function across species and thereby to follow the evolutionary history of the SLC1 gene family.

Z6100A Transcriptional landscape of the major pancreatic cells reveals conserved expression patterns amongst distant vertebrate species. *Bernard PEERS*, Estefania Tarifeno, Arnaud Lavergne, Keerthana Padamata, Alice Bernard, Marianne Voz, Isabelle Mainfroid. Ulg, liege, liege, BE.

Defining the transcriptome and the genetic pathways of pancreatic endocrine and exocrine cell types is crucial for elucidating the molecular attributes of disorders such as diabetes and pancreatic cancer. The comparison of these transcriptomes amongst distant vertebrate species highlight the genes under strong evolutionary constraints which have maintained their selective expression in pancreatic cells due to their crucial function in these cells.

We took advantage of zebrafish transgenic lines to isolate by FACS the major pancreatic cell types and we obtained highly purified preparations of endocrine α-, β- and δ cells as well as the exocrine acinar and ductal cells. Transcriptomic profiling by RNA-seq identified the transcriptomic signature of each cell type and highlighted novel cell-specific markers including transcription factors, signaling pathways components and lincRNAs. By performing interspecies comparisons, we identified hundreds of genes with conserved enriched expression in endocrine or in exocrine cells amongst human, mouse and zebrafish. This list includes many regulatory genes known as crucial for the differentiation and the function of endocrine and exocrine cells, but also pinpoints previously unrecognized regulators. While the transcriptomic signature of pancreatic endocrine and exocrine cells is well conserved amongst vertebrates, the signatures distinguishing the endocrine cell subtypes, and notably alpha (glucagon+) and beta (insulin+) cells, are much less conserved between zebrafish, mouse and human, with only a few genes displaying conserved cell subtype specific expression. This suggests that endocrine cell subtype identity may be determined by one or a few regulatory genes. The function of some identified endocrine regulators is presently addressed through CRISPR mutagenesis.

In conclusions, this study provides the molecular signature of the major zebrafish pancreatic cell types and identifies sets of genes with selective and evolutionary conserved expression in pancreatic endocrine or exocrine cells from fish to mammals, likely important in pancreas physiology and relevant to pancreatic diseases such as diabetes and cancer.

Z6101B The Functional Studies of miR-7132 on the Erythropoiesis. *Qianghua Xu*[1,2,3,4], Xingxing Hu[1]. 1) College of Marine Sciences, Shanghai Ocean University, Shanghai, China,201306; 2) Key Laboratory of Sustainable Exploitation of Ocean Fisheries Resources, Ministry of Education, Shanghai, China, 201306; 3) National Distant-water Fisheries Engineering Research Center, Shanghai Ocean University, Shanghai, China, 201306; 4) Collaborative Innovation Center for Distant-water Fisheries, Shanghai, China, 201306.

MicroRNAs are small non-coding RNAs, playing roles at post-transcriptional level by binding the 3'UTR of the target gene. Some studies indicated that microRNAs play important roles in the process of erythropoiesis. *Chionodraco hamatus* is a white-blooded Antarctic icefish, the only known vertebrate with a very few non-functional erythrocytes. Previous studies showed that highly upregulated expression of about one hundred microRNAs in the *C. hamatus* head kidney might inhibit the erythropoiesis of the Antarctic icefish. In our study, by using zebrafish microinjection technique, dual-luciferase reporter, and target prediction methods, we studied the functions of the miR-7132 in the process of erythropoiesis, which was highly expressed in the head kidney of the icefish. Results showed that, after being micro-injected with miR-7132, zebrafish embryos showed dramatic reduced expression level of hemoglobin by o-dianisidine staining, which indicated that overexpression of miR-7132 repressed the erythropoiesis process in zebrafish embryos. The dual-luciferase vector containing the 3'UTR of ALAS2, the limited enzyme in the process of hemoglobin production, was constructed and co-transfected with miR-7132, and the activity of luciferase was detected. The expression vector containing the GFP fluorescent protein was constructed. Zebrafish embryos were then micro-injected with the mixture including miR-7132 and the GFP plasmid. The expression of GFP protein was then detected by western blot analysis. Result showed that miR-7132 significantly reduced the relative activity of luciferase in 293T cells, The GFP fluorescent intensity was significantly decreased when injected with miR-7132. The study indicated that miR-7132 regulated erythropoiesis in the Antarctic icefish by repressing the expression of ALAS2.

Z6102C Zebrafish as a model to comparatively study male and female meiosis and sexually dimorphic responses to meiotic perturbations. *Yana P. Blokhina*, An D. Nguyen, Hester E. Roberts, Trent A. Newman, Daniel B. Chu, Bruce W. Draper, Sean M. Burgess. University of California, Davis, Davis, CA.

Aneuploidy is the leading cause of birth defects and spontaneous abortions in humans. The majority of aneuploidies are maternally derived, and most of the clinically relevant cases arise from segregation errors in meiosis I. During meiosis I, key steps leading to the formation of a stable bivalent must be undertaken with precision in order to ensure proper segregation of homologous chromosomes. In our research we use the zebrafish, *Danio rerio*, to comparatively study early meiotic processes in males and females with the goal of understanding which factors

contribute to aneuploidy generation in the two sexes. A thorough examination of these processes has been hindered in mammals by the limited accessibility of female oocytes going through early prophase I. In zebrafish, however, the gonad is transparent and easily accessible, and germ cells in both males and females undergo meiosis throughout their lives (Draper, McCallum and Moens, 2007). While previous studies have shown telomere clustering and Sycp3 loading in zebrafish males (Saito K et al., 2011 and 2014), there are still many unanswered questions. Most notably there has not been a thorough study of how zebrafish male and female meioses differ, and how the two sexes respond to perturbations in meiosis. We have created loss of function mutations in genes with key roles in meiotic chromosome dynamics. The first is in spo11, which encodes the nuclease that generates programmed double strand breaks which initiate homologous recombination. The second is in rad21l1 that encodes a meiosis-specific cohesin subunit found only in vertebrates. Both *spo11* and *rad21l1* mutants have sexually dimorphic phenotypes. While *spo11* males are completely infertile and lack sperm, the *spo11* females are fertile but most of their offspring are highly deformed and aneuploid. The *rad21l1* mutants by contrast have a defect in maintaining the female phenotype with over 97% of homozygotes developing into males which appear to be fully fertile. Interestingly, in *rad21l1/tp53* double mutants, the defect in maintaining femaleness is rescued but most of the double mutant females' offspring are deformed. This phenotype is distinctly different from the *spo11* aneuploid offspring, suggesting the defects may be due to some other lesion not related to aneuploidy. Together, our results support zebrafish as a coherent model that demonstrates both similarities and differences between meiosis in the two sexes.

Z6103A Igf3 and Amh, two Fsh-responsive growth factors, regulate spermatogonial differentiation in a concerted manner. *J. Bogerd*[1], R. D. V. S. Morais[1], R. H. Nóbrega[2], D. Crespo[1], H. J. G. van de Kant[1], R. Male[3], R. W. Schulz[1,4]. 1) Utrecht University, Utrecht, The Netherlands; 2) São Paulo St. University, Botucatu, Brazil; 3) University of Bergen, Bergen, Norway; 4) Institute of Marine Research, Bergen, Norway.

Follicle-stimulating hormone (Fsh) modulates fish spermatogenesis in a steroid-independent manner by modulating the expression of growth factors controlling spermatogonial proliferation and differentiation. Here, we find that two of these Fsh-responsive growth factors influence each other's activity on zebrafish spermatogonia: anti-Müllerian hormone (Amh) and the insulin-like growth factor 3 (Igf3). Fsh-time and -dose response experiments *ex vivo* demonstrate that *igf3* transcript levels are rapidly up-regulated, remain elevated, and respond to lower Fsh concentrations than are required to decrease *amh* mRNA levels. Immunofluorescence studies suggest that Fsh also decreases Amh protein levels while increases in Igf3 protein levels were comparatively small. Zebrafish Amh compromised Igf3-induced proliferation of type A undifferentiated (A_{und}) and type A differentiating (A_{diff}) spermatogonia. Proliferation of Sertoli cells associated with type A_{und} spermatogonia was also reduced by Amh. To better understand the inhibitory effects of Amh on germ cell development, we investigated Amh-induced changes in zebrafish testicular gene expression by RNAseq. Analyzing the differentially expressed genes demonstrates that several signaling pathways are potentially involved in mediating the inhibitory activity of Amh. The majority of the genes identified were down-regulated, such as the transcript levels of *igf3*, *insl3* and of steroidogenesis-related genes, all three stimulating germ cell differentiation. At the same time, Amh increased the expression of inhibitory signals, such as *inha* and *id3* transcript levels. Altogether, our results provide new information on how Fsh regulates zebrafish spermatogenesis by orchestrating the actions of different growth factors and other paracrine signaling systems, including the control of the multiple inhibitory effects of Amh.

Z6104B An improved method for gynogenesis in zebrafish produces fertile males. *Thomas A. Delomas*, Konrad Dabrowski. School of Environment and Natural Resources, The Ohio State University, Columbus, OH.

Analyzing recessive mutations typically requires the production of three generations: an original heterozygous carrier, an F_1 cross, and multiple F_2 crosses. This can be shortened to two generations by producing uniparental progenies from the heterozygous carrier through gynogenesis. Gynogenesis is typically performed using UV-irradiated zebrafish sperm, but this limits its use to females carrying an easily identifiable recessive mutation, so as to recognize any contamination from sperm that was not deactivated. This could be overcome by using UV-irradiated heterologous sperm that is capable of initiating development but, if inactivation is not complete, results in either inviable or distinguishable hybrids. Koi carp *Cyprinus carpio* was evaluated as a candidate for this purpose.

Hybridization was performed by artificially crossing 18 zebrafish females with one koi carp male. Embryonic development was successfully initiated by koi carp sperm. There was high progeny mortality in all tested pairs over the first 24h and complete mortality prior to the swim-up stage. Several distinct and consistent deformities were observed in the hybrid embryos: blastomeres of unequal size, short bodies, and edema.

Gynogenesis was performed using UV-irradiated koi carp sperm and either an early pressure or a heat shock treatment was used to restore diploidy. Survival to 21 days post fertilization was similar between progenies from the two types of shocks, averaging 2.2% and 2.5% for early pressure (n=3) and heat shock (n=5), respectively. Thus far, only males have been present in gynogenetic progenies produced (n=8). Samples of males resulting from 2 separate early pressure treatments were spawned naturally with non-sibling females. Control males (half-siblings of the gynogenetic males) were also spawned with the same females. The proportion of males that were fertile, fertilization rates and survival from fertilization to swim-up larvae was recorded. Fertilization rates were significantly lower than the control in one gynogenetic progeny ($p<0.10$), but not in the second. Survival from fertilization to the swim-up stage was not significantly different from the control in either progeny. This demonstrates that gynogenetic males could be used as broodstock for the rapid development of homozygous mutant lines. Males from a third early pressure shock progeny and from five heat shock progenies will be tested for fertility and these results will be presented.

Z6105C Wnt4a is expressed in the early gonad and is required for normal female sex determination. *Michelle Kossack*[1], Samantha High[2], Anastasia Utkina[1], Bruce Draper[1], John Postlethwait[2]. 1) Molecular and Cellular Biology, University of California Davis; 2) Institute of Neuroscience, University of Oregon, Eugene OR 97403.

Sex determination in zebrafish is not well understood. In AB and TU laboratory strains, sex determination occurs in the absence of a typical

sex chromosome, but animals directly from nature have a strong sex determinant on LG4. Early stage oocytes are necessary for primary female sex determination, and therefore it is hypothesized that oocytes produce a signal that act on the somatic gonad that maintains female sex or inhibits male sex differentiation. In mammals, Wnt4 is a signaling ligand that is essential for female development. We therefore asked if *wnt4a,* the single copy ortholog of *WNT4* in zebrafish*,* has a similar role in zebrafish primary sex determination. We found, using qPCR and *in situ* hybridization, that *wnt4a* is expressed in the somatic cells of juvenile gonads by 12 days post fertilization and continues in the follicle cells of adult ovaries. Thus *wnt4a* is a plausible candidate for the oocyte-produced sex determining factor. Fish homozygous for *wnt4a*(*fh295*), a TILLING allele that encodes a C-terminally truncated protein lacking residues shown to be important in WNT signaling, develop almost exclusively as male. Because the existing *wnt4a* TILLING alleles are C-terminal truncations and are therefore suspected dominant-negatives, we used CRISPR/Cas9 to produce two loss-of-function mutant alleles, *wnt4a(uc55) and wnt4a(uc56),* which result from a 17 and a 26 base pair insertion where in the protein is truncated to 68 or 33 amino acids, respectively. We found that homozygous adult mutants for both *wnt4a(uc55) and wnt4a(uc56)* develop predominantly as males. We further found that mutant males are sterile because reproductive ducts do not grow as rapidly toward the vent as wild-type ducts, and never connect to the genital orifice. However, sperm from macerated testes of *wnt4a* mutants produced normal offspring. Tissue surrounding the genital orifice in wild types strongly expressed *wnt4a*. These results show that Wnt4 is necessary for normal male reproductive duct development, but not for male sex determination. To further define the role of WNT signaling for female development and male duct development, we created CRISPR/Cas9 mutants in *rspo1*, which encodes a component of the canonical WNT signaling pathway. Our results strongly support the hypothesis that Wnt4a plays an important role in female sex determination and male reproductive duct development.

Z6106A Polycystic ovarian syndrome in zebrafish mutants for the TGF-beta signaling molecule Gsdf. *J. Postlethwait*[1], Y.-L. Yan[1], T. Desvignes[1], R. BreMiller[1], C. Wilson[1], M. Kossack[2], B. Draper[2]. 1) Univ Oregon, Eugene, OR; 2) Univ of California, Davis, CA.

In gonad development, somatic cells support germ cell development, and reciprocally, germ cells help sustain the development and function of somatic gonad support cells. Currently we lack a full understanding of mechanisms and molecules that perform these functions. To learn about gonad ó soma signaling, we used TALENs to knock out *gsdf* (gonadal soma derived factor), which encodes a ray-fin fish-specific TGF-beta signaling molecule. Gsdf is the major sex determinant in the Luzon medaka, but whether it performs this role in zebrafish is unknown. Several deletion alleles were isolated and all shown to produce similar female sterile phenotypes. Results showed that in wild types, gonadal expression of *gsdf* starts in the somatic cells surrounding the primary germ cells in indifferent gonads before 12 days post fertilization and continues into adulthood in granulosa cells in ovaries and Sertoli cells in testes. Mutant ovaries and testes both showed substantial down-regulation of *gsdf* transcript. Mutant ovaries never developed follicles beyond stage III and did not sequester yolk protein, and instead accumulated thousands of early stage oocytes, leading to sterility. Gene expression studies showed that ovarian follicle cells were abnormal in mutants and failed to express *cyp19a1a* (*aromatase*), *amh* (*antiMüllerian hormone*) and *gata4* normally. Mutant testes were also enlarged, but males were fertile. Mutant testes had normal expression levels of *sox9a* but elevated expression of *amh*. Zebrafish *gsdf* mutant females had aberrant accumulation of lipid in several organs, abnormal expression of the insulin receptor and several lipid metabolism genes. In addition, qPCR confirmed that estrogen receptor and vitellogenin were misexpressed in the livers of *gsdf* mutant females. Mutant ovaries down-regulated many genes involved in sex differentiation, steroid biosynthesis, hormone signaling, cell signaling, and apoptosis and proliferation. These experiments show that in zebrafish, *gsdf* does not have a major effect on sex determination, but rather provides a signal from the gonadal soma to the germ line that regulates oocyte maturation but not germ cell proliferation. Downstream consequences of the lack of Gsdf activity result in a phenotype that mimics human females with polycystic ovarian syndrome (PCOS), with accumulation of immature ovarian follicles, diminished expression of genes encoding steroid hormone biosynthesizing enzymes, obesity, diabetes, and female sterility, thus suggesting a role of TGF-beta signaling molecules in the etiology of PCOS.

Z6107B Zebrafish liver diurnal gene expression and comparative transcriptomics. *G. Breton*[1], G. Boyle[1], J. Foster[1], H. Priest[2], T. Mockler[2], K. Richter[3], D. Traver[3], S. Kay[3]. 1) Univ Texas Health Sci Center Houston, Houston, TX; 2) Donald Danforth Plant Science Center, St-Louis, MO; 3) Univ California at San Diego, La Jolla, CA.

From photosynthetic bacteria to mammals, the circadian clock evolved to track diurnal rhythms and enable organisms to anticipate daily recurring changes such as temperature and light. It orchestrates a broad spectrum of physiology such as the sleep/wake and eating/fasting cycles. While we have made tremendous advances in our understanding of the molecular details of the circadian clock mechanism and how it is synchronized with the environment, we still have rudimentary knowledge of its connections to diurnal physiology. One reason for this lack of understanding is the sheer size of the output network. Transcriptomic studies have identified more than 2000 clock-controlled genes (CCGs) with rhythmic expression patterns. Toward exploring this network in vertebrates, we selected *Danio rerio* as model system. As an initial step, by combining liver tissue sampling in a 2-days time series, transcription profiling using oligonucleotide arrays and bioinformatics analysis, we profiled rhythmic genes and identified several thousands rhythmic genes including ~200 clock-controlled transcription factors (CCTFs). Comparative transcriptomics between Zebrafish, mice and human datasets revealed interesting features of the output network. The results from a global analysis of the union and intersection between the datasets suggest that a large portion of the CCTFs may be involved in circadian gating. Undoubtedly, the Zebrafish model system will help identify new vertebrate outputs and their regulators and provide leads for further characterization of the cis-regulatory network.

Z6108C Profiling the active genomic elements of progenitor cells in the zebrafish optic tectum and telencephalon. *R. ESPOSITO*[1,2], A. Heuzé[1], L. Bally-Cuif[2], JS. Joly[1]. 1) CNRS Neuro-PSI, CASBAH group, Gif-sur-Yvette, FR; 2) CNRS Neuro-PSI, Zebrafish Neurogenetics group, Gif-

sur-Yvette, FR.

Zebrafish, as other teleost fish, display a remarkable capacity to produce neurons throughout life. This process arises from neurogenic niches distributed along the rostro-caudal axis of the brain, responsible for both constitutive neurogenesis and neuronal repair after injuries. Different progenitor subtypes, some exhibiting Neural Stem Cells (NSC)-like features, have been distinguished in adult neurogenic zones: self-renewing radial glial cells (RG; *i.e.* in the dorsal telencephalon, hypothalamus) and neuroepithelial-like cells (*i.e.* lateral and ventral telencephalon, optic tectum, cerebellum), which can also contribute to the generation of RG pools. The main interest of our laboratories is to dissect the genetic and molecular mechanisms controlling adult neurogenesis in the zebrafish telencephalon and optic tectum. To this aim, one approach consists in investigating the epigenetic state characterizing cell proliferation, quiescence and differentiation within the aforementioned neurogenic niches. Indeed, epigenetic mechanisms changing chromatin compaction and its nucleoprotein structure are part of processes controlling cell state, as biologically active genomic elements (*e.g.* enhancers, promoters, etc) need to be accessible to the transcription machinery, whereas inactive regions are sequestered in the hierarchical chromatin packaging. Therefore, the analysis of chromatin accessibility can provide information on the state or the potential of a cell in a given context. We are profiling the active genomic elements involved in zebrafish neurogenesis using ATAC-seq, a relatively new chromatin accessibility assay, which can be applied also to a very limited amount of starting material (5K cells). In order to isolate by FACS the cells to analyse, we are using fish lines in which specific regulatory regions drive the expression of GFP and/or RFP in the appropriate cells: glial and neuroepithelial progenitors, proliferating cells and differentiated neurons, for epigenomic profiling in the optic tectum, and quiescent RG, activated RG and transient progenitors, for the telencephalon. Our work should allow identifying *in vivo* the regulatory logic that specifies the identity and/or the different cell states/types (from progenitors to neurons) operating in two important neurogenic zones in the zebrafish adult brain, and will also permit a comparison between these two territories.

Z6109A Transcriptional Regulation of Heart Development in Zebrafish by ZNF143. *L. E. Huning*, Gary Kunkel. Texas A&M University, College Station, TX.

Regulation of transcription in eukaryotes is an intricate interplay between activator/repressor proteins and co-regulator proteins that bind together to form a molecular machine. This regulation is tightly controlled to ensure that cells produce the correct amount of proteins needed for development. An important activator protein that binds over 2000 mammalian promoters is Zinc Finger Protein 143 (ZNF143). ZNF143 binds to promoter regions of both small RNA genes along with protein coding genes, and has been implicated in the regulation of promoters important for cell cycle progression. Knockdown experiments of this protein caused several pleiotropic effects during early embryogenesis in zebrafish including heart, blood, and brain phenotypes. Although ZNF143 is involved in many different cellular processes, the overall function and mechanism of molecular control at promoter regions of developmental genes is still largely unknown. Phenotypic analyses following knockdown of ZNF143 via antisense morpholinos reveal developmental defects in expression patterns of known heart marker genes at different stages during cardiogenesis. Preliminary ChIP-seq analysis with 24 hour embryos demonstrated that ZNF143 binds to over 500 promoter regions of genes, with 8% of these being bidirectional. Gene ontology analysis with these promoters showed that ZNF143 binds to genes involved in an assortment of biological processes including metabolism, cellular transport and organization, and developmental genes. Current studies involve a targeted CRISPR/Cas9 knockdown of ZNF143 and its effect on cardiogenesis. In addition, zebrafish transgenic lines are being constructed with several ZNF143 target promoters and binding-deficient versions to investigate the molecular mechanism of ZNF143. Hypothesized mechanistic activities of ZNF143 that will be assessed include the amount and timing of RNA polymerase II recruitment, different histone modifications, and nucleosomal patterns that occur at target ZNF143 bound promoter regions.

Z6110B Program number not assigned.

Z6111C New insights into the role of DNA methylation in development and disease from a zebrafish model of ICF syndrome. *S. Rajshekar*[1,2], M. G. Goll[1]. 1) Memorial Sloan Kettering Cancer Center, New York, NY, USA; 2) Weill Cornell Graduate School of Medical Sciences, Cornell University, New York, NY, USA.

The modified base, 5-methylcytosine (5mC) is enriched at repetitive sequences such as satellite repeats that are located in the vicinity of centromeres. Loss of methylation at these repeats correlates with chromosomal instability and is detected in many cancers and the rare genetic disease Immunodeficiency, Centromeric instability and Facial abnormalities (ICF) syndrome. *ZBTB24* is mutated in ICF syndrome Type-2. However, the function of this gene is unknown and animal models have not been described. To understand how *ZBTB24* regulates DNA methylation near centromeres and to determine how centromeric hypomethylation contributes to disease pathology, we have developed a zebrafish model for ICF syndrome by generating loss of function mutations in the zebrafish ortholog of *ZBTB24* using TAL Effector Nucleases (TALENs). *Zbtb24* mutant zebrafish recapitulate features characteristic to ICF patients including distinct cranio-facial anomalies, slow growth and reduced lifespan. We demonstrate that *zbtb24* mutation results in a progressive, rather than acute, loss of 5mC at satellite repeats and that this hypomethylation correlates tightly with the onset of phenotypic abnormalities. Intriguingly, we detect an inflammatory RNA signature in *zbtb24* mutants prior to the onset of disease phenotypes. This observation suggests the presence of an endogenous inflammation based surveillance system that detects loss of centromere DNA methylation. We propose that during normal development this system protects against malignancy by eliminating affected cells before they accumulate substantial DNA damage.

Z6112A Identifying interacting ligands of human RORγ using transgenic zebrafish. *Rachel Sung*[1], Henry Krause[1,2]. 1) Department of Molecular Genetics, Terrence Donnelly Centre for Cellular and Biomolecular Research, University of Toronto; 2) InDanio Bioscience, Toronto.

The retinoic acid receptor-related orphan receptor gamma, or RORγ, is a member of the nuclear receptor ROR family and is involved in

important physiological processes including development, reproduction and metabolism. Its activity is regulated by the binding of small compounds, called ligands, which can induce conformational changes, which in turn, can influence the binding of cofactors, including transcriptional coactivators and corepressors,. There are two isoforms of RORγ. The first is RORγ, which is expressed in the liver, adipose tissue, skeletal muscle and kidneys, and is involved in glucose and lipid metabolism and regulating the circadian rhythm. The second is RORγt, which is expressed in the immune system, and is involved in thymopoiesis and secondary lymphoid organ development. It has been shown that RORγ is involved in the progression of various diseases, including metabolic and autoimmune diseases. These diseases can be controlled through natural or synthetic ligands that can either agonize or antagonize RORγ.

Previous *in vitro* screens have identified interacting ligands of RORγ, but many of these fail in humans due to metabolic inactivation, failure to reach target tissues and off-target toxicity; therefore, it will be much more effective to develop an *in vivo* screening system that can ensure that the ligand is interacting with the receptor in the correct *in vivo* setting. Our lab has developed an *in vivo* GFP reporter system, incorporated into the zebrafish genome, that allows high throughput screening to identify ligands that target RORγ. A drug screen using a compound library consisting of ~4000 natural compounds and approved drugs is being performed to identify new interacting ligands of RORγ. Using new identified ligands of RORγ, cofactors and target genes that are associated with RORγ can also be discovered, which will allow for further understanding of the role and function of RORγ as well as its involvement in diseases. Ultimately, the active drugs identified during the drug screen can be tested on various disease models.

Z6113B Regulation of brain and heart development in zebrafish by the autism risk factor CHD8. *J. A. Tracy*, G. Kunkel. Texas A&M University, College Station, TX.

Accessibility of the transcription machinery to regulatory elements upstream of genes is reliant on the location and stability of nucleosomes within the section of DNA. Remodeling these regions to allow binding of transcriptional regulators depends on the ATP-dependent movement of nucleosomes within the chromatin structure. The focus of this work is the ATP-dependent chromodomain helicase DNA-binding protein 8 (CHD8). CHD8 interacts with several factors that are relevant to the regulation of transcription and modulation of expression of genes implicated in crucial developmental processes and mutations within CHD8 have in multiple patients with autistic spectrum disorder. In addition to chromatin remodeling, CHD8 contains an A-kinase anchoring protein (AKAP) domain. AKAP proteins anchor protein kinase A (PKA), a kinase activated the pathway of gene regulation, to subcellular structures, thus allowing for spatial control and specialization of the PKA phosphorylation. Defects in AKAPs lead to various types of heart disease. Through the use of morpholino oligonucleotides and CRISPR/Cas9 to disrupt CHD8 expression, we have determined that CHD8 necessary for proper brain and heart development in zebrafish embryos. Reduction in CHD8 leads to disruption of expression patterns of several genes known to in brain and heart development. There are at least two isoforms of CHD8 that result from alternative splicing, and CHD8L. Interestingly, while CHD8S lacks the essential helicase domain required for nucleosome remodeling, we have that both isoforms of CHD8 are capable of activating gene expression at a ZNF143 targeted promoter but during zebrafish development.

Z6114C MicroRNA regulation of BMP signaling and its effects on vascular smooth muscle cells. *C. G. Watterston*, L. Zeng, A. Onabadejo, S. J. Childs. University of Calgary, Calgary, Alberta, CA.

Stroke is the third leading cause of death in North America and hemorrhagic stroke accounts for 12% of all stroke. As blood vessels develop it is essential that they are physically supported to ensure to supply blood to peripheral tissues. Vascular smooth muscle cells (vSMC) support the endothelial lining of blood vessels and can switch their phenotypic expressions from contractile (differentiated) to synthetic (undifferentiated). Synthetic vSMCs cannot properly support blood vessels the effects of which can lead to uncontrolled bleeding (hemorrhage). We aim to uncover the relationship between microRNAs (miRNAs) and their target genes using a zebrafish model in vascular stabilization. microRNA26 (miR26) targets smad1 downstream of BMP signaling *in vitro.*We show that knockdown of *miR26* leads to brain hemorrhage in developing zebrafish and that Smad1 is upregulated. Concomitantly overexpression of *miR26* leads to decreased Smad1.Overexpression of Smad1 in wild type fish also leads to hemorrhage and double knockdown of *miR26* and Smad1 rescues loss of *miR26*, suggesting that *miR26* mediates vascular stabilization via targeting of Smad1. We observe increased pSmad1/5/8 suggesting increased activation of the BMP pathway. A range of other phenotypes are also observed suggesting alterations in the BMP pathway including axial patterning defects.*miR26* is expressed in the vicinity of brain blood vessels and loss or gain of *miR26* leads to alterations in genes critical for vascular mural cell development including *pdgfrβ*, *acta2*, and *nmhc-b*. We also show decreased *acta2* positive cell coverage of blood vessels in *miR26* knockdown embryos.To test the role of BMP in vascular smooth muscle development, we applied the BMP receptor kinase inhibitor DMH1 to wild type and *miR26* knockdown. DMH1 treatment leads to a reduction in *acta2* positive smooth muscle cells in wild type embryos. DMH1is unable to rescue loss of *miR26*, which is expected if increased Smad1 resulting from *miR26* knockdown is unable to be phosphorylated by the BMP receptor.Taken together our results indicate that both loss and gain of pSmad1 leads to defects in vascular smooth muscle differentiation *in vivo*, and that *miR26* controls this fine balance to promote vascular maturation.

Z6115A Efficient CRISPR/Cas9 genome editing for heat shock-mediated conditional regulation in zebrafish. *Y. Wu*, I. Wang. National Taiwan University Hospital, Taipei, TW.

Purpose: Conditional mutation is crucial for determining stage- and tissue-specific functions of genes. Herein, we developed and characterized an inducible knockout platform composed of the heat-inducible hsp70l promoter and clustered regularly interspaced shot palindromic repeats (CRISPR)/Cas9 system, an easy and efficient strategy for generating gene-modified cells and organisms. **Materials and methods:** We generated a heat shock-dependent Cas9 zebrafish embryo by inserting an hsp70l promoter-driven Cas9 transgene expression

cassette through the Tol2 transposon system. To overcome the difficulty in identifying zebrafish germline integrations and facilitate observation of Cas9 expression, this cassette contains heart-specific *cmlc2*:EGFP and a selectable marker, P2A-mCherry. Real-time PCR and immunoblotting were performed to characterize heat-dependent, constitutive expression of Cas9 in zebrafish after heat shock. Furthermore, we designed and constructed plasmids containing zU6 promoter-driven *tyr* guide RNA and *cmlc2*:mCherry, which is a distinguishable marker used to confirm expression of gRNA. This plasmid was injected into one-cell fertilized Cas9 embryos. After heat shock, we estimated the efficiency of targeted mutagenesis of injected embryos through T7 endonuclease I assay and real-time PCRs. **Results:** Heat treatment of Cas9 transgenic embryos resulted in expression of mCherry fluorescence throughout the whole body without morphological abnormalities, and Cas9 protein was expressed 1 hr after the onset of heat shock, with high levels of Cas9 gene expression observed by 6-12 hr post-heat shock. In testing endogenous Tyr locus, we found that the mutagenesis efficiency reached approximately 50%. Mosaic phenotypes were observed in the injected embryos. **Conclusions:** The results indicate that our developed mutagenesis approach is efficient and could be used to generate conditional alleles throughout the zebrafish genome.

Z6116B Characterization of the *Meis2* locus. *Ted Zerucha*, Megan Tennant, Cody Barrett, Caroline Cochrane, Tyler Ferrara, Brantley Graham, Tray Neilson, Kyle Nelson, Zach Williams, Brandon Carpenter. Appalachian State University, Boone, NC.

The *Meis* genes are a member of the homeobox super-family of genes that code for the production of transcription factors. Homologs of the *Meis* genes have been identified in all animals studied and have been found to be expressed in similar patterns during the embryonic development of those animals. The products of the *Meis* genes are able to directly regulate the expression of target genes but are most well-known for functioning as cofactors, directly interacting with other transcription factors as well as DNA to facilitate transcriptional regulation. Most notably, they appear to act as co-factors of the evolutionarily well-conserved Hox proteins and have also been described as acting with other transcription factors on DNA. Despite being fairly well-characterized in terms of their molecular function and expression during development, little is known concerning how their expression is regulated. We have identified four highly conserved noncoding elements associated with the vertebrate *Meis2* gene and named them m2de1-4 (for *Meis2* downstream element). While M2de2-4 have to date only been found in land vertebrates, m2de1 is also found in teleosts including zebrafish. Interestingly these elements are found in the introns of an adjacent gene, *zgc:154061* in zebrafish, whose orthologs are always found in an inverted convergently transcribed orientation directly downstream of *Meis2* in vertebrates. Our hypothesis is that the genomic organization of these two linked genes has been preserved due to them sharing *cis*-regulatory elements. To test this, we have examined the expression patterns of *meis2a* and *zgc:154061* as well as the expression of a reporter transgene directed by m2de1 in zebrafish.

Z6117C Precise levels of the transcription factor *gata2*, modulated through a conserved *cis*-element, are required for generation of definitive hematopoietic stem cells. *T. Dobrzycki*[1,3], R. Patient[1,2], R. Monteiro[1,2]. 1) Weatherall Institute of Molecular Medicine, Oxford, UK; 2) BHF Centre of Research Excellence, Oxford, UK; 3) Wellcome Trust DPhil Programme in Chromosome and Developmental Biology, Oxford, UK.

Hematopoietic stem cells (HSCs) maintain the vertebrate blood system throughout life. They arise during embryogenesis from the hemogenic endothelium (HE) located in the floor of the main embryonic artery, the dorsal aorta. Our understanding of the mechanisms underlying HE specification remains incomplete, but precise regulation of the transcription factor Gata2 is crucial for the generation of HSCs. For example, CRISPR/Cas9-mediated deletion of a conserved intronic enhancer (i4 enhancer) leads to a decrease in *gata2a* expression and subsequent loss of HSCs. By contrast, knockdown of the Lim-domain-only protein Lmo4, previously identified as a binding partner of Ldb1, results in loss of HSCs and massively increased *gata2a* expression in the HE. HSC formation in *lmo4a* morphants can be rescued by inhibiting Gata2 activity. Thus, the dose of *gata2a* in HE is critical for *de novo* production of HSCs, and *gata2a* levels are controlled by a critical negative input from Lmo4. We have found that the zebrafish i4 enhancer drives GFP expression in endothelial cells, including the HE, and have established a transgenic zebrafish line to monitor its activity *in vivo*. This line provides high temporal resolution for monitoring changes in Gata2a activity in the hematopoietic lineage and we could detect increased i4 enhancer activity upon Lmo4 loss-of function. To unravel the molecular basis for the loss of HSCs upon altered Gata2a expression we have generated deletion mutants for the i4 enhancer and for *lmo4*a, in order to respectively lower and elevate the levels of Gata2a in the embryo. Our current focus includes transcriptome-wide gene expression analysis and genome-wide analysis of chromatin structure in both mutant backgrounds in endothelial cells, including the HE. This will determine the global impact on gene regulation caused by modulation of *gata2a* levels and will help us understand how the precise control of *gata2* specifies the HE and generates HSCs.

Z6118A *bif* modulates the BMP pathway to pattern lateral plate mesoderm into primitive red blood cells. *J. GHERSI*, J. BERTRAND. CMU, GENEVA, CH.

During embryonic development, gastrulation leads to the specification of mesoderm that will contribute to the cardiovascular system, the muscles, and many other tissues. In zebrafish, mesoderm appears at 6 hours post fertilization (hpf), and the first blood progenitors can be detected as early as 12hpf in the lateral plate mesoderm (LPM). To better understand the mechanisms involved in LPM patterning into blood, we performed transcriptome analysis to compare the first erythrocyte progenitors with the first angioblasts, sorted at 12hpf. We identified a new gene, *bif (BMP-inhibitory factor)* that is specifically expressed in the posterior LPM that will give rise to primitive red blood cells. *bif* is expressed as early as 11hpf in the LPM and then remains specifically expressed in erythrocytes. *bif* is a transcription factor of unknown function. Gain-of-function experiments resulted in an expansion of the blood marker *gata1* in the posterior LPM at 12hpf, in a similar way that was observed when BMP signalling is perturbed. Moreover, overexpression of *bif* resulted in the duplication of the tail axis at 24hpf, and the mis-expression of cloaca markers, two phenotypes also observed in BMP-impaired embryos. Further analyses by qPCR and in situ hybridization

showed that *bif* expression diminishes the expression of BMP target genes.

We thus conclude that *bif*, specifies the LPM towards blood fate by down-regulating BMP signalling. We are now building new transgenic tools, as well as mutants, in order to understand the full spectrum of *bif* actions.

Z6119B Cardiac lymphatic development in the adult zebrafish. *Michael Harrison*[1], Xidi Feng[1], Stefan Schulte-Merker[2], Ching-Ling Lien[1,3]. 1) Children's Hospital Los Angeles, Los Angeles, CA; 2) Cells-in-Motion, Cluster of Excellence, University of Muenster, Germany; 3) Keck School of Medicine, University of Southern California, CA.

An intricate network of cardiac blood and lymphatic vessels provide cardiac tissue with oxygen and nutrients and eliminate excess fluid from the interstitium. Lymphatic vessels are required to maintain normal heart function and their blockage or destruction leads to cardiac edema, fibrosis and inflammation. Despite their critical roles in physiology and pathology, little is known about lymphatic vessel growth and development in the heart. Building on our recent work on coronary vessel development, we have described the formation of the lymphatic vasculature system in adult zebrafish. Lymphatic endothelial cells reside on the bulbus arteriosus until 3 months of age when they sprout on to the ventricle, preferentially migrating down the coronary arteries. Over several weeks these initial sprouts form vessels that are in close proximity to the coronary arteries and extend branching vessels that partially cover the ventricle. We are currently investigating the role of CXC-signaling in guiding this process and the potential role lymphatic vessels play in heart development and regeneration.

Z6120C *foxc1a* and *foxc1b* exhibit distinct compensatory requirements during brain and trunk angiogenesis and haematopoietic stem cell formation in zebrafish. *Z. Jiang*[1,2], T. Evans[3], M. Loose[3], T. J. A. Chico[1,2], R. N. Wilkinson[1,2]. 1) Department of Infection, Immunity & Cardiovascular Disease, University of Sheffield, Medical School, Sheffield, UK; 2) The Bateson Centre, University of Sheffield, Sheffield, UK; 3) Medical School, University of Nottingham, Queen's Medical Centre, Nottingham, UK.

The cardiovascular system is essential for all aspects of tissue growth and physiology. Haematopoietic stem cells (HSCs) are derived from the embryonic artery during early development and give rise to all adult blood cell lineages throughout life. The shared origin of arterial endothelial cells (ECs) and HSCs means these cells share common mechanisms which regulate their formation. Our understanding of these mechanisms remain incomplete. In mammals, the transcription factors *foxc1* and *foxc2* are required for both cardiovascular and haematopoietic development, however, how these genes interact with endothelial signalling pathways to regulate these processes remains unclear.

We have generated novel zebrafish mutants in orthologues of mammalian *foxc1* (*foxc1a* and *foxc1b*) to determine the function of these genes during blood vessel and HSC formation. *foxc1a* mutants display aberrant cranial blood vessel formation and defective blood-brain barrier formation with almost total loss of central arteries (CtAs). *flt4* expression is drastically reduced within the primordial hindbrain channel (PHBC) of *foxc1a* mutants, indicating *foxc1a* may regulate the ability of ECs within the PHBC to receive VEGF. Arteriovenous differentiation is disrupted within the trunk of *foxc1a* mutants. While the dorsal aorta and posterior cardinal vein are present in *foxc1a* mutants, arterial gene expression is substantially reduced and venous expression is increased, indicating *foxc1a* is required for correct specification of arteries and veins. Segmental arteries (SeA) are correctly specified and sprout normally in *foxc1a* mutants, however *foxc1a; foxc1b* double mutants display ectopic secondary SeA branching indicating *foxc1a* and *foxc1b* genetically interact during angiogenesis. In keeping with observed reductions in arterial gene expression, *foxc1a* mutants exhibit reduced HSC numbers and HSC progeny. Interestingly, *foxc1a* mutants also display defective somite patterning as has been reported previously. Furthermore, somitic Wnt16 and Dlc/Dld signalling are known to instruct HSC formation non-cell-autonomously and *wnt16* and *dlc* expression are reduced in *foxc1a* mutants. Collectively, this indicates *foxc1a/b* play compensatory and pleiotropic roles in co-ordinating both blood vessel and HSC formation and may influence these processes via distinct pathways.

Z6121A Vegfa signaling promotes zebrafish intestinal vasculature development through endothelial cell migration from the posterior cardinal vein. *Andrew L. Koenig*[1], Kristina Baltrunaite[1], Neil I. Bower[2], Andrea Rossi[3], Didier YR Stainier[3], Ben M. Hogan[2], Saulius Sumanas[1]. 1) Division of Developmental Biology, Department of Pediatrics, Cincinnati Children's Hospital Medical Center, Cincinnati, OH 45229, USA; 2) Division of Genomics of Development and Disease, Institute for Molecular Bioscience, The University of Queensland, St Lucia, QLD 4073, Australia; 3) Department of Developmental Genetics, Max Planck Institute for Heart and Lung Research, Bad Nauheim 61231, Germany.

The mechanisms underlying organ vascularization are not well understood. The zebrafish intestinal vasculature forms early, is easily imaged using transgenic lines and in-situ hybridization, and develops in a stereotypical pattern thus making it an excellent model for investigating mechanisms of organ specific vascularization. Here, we demonstrate that the sub-intestinal vein (SIV) and supra-intestinal artery (SIA) form by a novel mechanism from angioblasts that migrate out of the posterior cardinal vein and coalesce to form the intestinal vasculature in an anterior to posterior wave with the SIA forming after the SIV. We show that vascular endothelial growth factor aa (*vegfaa*) is expressed in the endoderm at the site where intestinal vessels form and therefore likely provides a guidance signal. Vegfa/Vegfr2 signaling is required for early intestinal vasculature development with mutation in vegfaa or loss of Vegfr2 homologs causing nearly complete inhibition of the formation of the intestinal vasculature. Vegfc and Vegfr3 function, however, are dispensable for intestinal vascularization. Interestingly, ubiquitous overexpression of Vegfc resulted in an overgrowth of the SIV, suggesting that Vegfc is sufficient to induce SIV development. These results argue that Vegfa signaling directs endothelial cells to migrate out of existing vasculature and coalesce to form the intestinal vessels. It is likely that a similar mechanism is utilized during vascularization of other organs.

Z6122B DLC1 is a negative regulator of directed endothelial cell migration during embryonic vascular development. *T. Linnerz*, J. Y. Bertrand. Centre Médicale Universitaire, Geneva, CH.

The integrity of the vascular system is established during development. During vertebrate embryogenesis, the first endothelial precursors

arise in the lateral plate mesoderm (LPM) as early as 12hpf. At mid-somitogenesis stages, angioblasts migrate towards the midline, merge and organize into nascent cords giving rise to the major blood vessels (vasculogenesis). Subsequently, primary sprouting events occur from the pre-existing vessels (angiogenesis). We use the zebrafish model to investigate how the endothelial program initiates.

We are interested in *dlc1*, a gene encoding a RhoGTPase activating protein and tumor suppressor gene, which plays a role in the regulation of RhoA, B and C activity, hence influencing several cell processes such as migration or adhesion. *dlc1* is first expressed in the primordial angioblasts of the LPM, consistent with the high motility of these cells. Several gain-of-function approaches led to similar phenotypes: although arterio-venous specification was not impaired, angiogenic sprouting is greatly affected, resulting in poorly lumenized or hypersprouting intersegmental vessels (ISV) in the trunk of the embryo. As a result, blood circulation is disturbed leading to cardiac edemas and brain hemorrhages.

To further elucidate *dlc1*'s role in vascular development, we generated a mutant line with the CRISPR/Cas9 technology. Whereas *dlc1* knock-out mice die in utero preventing the study of any vascular phenotype, the *dlc1* null zebrafish survives until 5 days, allowing a better insight into its role in angiogenesis. The mutant fish has severe vascular defects that manifest in impaired primary blood circulation in aorta and vein, which is resulting in massive cardiac edemas. We will now use this new tool to investigate the angiogenic processes. Altogether, we will understand the physiological role of *dlc1* during development and reveal new mechanisms controlling angiogenesis in vertebrates.

Z6123C Heparin Receptor Involvement in Zebrafish Angiogenesis. *L. J. Lowe-Krentz*, S. L. N. Farwell, M. K. Iovine. Lehigh University, Bethlehem, PA.

Studies employing model systems from cell and tissue culture to zebrafish have determined critical role(s) for heparan sulfate chains of proteoglycans in vascular development and regeneration. Heparan sulfate chain interactions with growth factors and their receptors have been proposed to explain these requirements. Recently, our studies have confirmed the identification of a membrane protein (TMEM184A) that acts as a receptor for heparin (and heparan sulfate, by extension). This receptor plays a role in signal transduction and heparin uptake in cultured vascular cells. To examine the role of this receptor in a vertebrate organism, we employed zebrafish, and the specific *TG(fli1-EGFP)* transgenic line to evaluate the presence of the receptor and its function in angiogenesis. We have identified this protein (TMEM184A) in ontogenic and regenerating zebrafish vasculature through co-immunofluorescence with GFP in *Tg(fl1-EGFP)* zebrafish. The heparin receptor co-localizes with GFP in both arteries and veins in ontogenic tail fin rays from the fish. After amputation to approximately 50%, immunofluorescence confirms localization of the heparin receptor matching the GFP pattern in regenerates. In tissue culture systems, cell proliferation is increased in cells where TMEM184A is knocked down. Knock-down fin rays have larger numbers of GFP containing vascular cells, and the cells are more disorganized than either untreated or control morpholino treated fins. This effect is reversible. Transient knockdown using morpholinos results in significantly less TMEM184A staining in regenerating vessel cells within 24 hours of morpholino injection. These studies indicate expression of the heparin receptor in zebrafish endothelial cells and a modulatory role in angiogenesis. Coupled with information from cultured cells where heparin treatment decreases cell proliferation and receptor knockdown allows more extensive proliferation, these studies suggest that heparan sulfate chains from proteoglycans interact with the heparin receptor in this modulatory function.

Z6124A Effect on lymphoid transcriptional regulation factors correlate with the downregulation of *lmna* during hemotopoiesis. *l. shu*, F. Liu, H. Huang, H. Zhang, X. Wu, J. Wang, Z. He. Guizhou Medical University, guiyang, guizhou, CN.

Li-Ping Shu [*] Feng Liu [*] Hui-Min Huang, Heng-Lu Zhang, Xi-Jun Wu, Jun Wang, Zhi-Xu He [#](* co-author [#] correspongding author(hzx@gmc.edu.cn))

Abstract:objective Lamins are the major components of nuclear lamina underneath the inner nuclear membrane (INM). Lamins express in most cell and involve in the whole process of growth, which play a major role in cell stability and embryo development. While the effect on lymphoid transcriptional regulation factors correlate with the downregulation of *lmna* during hemotopoiesis remains unknown. **method** MO(Morpholino Oligomer) tagged to zebrafish *lmna* gene was microinjected into zebrafish embryos of different phases to downregulate the expression of *lmna*. The expression level of different transcriptional regulation factors such as *lmo2*, *scl*,*c-myb* and *runx1* were detected by Q-PCR. **result** The Q-PCR results show that the expression of transcriptional regulation factors *lmo2* and *scl*, which associated with primitive hemotopoiesis were downregulated in 18h, 24h, 30h and 36h groups compared with control group. *c-myb* and *runx1* were also downregulated. **conclusion** These results revealed that *lmna* may have a relationship with hemotopoietic transcriptional regulation factors and have a negative effect on embryo development.

Objective: To establish zebrafish model of G6PD dificiency.With dominant negative, expression of the mutant G6PD can impact the normal G6PD protein expression ,which result G6PD activity reducing.This modle can be used to study G6PD deficiency molecular mechanisms and provide an experimental basis for mass drug screening .**Methods**: To constrct a *gata1:g6pd*$^{M118\text{-}144}$-EGFP-PBSK-IsceI recombinant

plasmids.The plasmid were microinjected into tüebingen wild-type zebrafish embryos of single-cell stage.zebrafish embryos, which is injected into *gata1:g6pd*$^{M118\text{-}144}$-EGFP -PBSK-IsceI plasmid, express green fluorescent protein in the blood circulation that be treated as F0 generation G6PD transgenic zebrafish. Feeding F0 generation transgenic zebrafish until breeding period, each F0 generation transgenic zebrafish mate with wild-type zebrafish, the green fluorescent protein expression was observed in blood circulation in F1 generations transgenic zebrafish .Then using genomic PCR,whole mount in situ hybridization (WISH),Western blotting identify the Tg:*gata1:g6pd*$^{M118\text{-}144}$-EGFP F1 generation transgenic zebrafish on levels of DNA, mRNA, protein .**Results:** z*gata-1-g6pd*$^{M118\text{-}144}$*-EGFP*-pBSK-I-SceI recombinant plasmid is constructed and injected into wild-type zebrafish embryos.We screen zebrafish embryoes,which express green fluorescent protein as Founder 0 generation G6PD transgenic zebrafishs. we got five F0 generation G6PD transgenic zebrafishs. Expressing of the green fluorescent protein in F0 generation transgenic zebrafishs begins in ventral mesoderm at 11 hpf, and circulates with blood after 24 hpf ,and which can be passed on to the offspring. The *g6pd*$^{M118\text{-}144}$ is amplified from the genome of F1 generation transgenic zebrafish.With WISH,the mRNA of EGFP is detected at erythropoiesis site of F1 generation transgenic zebrafish. With Western blotting, expression of G6PD$^{M118\text{-}144}$-EGFP fusion protein is detected in F1 generation transgenic zebrafish.To sum up,we can identify that the *gata-1-g6pd*$^{M118\text{-}144}$*-EGFP* has integrated into the zebrafish genome and transcribed into mRNA, translated purposes fusion protein.**Conclusions** Identified the Tg:*zgata-1:g6pd*$^{M118\text{-}144}$-EGFP transgenic zebrafish on levels of DNA, mRNA, protein.Establishment the zebrafish disease models of G6PD deficiency can achieve in-depth study related mechanism in G6PD deficiency and high-throughput screening of antimalaric drugs to treat G6PD deficiency disease.

Z6126C Integrin Alpha 6 Is Required for Neurovascular Development Of The Hindbrain In Danio Rerio. *Vinoth Sittaramane*, Louise Zehr, Kayla Smith. Georgia Southern University, Statesboro, GA.

Stroke is one of leading causes of death and disability worldwide (CDC, 2014). Hemorrhagic stroke could be due to defective neurovascular development. Even though the occurrence of stroke happens in older age groups, genetic studies have found mutations (SNPs) in human integrin alpha 6 (ITGA6) linked to the predisposition of stroke. As of now, the roles of ITGA6 in the development of the neurovascular system are unknown. This study created itga6 deficient embryos using antisense nucleotides to investigate neurovascular development in zebrafish embryos using appropriate vascular transgenic lines. Deficiency in itga6 leads to severe loss of central arteries (CtAs), increase in endothelial cell protrusions, and dilation of several hindbrain blood vessels such as the basal artery (BA) and primordial hindbrain channels (PHBC). Itga6 mRNA injections were able to rescue deficient phenotypes, displaying return in number of CtAs, decrease in protrusions, and decrease in dilation. Further, time-lapse analysis also supported these findings in the deficient embryos showing an increase in endothelial protrusions with inability to make connections as seen in the controls. The loss of itga6 in embryos also displayed hemorrhaging in the hindbrain by 48hpf. These results indicate that itga6 does play a critical role in neurovascular formations. Itga6 is a transmembrane receptor for the extracellular matrix protein laminin enabling matrix remodeling during morphogenetic processes. During cancer metastasis Itga6 has been shown to cleave extracellularly allowing for cell migration. This study investigated whether integrin alpha 6's ability to cleave is also required for neurovascular development. Our studies have found that this cleavage mechanism in integrin alpha 6 is necessary for the CtA formation in the hindbrain as well.

Z6127A Deciphering the mechanism of action of ApoB lipoproteins on endothelial cells. *H. Tempelhof*, I. Avraham-Davidi, Y. Ely, K. Yaniv. weizmann institute of science, Rehovot, IL.

Apolipoprotein B (ApoB) is the primary structural protein in low-density and very low-density lipoproteins, and in chylomicrons. In addition to its established role in lipid metabolism, we have suggested in the past that ApoB negatively regulates angiogenesis during embryonic development. In this work we have used Talen and crispr technologies to generate zebrafish carrying mutations in two ApoB genes- *apoBa* and *apoBb.1*. In addition to complete depletion of lipoprotein production and secretion, the double mutant embryos were characterized by excessive angiogenesis. In contrast, a complementary model of hyperlipidemia and increased ApoB secretion, generated through overexpression of microsomal triglyceride transfer protein (*mtp),* resulted in inhibition of intersegmental vessel formation. Surprisingly, we have been able to detect the presence of ApoB inside the nucleus of endothelial cells both in cultured HUVECs and in FACS sorted zebrafish endothelial cells. These findings suggest that in addition to its well-established role in cholesterol transport, ApoB may act as a regulator of gene expression, functioning according to the metabolic state of tissues.

Z6128B Reck is a novel component of the canonical Wnt signaling pathway required for the formation of the brain blood vasculature and its barriergenic differentiation. *J. Torres-Vazquez*[4], Florian Ulrich[4], Jorge Carretero-Ortega[4], Carlos Narvaez[4], Belinda Sun[4], Eva Lancaster[4], Valerie Pershad[4], Sean Trzaska[4], Evelyn Veliz[4], Makoto Kamei[1], Andrew Prendergast[2], Kameha Kidd[1], Kenna Shaw[1], Daniel Castranova[1], Van Pham[1], Brigid Lo[1], Benjamin Martin[3], David Raible[2], Brant Weinstein[1]. 1) NICHD, NIH. Bethesda, MD; 2) University of Washington, Seattle, WA; 3) Stony Brook University, Stony Brook, NY; 4) New York University / Skirball Institute, New York, NY.

The cerebral vasculature provides the massive blood supply that the brain needs to grow and survive. By acquiring distinctive cellular and molecular characteristics it becomes the blood-brain barrier (BBB), a selectively permeable and protective interface between the brain and the peripheral circulation that maintains the extracellular milieu permissive for neuronal activity. In a forward genetic screen we isolated a mutant that specifically lacks most of the intracerebral central arteries but not other brain blood vessels. We found that the cerebral vascularization deficit of these mutants is caused by an inactivating lesion in reck (reversion-inducing cysteine-rich protein with Kazal motifs reck; which encodes a membrane-anchored tumor suppressor glycoprotein). Our findings highlight Reck as a novel and pivotal modulator of the canonical Wnt signaling pathway that acts in endothelial cells to enable intracerebral vascularization and proper expression of molecular markers

associated with BBB formation. Additional studies with cultured endothelial cells suggest that, in other contexts, Reck impacts vascular biology via the vascular endothelial growth factor (VEGF) cascade. Together, our findings have broad implications for both vascular and cancer biology.

Z6129C The function of *prdxI* during vascular development in zebrafish. *Chang-Yi Wu*, Po-Chun Huang, Hai-Hong Syue. Department of Biological Sciences, National Sun Yat-Sen University, Kaohsiung, Taiwan.

The balance of reduction-oxidation (redox) has been shown acting an important role in vascular growth. However, most studies have done in adult animals under pathological conditions, and very limited information about oxidative stress and vascular development during embryogenesis. Here, we report a novel biological function of *prdx1* (*peroxiredoxin1*) that play critical roles in vascular formation during zebrafish development. Prdx1 belongs to a member of the peroxiredoxin family of antioxidant enzymes. We showed *prdx1* is expressed in developing vessels and knockdown of *prdx1* by morpholino injection impairs the growth of ISV (intersegmental vessel) and CVP (caudal vein plexus), suggesting the role of *prdx1* in promoting vessels growth. We further showed the reduction of ISV cells is due to a decrease of cell proliferation and migration, but not results from cell death in non-endothelial cells. The molecular evidence of vascular defects in *prdx1MO* is related to the decreased expression of vascular markers, *flt4, mrc1*, *stabilin* and *ephrinb2*. Loss of *prdx1* results in vascular defects suggest the antioxidant function is important, thus, we test if oxidative stress could cause vascular defects in H_2O_2-treated embryos. Our data showed H_2O_2 treatment impaired CVP formation and caused mild ISV defects. While H_2O_2-treated embryo combined with knockdown of *prdx1*, synergetic effects are observed. In addition, exogenous N-acetylcysteine (*NAC*) treatment rescues the vascular defects in *prdx1MO*. Those data suggested the oxidative stress indeed can disturb vascular development. We further showed the different regulation pattern of antioxidant genes *SOD1, SOD2* and *catalase* in *prdx1* morphants from H_2O_2-treated embryos. To confirm the role of *prdx1* in vasculature, we overexpressed *prdx1* in the embryos and found overexpression of *prdx1* promotes ISV and CVP growth. Meanwhile, overexpression of *prdx1* can rescue the loss of *prdx1*. Those data suggest *prdx1* functions in vascular development necessary and sufficient. Interestingly, we found the increased expression of blood markers (*gata1, globin* and *lmo2*) coincident with the decreased expression of endothelial markers *flk1* and *fli* in *prdx1* MO, suggested *prdx1* likely regulate hemangioblast fate decision at earlier developmental stage. We further demonstrated *prdx1* likely interacts with Notch to control cell fate switch. Together, we showed *prdx1* play novel and critical roles in vascular growth during zebrafish development.

Z6130A A 24-hour Buffet: Effects of Culturing Zebrafish Under Continuous Illumination from Fertilization to Adulthood. *Thomas A. Delomas*, Mackenzie Miller, Konrad Dabrowski. The Ohio State University, Columbus, OH.

Investigation into the effect of continuous light on zebrafish biology and life cycle is lacking. This study examines growth rate, survival, and generation time of zebrafish raised under continuous illumination (24:0 photoperiod) from the time of fertilization to adulthood. Based on previous experiments in our laboratory with other cyprinid fishes, faster growth rate and shorter generation time under continuous illumination were predicted.

Larviculture methods utilizing rotifers, *Brachionus plicatilis*, and brine shrimp, *Artemia salina*, nauplii, were modified for this study. Zebrafish larvae were stocked in aerated stagnant water tanks at 5 days post fertilization (dpf) at a density of 100 larvae/L, which is 10 times higher than previously described. Feeding began at 6 dpf with live rotifers. At 12 dpf, half of the population was transitioned to live brine shrimp nauplii while the other half remained on rotifers for the duration of the study (46-50 dpf).

Fish achieved an average length of 16.1±0.7mm and weight of 61.6±6.7mg at 20 dpf, 2-5 and 10-30 times greater, respectively, than the length and weight described in the literature. Daily growth rate (%) was 39.7% from 12 to 20 dpf. Survival at 12 dpf (7 days post initial feeding), when larvae are most sensitive, was 75.6±10.6%. Once fish reached a size where gender could be visually distinguished (42 dpf), spawning pairs were set up daily (this included dark:light regime, 10:14, for 1-2 days) until a successful spawning occurred. Generation time (from egg to egg) was determined as 44 dpf (when the first pair spawned), 5 days earlier than the shortest generation time reported thus far in the literature (Aoyama et al. 2015. Zebrafish 12:288). This demonstrates that zebrafish can be successfully grown under continuous illumination to produce higher than average growth rate and shorter generation time than that suggested under light/dark regime. Using this method, five consecutive generations have been produced in 228 days. This rearing protocol will drastically reduce the time required for multigenerational experiments and mutant strain development, thereby considerably decreasing the cost of zebrafish culture.

Z6132C Optimization of Larval Zebrafish Husbandry: Getting More with Less. *David Zitser*, Nastassja Carusetta, Anish Bhandari, Robert Nissen. California State University of Los Angeles, Tarzana, CA.

The zebrafish *Danio Rerio* is a well-established model organism used to study normal development as well as disease states. While the use of dry feeds in zebrafish husbandry has grown substantially over the past decade, further optimization of the care and feeding of zebrafish breeding colonies may save significant time and resources. Thus, we sought to optimize larval care towards maximizing survival rate while also minimizing the amount of hands-on care required to achieve a still acceptably high survival rate. Many factors potentially affect larval survival rate. We sought to optimize food amount, feeding frequency, and water change frequency during the first 21 days of life. First, we optimized the quantity of 100-micron Golden Pearl (GP100) to be fed per tank of 30 larval zebrafish in one liter of fish system water. Second, we optimized the frequency of feedings and found that less frequent feeding may outperform daily feedings while simultaneously reducing the need for frequent water changes. Together, these changes yielded an average 81% larval survival rate (at 21dpf) with only 3 feedings per week and only a single water change per week, at which point the animals entered the adult colony and adult feeding regimen. These results may yield substantial savings of time and resources for breeding colonies.

Z6133A A zebrafish model of acute kidney injury associated with systemic infection induced by intravascular bacteria injection. *L. Cui*[1,2], X. Wen[1,2], S. Morrisroe[1,2], L. Brilli[1,3], X. Chen[1,2], N. Hukriede[1,3], J. Kellum[1,2]. 1) Center for Critical Care Nephrology, Pittsburgh, PA; 2) Department Critical Care Medicine, Pittsburgh, PA; 3) Department of Development Biology, University of Pittsburgh, Pittsburgh, PA.

Sepsis associated Acute Kidney Injury is a serious complication in critical ill patients, contributes to high mortality. To date, the underlying mechanisms responsible for kidney injury in sepsis remain poorly understood and treatments are still limited to supportive methods. The zebrafish is an economically attractive multicellular organism, provides unique visual access to the microscopic structure with cell-cell interactions. Both the embryonic and adult zebrafish show conserved components in both immune responses and functional nephrons with mammals, which makes this model promising for studying mechanisms and screening for treatment options. An acute nephrotoxic kidney injury model has been developed using gentamycin, but inflammation-associated AKI is more clinical relevant and yet no model in the zebrafish has been reported. E. tadar is a lethal pathogen in zebrafish, characterized by striking cytokine excretion and high mortality. Here we compared inflammatory findings of both bacteria injections into 3 days post-fertilization (dpf) zebrafish embryos as well as infection mediated kidney damage. We show dose-dependent mortalities for both E. coli and E. tadar intravascular injections, with E. tadar significantly higher than E. coli treated animals. We found remarkably decreased fluorescent dextran uptake and loss of tubule brush boarder occurred as early as 6-24 hours post injection in E. tadar treated larvae compared to E. coli treated ones as well as normal controls. Nephron-specific kidney injury molecular-1 (KIM-1) functions as phagocyte receptor, mediates uptake of dead cells and tissue debris. Immunofluorescence staining of KIM-1 appears at late time points post injection in both groups compared to no expressions in control groups. Prolonged expression of KIM-1 in mammalian kidney predicts AKI and maladaptive repair. These analyses have provided new insights for further understanding the physiological and molecular mechanisms that lead to kidney injury in the setting of infection and system inflammation.

Z6134B Host-Directed Therapies for Tuberculosis: Discoveries from a Zebrafish Chemical Screen. *M. A. Matty*, D. M. Tobin. Duke University, Durham, NC.

Mycobacterium tuberculosis (Mtb), the causative agent of tuberculosis, kills over 1 million people annually and drug resistance to current therapies is rapidly increasing. We have explored drug treatments to potentiate host responses to mycobacterial infection using a novel screening technique in Mycobacterium marinum (Mm) infected zebrafish to discover FDA-approved drugs that ameliorate Mm infection through host-directed processes. From this screen, we uncovered 10 novel compounds that reduce Mm burden in a host-dependent manner. Using CRISPR/cas9, we have found the target of one small moledule that ultimately benefits the host to control Mm infection by potentiating host innate immune signalling pathways. We have shown that this drug induces cell death and may alter the innate immune response through inflammatory cues. Utilizing the validated zebrafish:Mm infection model, this work will assist in development of novel therapeutics for human:Mtb infections.

Z6135C Role of Developmental Signaling Pathways in Mycobacterial Pathogenesis. *Allison Rosenberg*, David Tobin. Duke University, Durham, NC.

Tuberculosis (TB) kills 1.5 million people annually, with 8-9 million new active cases each year. The causative agent, *Mycobacterium tuberculosis (Mtb)*, manipulates host macrophages to survive within them. These infected macrophages, along with uninfected macrophages and other immune cells, aggregate into characteristic structures called granulomas where almost all bacteria reside in human *Mtb* infections. We have paired *Mycobacterium marinum (Mm),* the closest relative of the *Mtb* complex and a natural pathogen of ectotherms, with the zebrafish to establish a validated surrogate for human TB. The tuberculous granulomas that form in zebrafish recapitulate important features of human granulomas (organization, hypoxia, caseation necrosis) that are absent from standard mouse models. Here, we use the zebrafish to investigate how the central structure of mycobacterial infection is assembled and remodeled. We have used this model to make new findings about the tuberculous granuloma and have validated these findings in human specimens. Here, based on these findings and preliminary data, we hypothesize that macrophages, the central immune reservoir for pathogenic mycobacteria, deploy canonical developmental pathways, not traditionally considered in the context of immunity, in the construction of the granuloma. Using the zebrafish- *Mycobacterium marinum* model we will determine the role of developmental signaling in mycobacterial pathogenesis and granuloma formation.

Z6136A Investigating interleukin-2 receptor family signaling in zebrafish. *Robert Sertori*, Clifford Liongue, Alister C. Ward. Deakin University, Geelong, Victoria, AU.

The interleukin 2 receptor (IL-2R) family of class I cytokine receptors plays important roles in lymphocyte development and function. The mammalian IL-2R family utilize the shared signaling component interleukin 2 receptor gamma common (IL-2Rγc). Mutations of this receptor chain in humans or mice leads to severe combined immunodeficiency (SCID).

The purpose of this project was to examine the IL-2R family in zebrafish and generate a SCID zebrafish model.

Methodologies used include transcription activator-like effector nucleases (TALEN) induced mutagenesis, high resolution melt (HRM) and restriction fragment polymorphism (RFLP) to identify mutants and whole-mount *in situ* hybridization (WISH) and RT and QRT-PCR for expression analysis. Morpholino mediated knock-down was also used to explore the interleukin 15 receptor (il-15r).

Zebrafish possess 2 paralogues of *IL-2Rγc* with *il-2rγc.a* shown to have a conserved role in embryonic T lymphopoiesis. Therefore TALENs were targeted to *il-2rγc.a* to generate a SCID zebrafish model. Homozygous mutants were immunocompromised and showed reduced T cells at 5 dpf which was also evident at 28 dpf. B cells were expressed at 28 dpf indicating a T-B+ SCID model.

The zebrafish heterotrimeric receptor was also investigated for a conserved role in lymphopoiesis. Zebrafish only possess *il-15rα* at the *il-2rα*/*il-15rα* gene locus resulting in a single ligand specific chain that would signal with interleukin 2 receptor beta (il-2rβ) and il-2rγc.a. The

possible complex was investigated by morpholino mediated knockdown of *il-15rα*, *il-2rβ* and a possible *il-2rβ* like and examined for changes in *rag1* expression at 5 dpf.

Z6137B DBP is essentially required for zebrafish embryogenesis. *Seong-Kyu Choe*, Yong-Il Kim, SeongAe Kwak, Sushil Bhnadari, In-Koo Nam. Wonkwang University School of Medicine, Iksan, Jeonbuk, KR.

D-bifunctional protein (DBP) is a highly conserved enzyme involved in peroxisomal beta-oxidation. We investigated the role of DBP during zebrafish embryogenesis. Zebrafish *dbp* is expressed early during development. Morpholino-mediated Dbp knockdown generates embryo with small head, pericardial edema and short tail. In agreement with its involvement in peroxisomal fatty acid oxidation, yolk lipid consumption is highly reduced in Dbp knockdown embryos. Endoderm-derived organs such as liver and pancreas are almost absent in morphants. Dbp knockdown also affects other aspects of animal development, such as neuronal maturation, cartilage formation, blood cell development and vasculogenesis. Consistent with morphological defects upon Dbp knockdown, significant changes in the expression of various genes involved in ether phospholipid synthesis, mitochondrial biogenesis, peroxisomal protein import and beta-oxidation pathway in peroxisome. Taken together, these results indicate that Dbp deficiency causes severe developmental abnormalities some of which has not been reported yet in human or mouse studies, and suggest that zebrafish can be used as an animal model to study organelle functions in vivo.

Z6138C Ketohexokinase, a fructose metabolic enzyme plays an important role in somatogenesis and angiogenesis during early embryonic development. *C. Chun*, C. Chen, H. Chun, M. Segal. University of Florida, Gainesville, FL.

Ketohexokinase (Khk), also known as fructokinase is the first enzyme in a specialized catabolic pathway metabolizing dietary fructose to the glycolytic intermediate glyceraldehyde-3-phosphate. While the metabolic mechanism of glucose is tightly regulated by feedback mechanism, the metabolic mechanism of fructose bypasses feedback inhibition. Studies on metabolism of fructose have recently garnered attention due to the association of high fructose diets with an increased risk of diabetes and other diseases. These adverse effects in both human and animal models were exhibited during adult stage. However, the impact of fructose diet and Khk on fetal development has been overlooked. We utilized zebrafish as an animal model to study Khk function during early embryonic development. We utilized zebrafish as an animal model to study Khk function during embryonic development. mRNA of Khk is detected as early as 1-cell stage and an alternative transcript is detected from 10 to 48 hours post fertilization (hpf). We designed two morpholinos to block either translation or splicing of khk and injected into newly fertilized embryo. Knockdown (KD) of khk results in fused somites and defective intersomatic vessel (ISV). Utilizing CRISPR/Cas9 system we edit khk genomic DNA and observe similar phenotype to morpholino-based KD of khk. Taken together, these data suggest a role for khk in early embryonic development, especially in somatogenesis and angiogenesis. .

Z6139A Circadian modulation of autophagy rhythms directly through the nuclear hormone receptor Rev-erbα and indirectly via C/ebpβ in zebrafish. *Guodong Huang*, Fanmiao Zhang, Qiang Ye, Han Wang. Soochow University, Suzhou, Jiangsu, China.

Autophagy is a highly conserved intracellular degradation system, and recently was shown to display circadian rhythms in mice. The mechanisms underlying circadian regulation of autophagy, however, are still unclear. Here, we observed that numbers of autophagosomes and autolysosomes exhibit daily rhythms in the zebrafish liver, and *c/ebpβ* and various autophagy genes are rhythmically expressed in zebrafish larvae but significantly upregulated in *per1b* and TALEN-generated *rev-erbα* mutant fish, indicating that both Per1b and Rev-erbα play critical roles in autophagy rhythms. Luciferase reporter and ChIP assays show that the circadian clock directly regulates autophagy genes through Rev-erbα, and also regulates transcription of *c/ebpβ* through Per1b. We also found that fasting leads to altered expression of both circadian clock genes and autophagy genes in zebrafish adult peripheral organs. Further, transcriptome analysis reveals multiple functions of Rev-erbα in zebrafish. Taken together, these findings provide evidence for how the circadian clock regulates autophagy, imply that nutritional signaling affects both circadian regulation and autophagy activities in peripheral organs, and shed light on how circadian gene mutations act through autophagy to contribute to common metabolic diseases such as obesity.

Z6140B Involvement of The p62-Nrf2 Pathway as A Protection Mechanism against Spns1 Deficiency in Zebrafish. *A. Khan*[1], S. Lian[1], T. Sasaki[1], M. Kobayashi[2], S. Kishi[1]. 1) The Scripps Research Institute, Jupiter, FL; 2) University of Tsukuba, Japan.

The protein Nrf2 is a transcription factor which regulates the expression of various antioxidant genes in cells. p62/SQSTM1 functions as a cargo receptor for autophagy and also in the non-canonical activation of Nrf2. Using transgenic zebrafish that express multiple reporters which allow simultaneous monitoring of Nrf2 activation and autophagy, we demonstrate that chemical and genetic inductions of stress and autophagic responses are reciprocally linked to developmental senescence. Deficiency of the lysosomal sympoter Spns1 was exacerbated by loss of either Nrf2 or p53 individually. However, acceleration of senescence due to the loss of Nrf2 in *spns1*-mutant embryos was partially counteracted by the p53 defect, suggesting that Nrf2 plays a protective role against autolysosomal deterioration induced by Spns1 deficiency through a different mechanism from p53. Intriguingly, a newly identified chemical potentiator of Nrf2 in our system, but not other authentic Nrf2 activators, ameliorates *spns1*-mutant phenotypes. We further found that chemically and genetically enhanced p62 aggregations are involved in the mechanism of Nrf2-induced protection against Spns1-deficent pathogenesis. Together, these data suggest that chemical genetic boosting of the p62-Nrf2 axis protects against the deteriorative impact induced by Spns1 deficiency, a condition in which autolysosomal clearance is disrupted.

Z6141C Genetic Interaction between Spns1 and v-ATPase and Their Counteractive Dual Defects in Premature Autolysosomal Fusion and Developmental Senescence. *S. Lian*[1], T. Sasaki[1], K. Alam[1], W. Chen[2], D. Klionsky[3], S. Kishi[1]. 1) The Scripps Research Institute, Jupiter, FL; 2) Vanderbilt University School of Medicine, Nashville, TN; 3) University of Michigan, Ann Arbor, MI.

Spns1 [Spinster homolog 1 (*Drosophila*)] in vertebrates, as well as Spin (Spinster) in *Drosophila*, is a hypothetical lysosomal H^+-carbohydrate symporter, which functions at a late stage of macroautophagy (hereafter autophagy). The Spin/Spns1 defect induces aberrant autolysosome formation that leads to developmental senescence in the embryonic stage and premature aging symptoms in adulthood. However, the molecular mechanism of the specific pathogenesis still awaits elucidation. Using chemical genetic and CRISPR/Cas9-mediated genome-editing approaches in zebrafish, we investigated a mechanism that ameliorates Spns1 loss-mediated embryonic senescence as well as autolysosomal impairment. Unexpectedly, we identified the vacuolar-type H^+-ATPase (v-ATPase) subunit gene, *atp6v0ca* (ATPase, H^+ transporting, lysosomal, V0 subunit ca) as a spatiotemporal suppressor for senescence induced by the loss of Spns1, while the sole loss of Atp6v0ca led to senescent embryos. Moreover, we discovered that the concurrent heritable defect of both *spns1* and *atp6v0ca* still induced premature autophagosome-endosome and autophagosome-lysosome fusion without sufficient acidity in the lysosome. Our data suggest that Spns1 and the v-ATPase orchestrate proper endo-lysosomal biogenesis with optimal acidification that is critically linked to developmental senescence and survival.

Z6142A A transgenic approach to visualize mitochondrial dynamics associated with renal function and disease. *Y. Sugano*[1,2], R. Tomar[1,2], E. Merkel[1,2], I. A. Drummond[1,2]. 1) Massachusetss General Hospital, Charlestown, MA; 2) Department of Genetics, Harvard Medical School, Boston, MA.

The kidney demands a high metabolic energy supply for its proper function. Mitochondria are the major source of energy supply in aerobic cells. Accumulating amounts of evidence implicate that mitochondria play a central role in renal function. For instance, individuals with mutations in genes required for mitochondrial coenzyme Q10 (CoQ10) biosynthesis pathway, such as *ADCK4* and *COQ6*, develop steroid-resistant nephrotic syndrome characterized by edema and severe proteinuria. Despite the importance, however, little is known about mechanisms by which altered mitochondrial function leads to development of renal disease. In this study, taking advantage of the optical clarity of embryos, we aim to establish the zebrafish as an *in vivo* system to analyze mitochondrial properties in the kidney. A previous work of others has developed a transgenic zebrafish with mitochondria targeted CFP and membrane targeted YFP under the UAS effector element [Tg(UAS:memYFP, mitoCFP)]. Crossings of this UAS effector line into Gal4 driver lines with *podocin* and *cdh17* promoter [Tg(*podo*:Gal4) and Tg(*cdh17*:Gal4)] drove specific expression of the transgenes in glomerular podocytes and tubular epithelial cells, respectively, in the pronephros, providing an intravital imaging platform to study mitochondria. We are currently investigating spatiotemporal characteristics of mitochondria by live imaging in these transgenic zebrafish. Zebrafish mutants for *adck4* and *coq6* are also being generated by CRISPR/Cas9 system in order to present models for nephrotic syndrome caused by mitochondrial defects. Combinations of the reporter fish lines with these mutants would serve as a novel and easily accessible system to study relevance of mitochondria in human glomerular disease.

Z6143B Characterizing the craniofacial *Tft^{9N}/ddx10* zebrafish mutant. *K. Alharthi*[1], P. Yelick[1], W. Goessling[2]. 1) Tufts University of Dental Medicine , Boston, MA; 2) 2Harvard Medical School, Boston, MA.

Craniofacial abnormalities including craniosynostosis and cleft lip and/or palate are considered among the most common congenital defects, occurring in 1/700 live births. Genetic mutations are known to play important roles in these craniofacial defects, but we have yet to elucidate the complex molecular processes leading to normal and syndromic craniofacial development. Regulatory factors controlling development are highly conserved in vertebrates, and over the years the zebrafish has emerged as a powerful animal model for studying human development. In addition to structural similarities between zebrafish and mammalian craniofacial development, the expression and regulation of the major signaling transduction pathways are also highly conserved. These characteristics, combined with experimental advantages of the zebrafish model, make them very attractive model .Zebrafish are particularly well suited for forward genetic mutagenesis screens, which have been used to identify a variety of craniofacial mutants relevant to human development and disease. Similarly, we used this approach to identify a number of skeletal/craniofacial mutants, including the *Tft^{9n}* mutant. Next generation sequencing was then used to identify *ddx10* as a candidate gene. The human *ddx10* DEAD (Asp-Glu-Ala-Asp) box polypeptide 10 is an RNA helicase that has been implicated in diverse cellular processes involving alteration of RNA secondary structure such as translation initiation, nuclear and mitochondrial splicing, and ribosome and spliceosome assembly. RNA helicases also contain ATPase activity, which helps to unwind secondary structures of mRNA. Previous studies showed that *ddX10* plays complex roles in tumor development, mutations in ATP-dependent RNA helicases result in deregulated protein function. There are no known associations of *ddx10* to craniofacial disorders at this time.The goals of this study are to define phenotypic abnormalities of *Tft^{9n}* mutants and to validate the candidate gene, *ddx10*. Identified *Tft^{9n}* heterozygous adults are being used to generate developmentally staged embryos for Immunohistochemical (IHC) analysis of Ddx10 protein expression, and to characterize wild-type and mutant ddx10 mRNA expression. Single cell injection of ddx10 mRNA is being performed to demonstrate rescue of the mutant phenotype. Preliminary analyses show that Ddx10 is expressed in muscle, cartilage and the neurocranium, consistent with the affected tissues in these mutants. These studies demonstrate, for the first time, roles for ddx10 in craniofacial development. These studies were supported by NIH/NIDCR R01DE018043 (PCY). .

Z6145A The regenerating fin as a model to examine the skeletal defects of Roberts Syndrome. *Rajeswari Banerji*[1], Diane M. Eble[2], M. Kathryn Iovine[3], Robert V. Skibbens[4]. 1) Lehigh University, Bethlehem, PA; 2) Lehigh University, Bethlehem, PA; 3) Lehigh University, Bethlehem, PA; 4) Lehigh University, Bethlehem, PA.

Roberts syndrome (RBS) is a rare genetic disorder characterized by craniofacial abnormalities, limb malformation, and often severe mental

retardation. RBS arises from mutations in *ESCO2* that encodes an acetyltransferase that modifies the cohesin subunit SMC3. Cohesins are critical for both inter-molecular DNA-DNA tethering (such as between sister chromatids) and intra-molecular DNA tetherings (stabilizing the base of DNA loops). It remains unclear which activity is adversely affected, although current models suggest that RBS arise through mitotic failure and limited progenitor cell proliferation due to premature sister chromatid separation. However our findings using the zebrafish regenerating fin reveal that *Esco2* depletion results in significant defects in both tissue regeneration and bone segment growth in the absence of elevated levels of apoptosis. In pursuing evidence obtained from genomic studies in mice and zebrafish, we found that Esco2 is a critical regulator of *cx43/gja1* (encodes the gap junction connexin subunit required for cell–cell communication) expression. The link between Esco2 and Cx43 is of immense interest since *cx43* mutations cause oculodentodigital dysplasia (ODDD) in humans and the skeletal defects of the mutant *short fin* (*sof*^{b123}). ODDD patients exhibit developmental defects that overlap with those of both RBS and a related disorder CdLS, conceptually linking ODDD to cohesinopathies. Among additional evidence that Esco2 and Cx43 function in a common pathway, we demonstrated that miR-133-dependent *cx43* overexpression rescues *esco2*-dependent growth defects. Further, preliminary evidence suggests that the target of Esco2-dependent acetylation, Smc3, is similarly critical for *cx43* expression. These results provide strong evidence that ESCO2 plays a transcriptional role critical for human development and that RBS arises through dysregulation of developmental programs.

Z6146B Zebrafish mutants lacking kiaa0753, a regulator of centriole duplication, phenotypically mimic human ciliopathies. *K. S. Bishop*[1], C. Chen[1], A. Weech[1], B. Carrington[1], W. Pei[1], P. M. Zerfas[1], M. English[1], E. A. Burke[1], M. Gunny-Aygun[1], T. Vilboux[2], S. Burgess[1], W. Gahl[1], R. Sood[1], M. C. Malicdan[1]. 1) National Human Genome Institute/NIH, Bethesda, MD; 2) Division of Medical Genomics, Inova Translational Medicine Institute, Falls Church, Virginia.

Centrosomes are microtubule organizing centers that include a pair of centrioles, one of which functions as a basal body serving as a template for cilia formation. Abnormalities in centriole biogenesis, centrosome structure/function, or formation and maintenance of cilia result in a heterogeneous group of human diseases, including central nervous system disorders, cancer and ciliopathies. We and others have recently described the human ciliopathies oral-facial digital syndrome type VI and Joubert Syndrome due to loss-of-function mutations in *KIAA0753*, a gene involved in centriole duplication. Current knowledge on how these mutations in *KIAA0753* affect basal body function and ciliogenesis is limited. In this study, we generated two *kiaa0753* null mutants in zebrafish using the CRISPR/Cas9 system. We observed that the Kiaa0753 protein is critical in zebrafish survival because mutants died between days 5 to 15. We demonstrated that the *kiaa0753* null mutants exhibited a phenotype associated with cilia defects, including a curved body, edema, retinal abnormalities, renal cysts, and lack of a swim bladder. Further analysis of the neural masts revealed that the mutant fish had shorter and deformed cilia. Cultured cells from mutant embryos showed defects in cell proliferation, supporting the importance of kiaa0753 in cell division. Our novel zebrafish model shows the importance of *kiaa0753* in embryonic development, specifically in ciliogenesis, and can be a useful tool for understanding the biology of centrosomes.

Z6147C Zebrafish as a model for eye disease: congenital cataracts. *Lindy K. Brastrom*, C. Anthony Scott, Diane C. Slusarski. Department of Biology, University of Iowa, Iowa City, IA.

Eye disease and visual impairment coupled with age-related vision loss are a significant public health concern. Modern genomics has enabled the identification of an unprecedented number of genetic variants, many of which are extremely rare, associated with blinding disorders. Zebrafish pose many advantages as a human eye disease model. Key among these are their rapid generation time, small size, eye structure similar to humans, and ability to screen many at a time. By 5 days-post-fertilization (dpf) zebrafish have quantifiable behavioral responses to visual stimuli. Our lab has adapted vision testing in zebrafish to facilitate high-throughput in vivo screens: Visual Interrogation of Zebrafish maNipulations (VIZN) and OptoMotor Response (OMR). VIZN uses interruptions in constant light to garner a startle response. This vision startle assay looks at the ability of the fish to see in a general capacity. Fish that are visually compromised will not respond to the interruption of light. Automated data collection and software to handle the large spreadsheets have been developed to provide optimization in the number of screens we can accomplish. While the VIZN assay works for blinding disorders, there is a need to test for partial vision loss such as those exhibited in cataracts. We are currently adapting OMR to assay partial vision loss. This is done by stripes of white and black passing under a plate of fish. Fish that can see will respond by orienting their body perpendicular to the lines. Vision impaired fish will be unable to respond and thus not orient themselves to the lines. The goal is to combine both assays to evaluate the spectrum of visual impairments. We are currently assessing conditions to test for partial vision impairment. These tests will allow us to screen many genes related to loss of vision quickly and efficiently using zebrafish. .

Z6148A Comparison of locomotion and cerebellar morphology in CRISPR snx14, pink1 and pla2g6 F0 mutants. *E. Buglo*[1], A. Abrams[1], R. Kozol[2], A. Rebelo[1], J. Dallman[2], S. Zuchner[1]. 1) Dr. John T. Macdonald Department of Human Genetics and John P. Hussman Institute for Human Genomics, University of Miami Miller School of Medicine, Miami, FL; 2) Department of Biology, University of Miami, Miami, FL.

Creating a process that would allow for high-throughput and fast correlation of phenotypes to genotypes in a vertebrate model system is a valuable tool for gene discovery and functional confirmation. Zebrafish has many advantages as a model for neurodegenerative disorders and genetic screens, such as easy and fast generation of embryos, ease of direct injection, availability of transgenic lines, as well as measurable locomotive behaviors. Genetic screens in CRISPR/Cas9 induced F0 generations are time and cost-effective, but producing a reliable phenotype has been a challenge.

The inherited movement disorders such as cerebellar ataxia have not been clearly established in a zebrafish model, despite over 50 known ataxia disease genes in humans. It also has not been assessed whether locomotive phenotypes can be measurably distinguished between different movement disorders.

In this study we produce mosaic genotypes in F0 generation in zebrafish using CRISPR/ Cas9 targeting a known ataxia gene snx14, a gene for Parkinsonism disease (pink1), and pla2g6, a gene involved in a complex phenotype with parkinsonism, ataxia and neuroaxonal dystrophy. We perform high-throughput movement analysis using a video tracking system Danio Vision (Noldus Ethovision software). We estimate the differences in locomotive manifestations between Parkinsonism and ataxia. We then evaluate the cerebellar morphology of these mutants in a transgenic line with a Purkinje cell fluorescent marker (Aldoca: GAP-Venus). We then perform next generation deep sequencing to measure the Cas9 cutting efficiency at >10,000 read depth in these mosaic animals. Finally, genotypes are correlated with movement as well as cerebellar morphology. This allows conclusions regarding the necessary levels of genome editing to produce observable and measurable phenotypes, also addressing the question whether genetic mutations linked to movement disorders with distinct clinical symptoms in people produce distinct motor deficits in zebrafish models.

Z6149B Understanding Fanconi anemia core complex and associated proteins by multiplexed CRISPR/Cas9-mediated knockout mutant generation. *Blake Carrington*, Gabrielle Robbins, Kevin Bishop, Gaurav Varshney, John McElderry, Marypat Jones, Settara Chandrasekharappa, Raman Sood. National Human Genome Research Institute/ NIH, Bethesda, MD.

Fanconi anemia (FA) is a rare, mostly recessive, DNA repair deficiency disorder. Chromosomal instability is a cellular phenotype of FA, particularly when cells are exposed to DNA crosslinking agents. FA patients display developmental abnormalities, bone marrow failure (BMF), and predisposition to cancer including acute myeloid leukemia. Genetically, FA is a heterogeneous disease with 19 genes identified so far, and the encoded proteins participate in the FA/BRCA pathway that orchestrates repair of DNA damage caused by interstrand crosslinks. Eight FA proteins form a core complex and, along with FA associated proteins (FAAP), provide a key function that results in ubiquitination of two other FA proteins, FANCD2 and FANCI, a critical step in the pathway. But for FANCL and FANCT/UBE2T, biochemical functions of other Core proteins are yet unknown. Only a fraction of FA gene homologs are present in any invertebrate model organism, and thus zebrafish offers an opportunity to explore the functions of FA genes, particularly in understanding BMF, as hematopoiesis in zebrafish is well studied. We can knockout multiple genes in zebrafish with ease, so this allows exploring the consequence of loss of two or more genes that encode proteins known to interact. Except *FANCS/BRCA1*, homologs of all FA genes have been identified in zebrafish. Therefore, we used the CRISPR/Cas9 mediated targeted mutagenesis to generate loss of function mutants in *fanca, fancb, fancc, fancd1/brca2, fancd2, fance, fancf, fancg, fanci, fancj/brip1, fancl, fancm, fancn/palb2, fanco/rad51c, fancp/slx4, fancq/ercc4*, *fanct/ube2t*, and two FA-associated genes (*faap100* and *faap24*). We designed two sgRNAs/gene and tested them for target-specific activity using our CRISPR-STAT method. We performed multiplexed mutagenesis by pooling the sgRNAs to FA genes based on their known interactions. We used our fluorescent PCR method to identify germline-transmitting founders with mutations in individual or multiple genes that were pooled together. We have begun the phenotypic characterization of all mutants. We will present data on the embryonic phenotypes for each of the genes when mutated individually and in combination with its interacting partners.

Z6150C Model of lymphedema and rescue by regulating MEK/ERK activity. *J. Chan*[1,2], A. Dasgupta[1], S. Hazy[1], J. Mably[1,2]. 1) Skin of Color Research Institute, Hampton University, Hampton, VA; 2) Department of Biological Sciences, Hampton University, Hampton, VA.

The lymphatic system transports fluids and facilitating the return of extravasated cells and macromolecules back into the blood circulation. Obstructions in lymphatic vessel function, known as lymphedema, can occur as a primary or a secondary disorder. Milroy's disease is an example of a genetic or primary lymphedema where mutations in one allele of the VEGFR3 gene leads to pervasive lymphatic malfunction resulting in the accumulation of fluids in the lower limbs. In zebrafish, this disorder can be modeled by mutations in this receptor or its ligand, VEGF-C. In secondary lymphedema, an injury to lymphatic vessels can occur after surgery, causing a blockage in the lymphatic system and fluid accumulation in affected tissues. In both cases, pressure and massage have been the only treatments over the last 200 years. To understand the signaling pathways that might be involved in inducing lymphedema, we investigated the ability of preclinical cancer drugs targeting the VEGFRs, MEPK/ERK or PI3K/mTOR to disrupt lymphangiogenesis. We found that MEK1/2 inhibition over a 6-hour period at 3 days post fertilization to provide a dramatic blockade lymphatic function that cannot be recovered by drug removal. To determine whether transgenic overactivation of these pathways may rescue this phenotype, we created 2 transgenic lines, using the fli1 promoter to drive endothelial expression. Treatment with the MEK1/2 inhibitor typically impeded the formation of the thoracic duct in greater than 80% of zebrafish larvae. In the transgenic fli1::MEK1DD line, this lymphatic vessel is effectively rescued. However, increased endothelial mTORC1 in a fli1::rhebS16H transgenic line had no effect. To provide further mechanistic insight into the signaling components required for proper lymphangiogenesis, we are currently examining the ability of a number of chemical compounds for their ability to rescue this phenotype.

Z6151A Larval phenotype of the zebrafish model of Smith-Lemli-Opitz syndrome. *C. V. M. CLUZEAU*[1], K. M. TABOR[2], K. BURKERT[1], J. PICACHE[1], C. A. WASSIF[1], D. S. ORY[3], B. FELDMAN[2], H. A. BURGESS[2], F. D. PORTER[1]. 1) PEMG, NICHD, NIH, Bethesda, MD; 2) DDB, NICHD, NIH, Bethesda, MD; 3) Washington University School of Medicine, St. Louis, MO.

Smith-Lemli-Opitz syndrome (SLOS) is an autosomal recessive disorder characterized by multiple malformations, cognitive impairment and abnormal behavior, including autistic traits. Mutations of the 7-dehydrocholesterol reductase (*DHCR7*) gene, encoding the last enzyme in the cholesterol biosynthetic pathway, result in decreased cholesterol and accumulation of 7-dehydrocholesterol (7DHC). To gain insights into the pathophysiological mechanisms and produce a model allowing cost-effective *in vivo* drug screening, we disrupted the zebrafish *dhcr7* gene using Transcription Activator-like Effector Nucleases. We showed that fish homozygous for a frameshift mutation present the characteristic accumulation of 7DHC and decreased cholesterol in both liver and brain from 2 weeks old. Homozygous mutants also display delayed growth from 3 weeks old, and the transition from larval to adult features (*i.e.* body pigmentation, squamation and fins) is also delayed. The yolk from

eggs produced by mutant females contains high levels of 7DHC. The mutant progeny of the mutant females (maternal zygotic, MZ fish) have high levels of 7DHC during their first week of life, whereas their control siblings (M heterozygous fish) are only exposed to 7DHC until 4 days post fertilization. Interestingly, only the MZ fish present an abnormal acoustic startle response at 1 week old compared to control fish, with decreased responsiveness and altered movement kinematics for non-Mauthner escapes. Treatment of M heterozygous individuals with AY9944, a dhcr7 inhibitor, prevents them from correcting the biochemical defect and leads to a behavioral defect similar to the one observed in MZ fish. Surprisingly, given their exposure to high 7DHC levels during development, MZ larvae are morphologically normal. 7DHC has been shown to alter protein content in lipid rafts and modify membrane fluidity, which could impact signaling between cells during development. Fish are known to adapt to shifts in environmental temperature and membrane fluidity by modifying membrane lipid composition. We hypothesized that mutant embryos use such a mechanism to maintain normal membrane fluidity and signaling. Our preliminary results indeed identified several fatty acid chains in the phosphatidylethanolamine series as upregulated in MZ fish compared to controls. Future work will focus on characterizing the brain structure and transcriptome of *dhcr7*-deficient fish to elucidate the causes of the mutant abnormal behavior, and on analyzing the lipid content in mutant larvae to better understand the compensatory mechanism that preserves membrane fluidity.

Z6152B Generating zebrafish models of human disease to facilitate drug discovery. *Ann E. Davidson*, Sarah A. Hutchinson, James J. Dowling. Hospital for Sick Children, Toronto, ON, CA.

Advances in next generation sequencing have greatly accelerated the identification of novel disease-associated gene mutations. However, a prevailing challenge continues to be validation of the function of these variants, particularly in rare diseases. We have established a Zebrafish Genetics and Disease Models Facility that combines shared expertise and infrastructure at the Hospital for Sick Children, creating a pipeline from gene identification to functional validation and drug discovery. With international accessibility, our facility aims to provide the services required to efficiently generate and analyze zebrafish models that accurately recapitulate human disease. We use a high throughput CRISPR-Cas9 mutagenesis system along with high resolution melt (HRM) analysis to generate mutations in zebrafish that are targeted to putative human disease loci. We also utilize transgenic techniques to create "humanized" models of disease, as well as CRISPR-Cas9 to develop knock-in models of human mutations at conserved zebrafish loci. Additionally, we offer phenotypic analysis and drug discovery services. We are currently developing models for a diverse set of diseases including inflammatory bowel disease, pediatric cancer, cardiac arrhythmia and childhood muscle disease. In less than 2 years since establishment, we have tested nearly 100 gRNAs with a 30% success rate. To date, we have worked with 11 individual labs to generate 24 targeted mutations in 19 genes. Currently, our screening has yielded 18 successfully targeted F0s and 8 successfully generated F1s. In this study, we will present the results of our large-scale mutation generation effort, as well as the preliminary characterization of our first successful mutant strains.

Z6153C Functional Characterization of Epilepsy Related Genes in Zebrafish. *T. D. Fuller*[1,2], T. A. Westfall[1], D. C. Slusarski[1]. 1) Department of Biology, University of Iowa, Iowa City, IA; 2) Interdisciplinary Graduate Program in Genetics, University of Iowa, Iowa City, IA.

Statement of Purpose: Epilepsy is a chronic condition of recurrent seizures which affects approximately one percent of the general population. Though several causative genes have already been identified, these account for only a small percentage of all the genetically caused cases of epilepsy. Further, even when genes are identified, we lack tractable animal models to rapidly translate these findings into mechanistic insights and ultimately new anti-epileptic therapies. For this reason, the zebrafish is increasingly being used as a model of epilepsy due to its high genetic and physiologic homology to humans and its seizure-like behavior in response to various pharmacological and genetic manipulations. Using High throughput sequencing, a significant number of gene variants are being identified, yet their role in the disease state remain unknown. My project utilizes the zebrafish and focuses on characterizing the functional role of 15 genes in the NIH Undiagnosed Diseases Program for which mutations have been associated with epilepsy, and for which zebrafish orthologues have been identified. **Methods:** I isolated the zebrafish orthologues and characterized gene expression patterns by RTPCR and whole mount in situ hybridization techniques. We previously demonstrated that knockdown of Prickle (PK), a gene associated with human epilepsy, sensitizes zebrafish to seizure-inducing drugs through the use of larval motility assays. To facilitate high-throughput in vivo screens, I adapted this approach and developed a code to rapidly and efficiently analyze the generated data sets. This allowed for the characterization of the 15 candidate genes in the context of seizure sensitization. **Results:** Of the fifteen candidates, I found five: syne1b, sms, ccdc89, wscd1, and nid2a, to result in seizure sensitization when knocked down in the zebrafish. I show that each of these genes is expressed in specific regions in the brain during critical times of neuronal development. Further, I find genes expressed in the retina result in axon defects when knocked down.

Z6154A Determining the roles of mab21l2 in vertebrate eye development. *N. N. Gath*[1,2,3], J. M. Gross[1,2]. 1) University of Pittsburgh Medical School, Department of Ophthalmology, Pittsburgh, PA; 2) Fox Center for Vision Restoration, Pittsburgh, PA; 3) University of Texas at Austin, Austin, TX.

The eye is a complex organ, formed by many coordinated developmental processes. When these processes go wrong, clinically significant eye disorders can result. One such case is modeled by a zebrafish mutant in *mab21l2*. This gene is highly conserved amongst vertebrates, but very little is known about its function. No structural motifs are predicted for the protein, and its biological activity is unknown. *mab21l2* mutants present with lens defects and coloboma. Humans with mutations in *MAB21L2* possess colobomas and associated eye defects, but the molecular and cellular underpinnings of these defects are unknown. The goal of this project is to discover the mechanisms by which *MAB21L2* mutations result in developmental abnormalities in the eye. Evidence suggests mab21l2 may be a transcriptional regulator required to maintain proliferation during lens development and choroid fissure closure. Preliminary evidence supports chromatin association of mab21l2, where it could indeed be involved in transcriptional regulation. Preliminary work has also begun to explore the phenotypes and progression of defects in

the mutant zebrafish eye. Some mutants appear to completely fail to begin lens morphogenesis, while others begin morphogenesis with a slight delay and slower rate of growth, leading to dramatic differences in lens size at later ages. Identifying the functions of mab21l2 and the pathways it is involved with will increase the understanding of this enigmatic protein as well as conserved mechanisms governing eye development in humans.

Z6155B Loss of type I collagen telopeptide lysyl hydroxylation causes musculoskeletal abnormalities in a zebrafish model of Bruck syndrome. *Charlotte Gistelinck*[1], Paul Eckhard Witten[1], Ann Huysseune[1], Pascal Simoens[1], Sofie Symoens[1], Fransiska Malfait[1], Amelie De Muynck[1], Anne De Paepe[1], Ronald Y. Kwon[2], MaryAnn Weis[2], David R. Eyre[2], Paul J. Coucke[1], Andy Willaert[1]. 1) Ghent University, Gent, Belgium; 2) University of Washington, Seattle, USA.

Bruck syndrome (BS) is a disorder characterized by joint flexion contractures and skeletal dysplasia that shows strong clinical overlap with the brittle bone disease Osteogenesis Imperfecta (OI). BS is caused by bi-allelic mutations in either the *FKBP10* or the *PLOD2* gene. *PLOD2* encodes the lysyl hydroxylase 2 (LH2) enzyme, which is responsible for the hydroxylation of lysine residues in fibrillar collagen telopeptides. This hydroxylation directs cross-linking of collagen fibrils in the extracellular matrix, which is necessary to provide stability and tensile integrity to the collagen fibrils. To further elucidate the function of LH2 in vertebrate skeletal development, we created a zebrafish model harboring a homozygous *plod2* nonsense mutation resulting in reduced telopeptide hydroxylation and cross-linking of bone type I collagen. Adult *plod2* mutants present with a shortened body axis and severe skeletal abnormalities with evidence of bone fragility and fractures. The vertebral column of *plod2* mutants is short and scoliotic with compressed vertebrae that show excessive bone formation at the vertebral end plates, and increased tissue mineral density in the vertebral centra. The muscle fibers of mutant zebrafish have a reduced diameter near the horizontal myoseptum. The endomysium, a layer of connective tissue ensheathing the individual muscle fibers, is enlarged. Transmission electron microscopy of mutant vertebral bone shows type I collagen fibrils that are more widely spaced and less organized. In conclusion, *plod2* mutant zebrafish show molecular and tissue abnormalities in the musculoskeletal system that are concordant with clinical findings in BS patients. Therefore, the *plod2* zebrafish mutant is a promising model for the elucidation of the underlying pathogenetic mechanisms leading to BS and the development of novel therapeutic avenues in this syndrome.

Z6156C Establishing a zebrafish model for giant axonal neuropathy. *S. Gurung*, J. Fajardo, R. Kennedy, E. Asante, E. Murray, D. Hummel, K. Jasmer, M. Hannink, A. Chandrasekhar. University of Missouri, Columbia, MO.

Giant Axonal Neuropathy (GAN) is a rare neurodegenerative disorder affecting axons in the peripheral and central nervous system, accompanied by axonal swellings and axon loss. Disease onset is around 3 years of age, and is characterized by muscle weakness, impaired sensation, gait disturbance, mental retardation, and seizures. While GAN is caused by presumptive loss-of-function mutations in the human *GAN* gene, the etiology of the disease is poorly understood. We aim to establish a zebrafish model of GAN to gain insight into the cellular and biochemical mechanisms underlying the disease phenotype. *GAN* encodes a 468 amino-acid protein, Gigaxonin, a member of the BTB-Kelch superfamily involved in the ubiquitin-proteasome pathway. In mice, *gan* is expressed extensively in multiple tissues, including the brain and spinal cord. Similarly, zebrafish *gan* is expressed from 18 hpf to 4 dpf, with high expression in the brain at 4 dpf.

To investigate roles of *gan* in disease, we generated loss-of-function mutations in *gan* using the CRISPR/Cas9 system. Using guide RNA targeted to the 2nd exon (AA 84-90 of Gigaxonin), we identified two alleles with frameshift mutations resulting in premature stop codons. Since sensory-motor functions are compromised in GAN patients, we examined two behaviors in zebrafish *gan* mutants involving sensorimotor circuits: touch-evoked escape response and food intake. Wild type and mutant larvae exhibited normal escape responses when touched in the trunk. In contrast, a significantly larger proportion of mutants responded when touched on the head, consistent with extensive *gan* expression in the hindbrain, where touch responses are processed. Feeding is a complex behavior requiring the coordination of sensory (vision, olfaction) and motor (jaw movement, locomotion) activities. At 7 dpf, mutant larvae exhibited a significant decrease in food intake compared to wild type siblings, consistent with *gan* expression in the hindbrain, where the motor neurons driving jaw movements are located. These data suggest that zebrafish *gan* mutants have defects in sensorimotor functions consistent with the defects seen in the mouse GAN model and in human patients, and may represent a good model for GAN in a simple vertebrate.

Z6157A Functional study of appetite regulation in the arcuate nucleus of hypothalamus by zebrafish orexigenic models. *G. M. Her*[1], Y.-W. Hsieh[1], S.-H. Lai[1], C.-Y. Lai[1], C.-Y. Lin[1], K.-Y. Yeh[2]. 1) Department of Bioscience and Biotechnology, Keelung, Taiwan, TW; 2) Chang-Chung Memorial Hospital, Keelung,Taiwan.

Energy homeostasis is maintained by balancing energy intake and expenditure. Many signals regulating energy intake are conserved between the human and zebrafish. NPY (neuropeptide Y) and AgRP (Agouti-related peptide) are neuropeptide and specifically produced from the AgRP/NPY neuron in arcuate nucleus. Both NPY and AgRP promote the growth of adipose tissue and increased appetite. AgRP/NPY neurons counteract another arcuate nucleus cell population. The POMC (proopiomelanocortin) neurons, which are considered anorexigenic. α-MSH (α-melanocyte-stimulating hormone) is a peptide hormone derived by POMC, to be in part responsible for the decreases in food intake and increases in energy expenditure. α-MSH exerts its effect by binding to the MC4R (melanocortin 4 receptors). We have established obsogenic zebrafish by overexpression orexigenic genes including Agrp, and NPY and four TALEN knock-out obsogenic genes, (Carboxypeptidase E (CPE) , nescient helix loop helix 2 (nhlh2), MC4R and POMC). We also generated zebrafish fat models by transgenic overexpression lipogenic (PPAR-γ, DGAT2, and sar1b) and adipocytic genes (ATF4 and Mdx3). We also generated partially deled POMC gene resulted α-MSH talen knockout mutant. As the insights into our research aims for studying lipid metabolism in those zebrafish models, it is very likely that establishment of compound superobesity fish (SOBF) models for studying the connection between obesity (lipogenesis) and metabolic diseases. To observe

lipogenesis gene expression and obesity in SOBFs, we performed feeding tests which SOBFs fed with HFD (high fat diet) and ND(normal diet) and then examined by Nile Red and Oil Red O staining. We demonstrated the application of SOBFs by a high-throughput fluorescence-based assay system. Those results demonstrate that these SOBFs are valuable models for analysis metabolic syndrome and Energy homeostasis.

Z6158B Establishment of stable zebrafish genetic models for studying myotonic dystrophy. *M. N. Hinman*[1], J. S. Eisen[1], J. A. Berglund[2], K. Guillemin[1]. 1) University of Oregon, Eugene, OR; 2) University of Florida, Gainesville, FL.

Myotonic dystrophy (DM) is a genetic disorder most known for causing muscle weakness and myotonia, but it affects many body systems including the gastrointestinal (GI) tract. DM patients often experience altered GI tract motility and small intestinal bacterial overgrowth, but the underlying mechanisms are poorly understood. DM is caused by expansion of a CUG repeat RNA that is encoded by the 3' UTR of the DMPK gene. The MBNL family of RNA-binding proteins are sequestered by the CUG repeats, preventing them from regulating alternative splicing.

We generated several zebrafish DM models by creating CRISPR mutants of each MBNL gene and by inserting transgenes that overexpress CUG repeats globally and in specific tissues. Preliminary studies indicate that DM model fish exhibit some of the same alternative splicing changes that are seen in humans.

We will use these models to study the digestive phenotypes of DM and how microbiota contribute to them. Specifically, we will compare gut motility between WT and DM model fish, and will investigate the specific cell types that contribute to any phenotypes. We will ask how bacteria are altered in DM models, and whether this leads to intestinal inflammation. In addition, we will use germ-free fish to ask whether altered microbiota are necessary or sufficient to cause DM-related digestive phenotypes. Finally, we will investigate how alternative splicing changes contribute to digestive phenotypes.

Overall, these studies will provide important insight into the mechanisms behind the digestive symptoms of DM and the role, if any, that microbes play in them.

Z6159C Novel genes critical for hypoxic preconditioning in zebrafish are regulators of insulin and glucose metabolism. *F. B. Imam*, D. Zhang, G. G. Haddad. UC San Diego, La Jolla, CA.

Fine metabolic regulation to adjust for changes in oxygen and energy availability is a conserved, ubiquitous survival strategy of cells and tissues to unpredictable environments. Severe oxygen deprivation can overwhelm these protective strategies and is a common cause of major brain, heart, and kidney injury in adults and newborns alike. Intriguingly, mild hypoxia can be preventative against a later, more severe hypoxia exposure via "hypoxic preconditioning"—a protective phenomenon that is not yet fully understood. We have therefore established and optimized an embryonic zebrafish model to study hypoxic preconditioning in detail using a functional genomic approach. Using this developmental zebrafish model, we validated five novel hypoxia-protective genes from hundreds of hypoxia-regulated genes we identified via differential expression microarray: *irs2a*, *crtc3*, and *camk2g2* have been previously implicated in insulin and glucose metabolism, while *btr01* and *ncam2* are previously uncharacterized. Furthermore, we have generated null mutants using CRISPR in three of these genes (*irs2a*, *crtc3*, *btr01*) and have begun to characterize hypoxia-induced cellular and transcriptional mutant phenotypes. These results extend our understanding of the mechanisms of hypoxic preconditioning and affirm the discovery potential of this novel vertebrate hypoxic stress model.

Z6160A Identifying Mechanisms of Gastrointestinal Distress in Zebrafish Based Autism Models. *D. James*, E. Storrs, R. Kozol, J. Dallman. University of Miami, Miami, FL.

More than 70% of individuals with Autism Spectrum Disorder (ASD) experience moderate to severe Gastrointestinal (GI) distress with unspecified cause. Multiple studies have shown that individuals with ASD experience GI distress at a statistically higher percentage when compared to typically developing individuals, and that the type of GI distress (vomiting, diarrhea, allergy/intolerance) is highly variable. Due to the heterogeneity of both the autism spectrum and associated GI distress, combined with the relative ambiguity associated with potential roles for the microbiota, no strategies currently exist to address GI distress on a physiological or systems level (Hsiao, 2014). As a first step towards developing these strategies, we are employing zebrafish ASD models to gain mechanistic insight into how genetic variants with high autism relatedness impact GI function. Here we focus on the high-confidence ASD gene *SHANK3*, deletions of which contribute to Phelan-McDermid Syndrome (a form of ASD). This syndrome has gastroesophageal reflux and other gastrointestinal issues reported in nearly 50% of cases.

Our prior work has shown that knockdown of *shank3a* in zebrafish cause delayed mid- and hindbrain development (Kozol et al. 2015). Such delayed hindbrain development could have significant implications for GI regulation. Additionally, gene families like those of SHANK3 arose evolutionarily well before the appearance of neurons, suggesting a potential role in cell-to-cell contact or epithelial function, which could influence GI function (Alie and Manuel 2013).

To begin to address these diverse hypotheses, our initial study has two goals; 1) to test GI function in *shank3a/b* mutants/morphants and 2) to produce a viable reporter line that labels tissues expressing Shank3. Using standard cloning techniques, we adapted a strategy published by (Jia Li *et al.* 2015) to make a plasmid that would enable us to engineer the last exon of *shank3a.* The plasmid tags the endogenous protein with an HA epitope linked by a cleavable P2A peptide to a GFP reporter. By targeting the upstream intron using CRISPR/Cas9, we plan to insert our modified last exon upstream of the endogenous last exon. To test the efficacy of our guide RNAs *in vitro*, we will use our donor plasmid, as the guides should cut both the last intron insertion point, and the cloned intronic segment in the plasmid. Engineering endogenous *shank3* in this way will allow us to localize endogenous *shank3a* using HA antibodies in GFP expressing cells, circumventing low expression issues seen with *in situ* hybridization (especially in diffuse tissues like the enteric nervous system). With shank3a as a test case, we hope to vet this strategy to gain insight into mechanisms underlying ASD-associated GI distress.

Z6161B Functional Analysis of *Parla* and *Parlb* Paralogs in Zebrafish. *M. Jung*, S. Noble, M. Ekker. Center for Advanced Research in Environmental Genomics (CAREG), Department of Biology, University of Ottawa, Ottawa, ON, CA.

Parkinson's disease is a highly prevalent multifactorial neurodegenerative disorder caused by a complex cascade of interactions between various genetic and epigenetic factors. Due to this, the majority of cases are termed idiopathic, however, about 10% of PD cases are due to defined genetic factors. Interestingly, both idiopathic and familial cases of PD share mitochondrial dysfunction as a central component in the pathology of the disease. The mitochondrial protease, presenilin-associated rhomboid-like (PARL), is a Parkinson's disease-linked gene, functioning in regulated intramembrane proteolysis in the inner mitochondrial membrane. PARL is associated with diverse processes including mitochondrial dynamics, and is seen to actively inhibit unnecessary apoptosis and mitophagy in *Drosophila* and yeast. Here, we investigated the role of the two zebrafish *parl* paralogs, *parla* and *parlb*, through transient morpholino mediated loss and stable CRISPR-Cas9 mediated mutagenesis. Our morpholino results show a transient loss of *parla* and/or *parlb* function resulted in defects in the dopaminergic neurons, including mild neurodegeneration and mispatterning in the ventral diencephalon. Morphants exhibited extensive cell death throughout the entire body, as well as increased larval mortality. Additionally, for the first time in vertebrates, our results show evidence that the *parl* genes may function upstream of *pink1*, in a conserved pathway between *Drosophila* and zebrafish. In order to study the effects of heritable loss of *parl* function, *parla* and/or *parlb* mutant lines were produced via the CRISPR-Cas9 system. Several mutant zebrafish lines have been identified and current efforts focus on characterizing these mutant lines for further phenotype assessments. This research will shed light on the specific roles played by each of the two *parl* genes in zebrafish, potentially leading to a better understanding of Parkinson's disease etiology.

Z6162C Characterization of DPP6 Neuronal Expression in Zebrafish (*Danio rerio*). *E. P. Kite*[1], L. Burghi[2], K. Hu[2], M. Geng[2], B. R. Bill[1]. 1) University of Texas at Tyler, Tyler, TX; 2) University of California Los Angeles, Los Angeles, CA.

Autism spectrum disorders (ASDs) are a heterogeneous set of developmental disorders with complex etiology. *Dipeptidyl-Pepitdase 6* (*DPP6*) is a proposed autism candidate gene. Mouse models have been informative for function of this potassium channel regulator; however, a zebrafish model could provide a vehicle for high-throughput pharmaceutical screens or gene-gene interaction studies. Therefore, our goal was to determine the suitability of the zebrafish homologs for these studies. In zebrafish, there exists two homologs of *DPP6*, *dpp6a* (63.4% identity to *DPP6*) and *dpp6b* (59% identity to *DPP6*). Utilizing qRT-PCR and *in situ* hybridization, we identified expression of *dpp6b* as early as 2 days post fertilization (dpf) continuing through adult. Specifically, we observed staining within the zebrafish thalamus, hypothalamus, periventricular Gray of the optic tectum, and torus longitudinalis utilizing *in situ* hybridization for *dpp6b* expression. A more extensive analysis was performed with immunohistochemistry utilizing a commercial antibody raised against the human *DPP6* synthetic peptide, expression was observed in brain areas similar to that of the *in situ;* however, we saw broader staining in the cerebellum, fasciculus retroflexus, and several sensory-associated neurons. Based on conservation, expression, and the ability of the human antibody to cross react with the zebrafish dpp6, we propose that the zebrafish homologs will be functionally similar; therefore, a good tool for future studies. Preliminary studies with morpholino oligonucleotides and TALEN knockouts are being developed to determine anatomical and behavioral neuronal phenotypes.

Z6163A Precision medicine for hearing loss: zebrafish based drug screen. *A. Koleilat*[1], A. Lambert[2], T. Wiggin[2], M. Masino[2], S. Ekker[1], L. Schimmenti[1]. 1) Mayo Clinic, Rochester, MN; 2) University of Minnesota, Twin Cities, MN.

Homozygous recessive mutations in *MYO7A* cause Usher Syndrome Type 1 (UST1), characterized by profound congenital deafness and retinopathy. The *mariner* mutant is a zebrafish model of UST1 caused by mutations in *myo7aa* and exhibits deafness and circular swimming. The objective of this study is to facilitate drug screening that rescue the mutant swimming phenotype. We assessed zebrafish swimming and evaluated the efficacy of drugs by measuring average global change in body orientation (AGC). The AGC for wildtype fish was 680 +/- 130 radians/s. In contrast, the mutant fish had an AGC of 1100 +/- 300 radians/s ($p<0.0001$). Using a L-type calcium channel agonist, (±) Bay K 8644 the AGC was 780 +/- 200 radians/s. The drug did not have any adverse reactions on the wildtype fish. The AGC of the mutant fish incubated in 5 µM of (±) Bay K 8644 differed from the control mutant fish ($p<0.0001$) and did not differ from wildtype control fish ($p=0.0451$). We tested a second L-type calcium channel agonist, FPL 64176. Values of the AGC did not present statistical significance between the *mariner* mutants in the compound compared to the mutant controls. However, the pattern of swimming for the *mariner* mutants incubated in 0.5 µM FPL 64176 more closely resembles wildtype swimming. These preliminary studies support that using L-type calcium channels shifts swimming behavior towards wildtype swimming. This represents a significant step towards discovering compounds to treat hearing loss caused by mutations in MYO7A.

Z6164B Validation of a zebrafish FOP model. *M. LaBonty*, N. Pray, P. C. Yelick. Tufts University, Boston, MA.

Introduction: The zebrafish Type I BMP/TGFβ family member receptor, Acvr1l, modulates BMP/TGFβ signaling to promote cartilage and bone formation. Activating mutations in the human ortholog of Acvr1l, ACVR1, are associated with Fibrodysplasia Ossificans Progressiva (FOP), a disease characterized by the gradual ossification of fibrous tissues, including skeletal muscle, tendons, and ligaments. The **objective** of this work is to validate and characterize a zebrafish model for FOP to elucidate the molecular mechanisms driving heterotopic bone formation in FOP and other human diseases.

Methods: Gateway cloning, transgenesis, automated heat shock system, fluorescence imaging, Alcian blue stain, Alizarin Red Stain, µCT, histology, IHC

Results: Gateway cloning was used to create a vector containing the Hsp70 heat shock (HS) promoter driving the expression of mCherry-tagged constitutively active (CA) Acvr1l. Constructs were injected into single cell stage BMP response element reporter (BRE-GFP) zebrafish to create stable transgenic hs-CA-Acvr1l-mCherry::BRE-GFP lines. Developmentally staged transgenic animals were subjected to daily one-hour heat

shock treatments (3 weeks to 8 months) to induce CA-Acvr1l expression. An Activin A injection injury model was developed for heat shocked CA-Acvr1l expressing animals to define the time course of HO progression in these animals. We are currently performing μCT and Alcian blue/Alizarin red staining on these animals to characterize mineralization defects and to identify sites of heterotopic ossification (HO) as observed in human FOP patients. In addition, we are performing paraffin embedding and sectioning on selected specimens to perform histological and immunohistochemical analyses. Preliminary results show that CA-Acvr1l-expressing zebrafish exhibit enhanced/accelerated mineralization, vertebral fusions, osteochondroma formation, and HO phenotypes, as compared to HS WT and non-HS CA-Acvr1l transgenic zebrafish controls. IHC analyses of activated BMP/TGFβ signaling (pSmad1/5, pSmad2/3), and chondrocyte (Collagen II, Sox9), endothelial cell (Tie2, vWF) and osteoblast differentiation markers (Runx2, Osteocalcin) are being used to characterize these defects on a cellular level. Conclusions: HS-inducible CA-Acvr1l transgenic zebrafish provide an informative model for HO development in human FOP.

Z6165C Zebrafish as a disease model for Epidermolysis Bullosa Simplex. *S. A. MacDonnell*, M. A. Akimenko, R. Lalonde, J. Zhang. University of Ottawa, Ottawa, Ontario, CA.

Epidermolysis Bullosa Simplex (EBS) is a rare human genetic skin disorder that results from mutations in the *keratin 14*, *keratin 5*, or *plectin* genes, and occurs in 1 out of 20 000 live births. In most cases, EBS is caused by dominant-negative missense mutations in the *cytokeratin 5* (*K5*) or *14* (*K14*) genes. The primary symptom of EBS is the formation of blisters on the hands and feet of affected individuals. This project will focus on creating a zebrafish model for the disease using a two point mutation of *keratin 5,* identified to be linked with EBS in humans through the I161S and E477K mutations. The I161S and E477K mutants have been linked with mild and severe forms of the disease, respectively. Both of these mutations are found in the central rod domain of the keratin, which is involved in keratin assembly. The zebrafish and human *keratin 5* proteins share an 83.2 percent similarity in this domain. Moreover, the isoleucine (I161) and glutamic acid (E477) are also conserved. *Keratin 5* is ubiquitously expressed in the surface epithelial tissue of zebrafish embryos, as in humans. Using site-directed mutagenesis, we inserted point mutations in the zebrafish *krt5* cDNA to mimic the I161S and E477K mutations observed in humans. Our lab has recently characterized a *cis*-acting regulatory element specific to the ectoderm of the median and pectoral fin fold of developing zebrafish. To ensure embryo survival, we have used these elements to ectopically express mutant *keratin 5* only in the fin fold ectoderm. Mutant *keratin 5* is linked to an eGFP reporter gene via the 2A peptide for screening purposes. Multiple transgenic lines for the I161S mutation, *Tg(epi+β-globin:ker5 I161S-2A-eGFP)*, have recently been established. Preliminary phenotypic analysis shows little to no blistering. However, trauma or friction may cause blisters to form, as is the case in many forms of EB in humans. In an attempt to induce blistering, the zebrafish are currently being observed under different environmental stressors. Simple microscopy will be used to detect phenotypic defects in the skin, such as the formation of blisters. Further phenotypical analysis will include the structural integrity of the fin and the potential formation of keratin aggregates. The integrity of the keratin filament network in affected fins compared to wild type fins will be determined using atomic force microscopy. We will examine the keratin network and the possibility of keratin aggregates using immunohistochemistry and electron microscopy on the mutant fish as well as wild type fish. Our goal is to create a disease model for EBS that will be used for high throughput drug screening to identify candidate drugs to cure or alleviate the symptoms of EBS.

Z6166A Ewsa inhibits TP53-mutation dependent tumorigenesis in zebrafish. *Justin Mehojah*[1], Richard Galbraith[2], Hyewon Park[1], Mizuki Azuma[1]. 1) University of Kansas, Lawrence, KS; 2) Lawrence Memorial Hospital, Lawrence, KS.

ABSTRACT

Ewing sarcoma is a pediatric cancer of bone and soft tissue. The common molecular abnormality identified in this disease is a chromosomal translocation, which results in the expression of a chimeric fusion protein containing *EWS (Ewing sarcoma breakpoint region 1)*-derived sequences in the amino terminus fused to the carboxyl-terminus of an ETS transcription factor (*FLI1*, *ERG, ETV1, ETV4*, or *FEV*). Despite that the loss of *EWS* allele is a common character observed in this sarcoma, whether it contributes to the pathogenesis of Ewing sarcomas is unknown. To address this question, we utilized a zebrafish mutant for *ewsa* (a homologue of human EWS). Both *ewsa/wt,* Zygotic *ewsa/ewsa* and Maternal-Zygotic (MZ) *ewsa/ewsa* did not develop tumors. The MZ *ewsa/ewsa* mutants displayed a higher percentage of cells with aneuploidy at 27 hpf, compared to wildtype zebrafish. These results suggest that Ewsa maintains chromosomal stability. Because Ewing sarcoma is often associated with an impaired P53 pathway, we further generated a double-mutant line by intercrossing *ewsa/wt* and *tp53(M214K)/wt* mutants. As a result, the incidence of tumorigenesis in the *tp53/wt;ewsa/ewsa* line and the *tp53/wt*;*ewsa/wt* line was higher than in the *tp53/wt*;*wt/wt* line. The result suggests that endogenous Ewsa inhibits tumorigenesis in *tp53/wt* zebrafish. Moreover, the tumor samples obtained from (*tp53/wt;ewsa/wt*) or (*tp53/wt;ewsa/ewsa*) zebrafish were converted to (*tp53/tp53;ewsa/wt*) or (*tp53/tp53;ewsa/ewsa*). The result suggests that zebrafish from the (*tp53/wt)* line developed tumors by undergoing LOH (Loss of Heterozygosity) to the (*tp53/tp53)*, and wildtype Ewsa plays a role in inhibiting LOH induction. Here, we propose that the loss of *EWS* allele as a result of formation of *EWS*-fusion gene may play a role in the pathogenesis of Ewing sarcoma development.

Z6167B Discovery of neuroprotective small molecules to treat Parkinson's disease. *H. Mo*[1,2], J. Kim[1], H. Liu[1], S. Chen[1], M. Arkin[1], M. Keiser[1], B. Huang[1], S. Guo[1]. 1) University of California,San Francisco, San Francisco, CA; 2) Tsinghua University,Beijing,China.

Background: Parkinson's disease (PD) is a progressive neurodegenerative disorder. Characterized by the loss of dopamine (DA) neurons in the substantia nigra (SN), the majority of PD cases are idiopathic with a small percentage being genetically determined. Studies of both sporadic and inherited forms of PD point to mitochondrial (mito) dysfunction and oxidative stress as underlying pathophysiological mechanisms.

Objective: 1. Optimize primary screening assay employing the chemo-genetic larval zebrafish DA neuron degeneration model. 2. Carry out a primary screen of compounds library through organism-based high content imaging to find candidate hits.

Methods: we have developed a chemo-genetic DA neuron degeneration model in larval zebrafish. This model expresses the bacterial enzyme nitro-reductase (NTR) in DA neurons. Upon addition of the prodrug metronidazole (MTZ, a commonly used antibiotic), NTR converts MTZ into a toxic compound that renders DA neuron degeneration. For screening, we have established whole organism-based high content imaging platform from which we can directly visualize the integrity of these neurons

Results: We have figured out the best conditions of Mtz treatment for our model and tested Z' factor (Z'=0.38) for assay evaluation and validation. For screening, we have validated 40 pairs of candidate hit compounds selected from a primary screen of 3,000 compounds and found a potential compound that led to a significant increase in DA neuron fluorescent intensity compared to MTZ-treated negative controls.

Z6168C Braciole: a novel motile cilia mutation which exhibits neural randomization and scoliosis. *Nicholas Morante*, Shin-Yi Lin, Stuart Carter, Eunice Lee, Daniel Grimes, Rebecca Burdine. Princeton University, Princeton, NJ.

Primary ciliary dyskinesia (PCD) is a relatively rare genetic condition, affecting around 1 in 10,000 people, that is caused by defects in ciliary motility. PCD patients often exhibit infertility, left-right (L-R) axis randomization, otitis media, and bronchiectasis. The involvement of motile cilia in the development of in these defects has been the focus of much research on motile cilia. However, in addition to these disorders, recent findings have unearthed new potential associations between motile cilia and diseases, notably in the etiopathogenesis of adolescent idiopathic scoliosis (AIS), highlighting the need for a close re-examination of the consequences motile cilia defects in vertebrates. Here we describe the characterization of a novel motile cilia mutant, *braciole (brcl)*, which exhibits developmental defects associated with motile cilia abnormalities. We demonstrate that *brcl* encodes a novel *dyx1c1* mutation that results in a loss of ciliary outer dynein arms and complete cilia immotility. We further develop a technique to allow us to rescue embryonic defects and thereby characterize later roles for motile cilia in juveniles and adults. We find that *dyx1c1*is required to maintain spine straightness during growth and that mutation causes three-dimensional spinal curvatures that closely model idiopathic scoliosis.

Z6169A Exploring the roles of Cytoskeletal Protein Mutations in Amyotrophic Lateral Sclerosis. *Kim Nguyen*, Kathryn Sheldon, Lisa Schneper, Zhonghua Gao, Keith Cheng, Zachary Simmons, Sue Patrick, Kendall Dubois, Tiffany Bohr, Syndi Reed, James Broach. Penn State Hershey Coll of Medicine, Hershey, PA.

Amyotrophic Lateral Sclerosis (ALS) is a rapid progressive degenerative disease of motor neurons that control muscles of limbs, tongue, and lungs. Unfortunately, this destructive disease still remains untreatable largely due to a limited understanding of disease mechanisms and the absence of a suitable model organism for drug screening. Currently, known causative genetic mutations only account for ~6% of ALS cases despite the total ALS heritability being 50%. Not only is there a tremendous knowledge gap in the genetic basis of ALS, but also the associated clinical phenotypes are complicated and disconnected to the known genetics. Therefore, the goal of our study is to *identify and characterize the genetic factors underlying the disease and to specifically correlate these alterations to various groups of ALS clinical features*. To understand genetic mechanism underlying ALS, we have recruited familial ALS (fALS) patients, sporadic ALS (sALS) patients, and sALS trios consisting of ALS patient and their unaffected parents. Consented patient samples were subjected to exome-sequencing, whole-genome sequencing, and SNP array analysis. As a result, we identified, in addition to rare damaging variants in ALS causative genes such as SOD1 and TDP43, de-novo compound heterozygous mutations in cytoskeletal-related proteins such as DNAH2, DYNC2LI1, STARD9 and NRP2. To functionally validate candidate genes, CRISPR knockout technology was performed in mouse embryonic stem cells (mESC) and the zebrafish model system. Two CRISPR targets per gene were generated and used for the knockout to allow for easy validation tests with PCR and RT-PCR. At present, homozygous knockout mouse embryonic stem cells and heterozygous knockout F1 zebrafish are available. Crosses are underway to produce homozygous knockout F2 embryos. In parallel, *ex vivo* differentiations of mESC are in progress to compare neurite outgrowth of motor neurons between the knockout and the wildtype. Preliminary results of NRP2-CRISPR injected embryos demonstrate a bent-body phenotype, resembling the phenotype of ALS zebrafish. DNAH2-, DYNC2LI1-, and STARD9-CRISPR injected embryos also showed slight locomotive defects. Taken together, our results suggest that dysregulation of cytoskeletal-related proteins could play an important role in ALS disease mechanism. Contributing to the field, we have identified probable causing genes of ALS, and provided cellular and whole-organism ALS models that are pathway-specific for specialized ALS drug screening.

Z6170B Mechanism that links vesicular fusion defects and apoptosis in photoreceptors. *Y. Nishiwaki*, M. Suenaga, M. Araragi, I. Masai. Okinawa Institution of Science and Technology Graduate University, Okinawa, Japan.

Intracellular protein transport is mediated by budding and fusion of transport vesicles on intracellular membrane organelles and often linked to photoreceptor degenerations in human. However, it is unclarified how protein transport defects cause photoreceptor degenerations. We previously reported that mutations of β-SNAP/*napbb*, a vesicular fusion regulator, cause apoptosis in zebrafish photoreceptors, and found that this apoptosis depends on BNip1. BNip1 is a component of syntaxin18 (stx18) SNARE complex, which regulates retrograde transport from Golgi to ER. BNip1 contains the BH3 domain, which activates the Bax-dependent apoptosis. The absence of β-SNAP compromises the disassembly of stx18 cis-SNARE complex, which is generated by vesicular fusion. Accumulation of stx18 cis-SNARE complex activates Bax-dependent apoptosis through its BH3 domain. Thus, BNip1 induces apoptosis in response to vesicular fusion defects. To understand physiological roles of BNip1 for photoreceptor apoptosis, we examined the relationship between β-SNAP functions and BNip1-mediated apoptosis. In the β-SNAP mutant, photoreceptor degeneration largely occurs at 2-3 dpf in the stage when protein transport is highly activated. We found that over-expression of β-SNAP during 2-5 dpf is enough to suppress photoreceptor apoptosis in the β-SNAP mutant at least by 3 wpf, indicating that BNip1-dependent apoptosis correlates with an excessive activated vesicular transport state, suggesting that BNip1 may be one of safe guard that limits the upper threshold of vesicular transport.

Z6171C Development of a Novel Zebrafish Sepsis Model for High-throughput Drug Screens. *A. M. Philip*[1,2,3], Y. Wang[1,3], C. dosSantos[1,2], X. Y. Wen[1,2,3]. 1) St. Michael's Hospital, Toronto, Ontario, CA; 2) Institute of Medical Sciences, Univ. of Toronto, Toronto, Ontario, CA; 3) Zebrafish Centre for Advanced Drug Discovery, Toronto, Ontario, CA.

Sepsis is primarily a state of uncontrolled systemic inflammation. Despite decades of sepsis research involving mammalian models and over 100 clinical trials, sepsis remains a major healthcare burden. Severe sepsis strikes the young and old alike with an incidence of ~750,000 cases per year worldwide, and an estimated mortality rate of 50-80%. As an alternative to traditional animal models, zebrafish have recently emerged as a powerful vertebrate paradigm to study human pathologies and for phenotype-based high-throughput drug screening. Here we show that sepsis can be effectively modeled in the zebrafish. Lipopolysaccharide (LPS) was used to induce sepsis-like pathology in 3dpf zebrafish by water delivery. Through the use of several tissue-specific fluorescent-reporter mediated transgenic lines, fluorescent microangiography, histological assessment, and gene expression analyses, we strived to assess LPS-induced systemic inflammation. LPS delivery to zebrafish embryos at a concentration of 100µg/ml effectively models the dynamics of sepsis progression, leading to 90% mortality. Our zebrafish sepsis model exhibits the major hallmarks of human sepsis including widespread vascular leakage, edema and tissue damage, increased inflammatory cell infiltration and reactive oxygen species (ROS) production, reduced blood circulation and increased thrombocyte aggregation. We validated the suitability of the model for phenotype-based drug screening using fasudil, a drug known to rescue LPS induced vascular permeability in non-primate sepsis models. LPS induced mortality, tissue edema and ROS production were identified as fast and reliable read-outs for high-throughput drug screening. This novel zebrafish sepsis model is expected to provide unmatched potential to screen and validate large numbers of compounds that can modify sepsis pathology *in vivo*.

Z6172A A rapid and effective method for screening, sequencing and reporter verification of engineered frameshift mutations in zebrafish. *Sergey Prykhozhij*[1], Jason Berman[1,2,3]. 1) Department of Pediatrics, Dalhousie University, Halifax, NS, CANADA; 2) Department of Microbiology and Immunology, Dalhousie University, Halifax, NS, CANADA; 3) Department of Pathology, Dalhousie University, Halifax, NS, CANADA.

Clustered Regularly Interspaced Palindromic Repeats (CRISPR)/Cas9 adaptive immunity against pathogens in bacteria has been adapted for genome editing and applied in zebrafish (*Danio rerio*) to generate frameshift mutations in protein-coding genes. Although there are methods to detect, quantify and sequence CRISPR/Cas9-induced mutations, identifying mutations in F1 heterozygous fish remains challenging. Additionally, sequencing a mutation and assuming that it causes a frameshift does not prove causality because of possible alternative translation start sites and potential effects of mutations on splicing. This problem is compounded by the relatively few antibodies generated to zebrafish proteins limiting validation at the protein level. To address these issues, we developed a detailed protocol to screen F1 mutation carriers, and clone and sequence identified mutations. For verifying that mutations actually cause frameshifts, we created a fluorescent reporter system that can detect frameshift efficiency based on the cloning of wild-type and mutant cDNA fragments and their expression levels. As proof-of-principle, we applied this strategy to three mutations in *pycr1a*, *chd7* and *hace1* genes. In *pycr1a* gene involved in proline biosynthesis, we identified an insertion of 7 nucleotides that at the mRNA level caused exon skipping. The fluorescent reporter approach revealed effective frameshifting only for 2-nucleotide deletion in *chd7*, a chromatin remodelling factor gene, suggesting activity of alternative translation sites in the other two. Thus, in addition to providing a protocol for characterizing frameshift mutations in zebrafish, this approach highlights the importance of checking mutations at the mRNA level and verifying their effects on translation by fluorescent reporters when antibody detection of protein loss is not possible.

Z6173B *In vivo m*odeling of copy number variants in Marfan Syndrome and Autosomal Dominant Polycystic Kidney Disease-associated phenotypes. *D. Schepers*[1], C. Golzio[2], E. Davis[2], C. Claes[1], E. Reyniers[1], A. Raes[3], N. Katsanis[1], L. Van Laer[1], B. Loeys[1]. 1) Center of Medical Genetics, University of Antwerp and Antwerp University Hospital, Antwerp, Belgium; 2) Center for Human Disease Modeling, Duke University Medical Center, Durham, NC, USA; 3) Department of Pediatrics, Ghent University, Ghent, Belgium.

Thoracic aortic dissections are among the most life threatening forms of cardiovascular disease. Thoracic aortic aneurysm, preceding dissection, is a prominent clinical feature of several heritable connective tissue disorders, including Marfan syndrome (MFS). MFS is caused by mutations in *FBN1*, which encodes fibrillin-1, an important extracellular matrix protein. Mutations in *PKD1* or *PKD2*, two polycystin encoding genes, are responsible for autosomal dominant polycystic kidney disease (ADPKD). Aortic and arterial aneurysms also occur in ADPKD. *Vice versa*, kidney cysts have also been observed in MFS. This clinical overlap suggests a mechanistic link between ADPKD and MFS.

Here we describe a four generation family with nine affected individuals presenting with both thoracic aortic aneurysm and mild cystic kidneys. *FBN1*, *PKD1* and *PKD2* were excluded as disease causing genes by linkage analysis and/or sequencing. Subsequently, whole genome linkage analysis resulted in the delineation of a unique linked region on chromosome 16q21-q24.1. Exome sequencing was performed but no putative causal variants were found in the linked region. Copy number variation analysis identified two duplicated regions in the linkage interval, one (chr16: 86862531-870228808) gene-less and the other (chr16: 86357163-86725305) containing seven genes, including three genes encoding transcription factors of the FOX gene family (*FOXC2*, *FOXF1*, *FOXL1*), one gene encoding a methenyl tetrahydrofolate synthetase containing domain protein (*MTHFSD)* and three long non coding RNAs (*LOC732275*, *FENDRR, FLJ30679)*. The presence of the first duplication and its segregation in the family was confirmed using Multiplex Amplicon Quantification analysis. By overexpressing these genes separately and in combination with each other in zebrafish, we will explore the pathogenic mechanisms underlying not only MFS and ADPKD, but aneurysm and cyst formation in general. Preliminary results of these experiments, revealing a potential role for *FOXF1* in cyst formation, will be presented.

Z6174C The functional role of actin associated CORO2B in the pronephros of *Danio Rerio*. *A. M. Schwarz*, L. Ebarasi, E. Raschperger, J. Patrakka. Karolinska Institutet, ICMC, Stockholm, SE.

Diabetic nephropathy (DN) is worldwide the leading cause of end-stage renal disease (ESRD), which requires dialysis or a kidney transplant. Diabetes impacts negatively on all cells of the kidney. Podocyte cell injury has been shown to be a major driver in the initiation and progression of DN. The podocyte actin cytoskeleton plays an essential role in the proper organization and function of the glomerular filtration barrier. In this study, we describe a new interaction partner of podocyte actin organization, coronin, actin binding protein, 2B (CORO2B). CORO2B has already been associated to the connection of the plasma membrane with the actin cytoskeleton in neuronal cells. In human DN patients, CORO2B is downregulated. In fish, there are two coro2b genes, coro2ba and coro2bb. We initially employed a morpholino-based approach to elucidate the role of the coro2b genes in the zebrafish pronephros. The morphant larvae showed abnormal morphology of the pronephros, with fewer podocytes, as well as hydrocephalus. At a functional level, proteinuria was observed in collected fish water suggesting a functional defect in the glomerular filtration barrier. Mammalian podocyte cell culture experiments show that CORO2B is crucial for the organization and maintenance of the actin skeleton of podocytes and by extension, the glomerular filtration barrier. These data are currently being validated by a CRIPSR knockout strategy in zebrafish.

Z6175A Chaperones and chromatin remodelers: functional non-cilia roles for established ciliopathy proteins. *C. Anthony Scott*[1], Xitiz Chamling[2], Lisa M. Baye[1], Val C. Sheffield[3], Diane C. Slusarski[1]. 1) Department of Biology, University of Iowa, Iowa City, IA, USA; 2) Interdisciplinary Graduate Program in Genetics, University of Iowa, Iowa City, IA, USA; 3) Department of Pediatrics and Ophthalmology, Carver College of Medicine, University of Iowa, Iowa City, IA, USA.

Bardet-Biedl syndrome (BBS) is a genetic disease that affects cilia function and/or maintenance. Other cellular functions, however, have not been well investigated. In this study we provide evidence that implicates BBS proteins as modulators of cytoplasmic-nuclear transport in addition to their cilia roles. To date, 20 genes have been identified as causes of BBS in patients. While BBS genes are from diverse gene-families, many of the BBS proteins form two major complexes: the BBSome (BBS1, 2, 4, 5, 7-9, and BBIP10) and the BBS chaperonin complex (BBS6, 10, and 12). The BBSome, which localizes to the basal body, is the main functional complex and is involved in trafficking of cargo to the cilium. Correct assembly of the large BBSome is mediated by the BBS chaperonin complex. Our lab has established the zebrafish as an *in vivo* model for BBS, and we have previously identified cilia-dependent as well as cilia-independent phenotypes. This has led us to investigate functions of BBS proteins outside of their defined roles in the cilia. Because of the similarities between the cilia transition zone (CTZ) and nuclear pores we hypothesized that BBS proteins regulate nuclear-cytoplasmic transport in addition to ciliary transport. Using zebrafish in conjunction with human tissue culture we identified an interaction between BBS6 and the SWI/SNF chromatin remodeler SMARCC1 (BAF155). We determined that BBS6 is actively transported between the nucleus and the cytoplasm and that perturbations of BBS6, as well as other BBS chaperonin complex members, affects the sub-cellular localization of SMARCC1. We conclude that BBS6 has a functional role beyond being a scaffold for BBSome assembly. Our work demonstrates that BBS6 functions (likely with other BBS proteins) to modulate nuclear-cytoplasmic transport of nuclear proteins and disruption of this may manifest as disease. This highlights the importance of looking at disease causing genes and alleles from a broader perspective.

Z6176B Functional characterization of the disease-associated Bardet-Biedl Syndrome 1 (BBS1M390R) allele in zebrafish. *D. C. Slusarski*[1,4], C. A. Scott[1], L. M. Baye[2], Q. Zhang[3], T. Westfall[1], V. C. Sheffield[3,4]. 1) University of Iowa, Iowa City, IA; 2) Augustana University, Sioux Falls, SD; 3) Carver College of Medicine, University of Iowa, Iowa City, IA; 4) Wynn Institute for Vision Research, University of Iowa, Iowa City, IA.

Dysfunctional cilia underlie a number of human genetic conditions that affect multiple organs, causing blindness, heart disease, infertility, obesity and/or diabetes. One such ciliopathy is Bardet-Biedl Syndrome (BBS). There is considerable interest in understanding the molecular mechanisms involved in BBS as phenotypes associated with this disorder are commonly found within the general population. BBS1 is the most commonly mutated gene in BBS patients, and a single missense mutation causing a methionine to arginine substitution at position 390 (M390R) accounts for 80% of all BBS1 mutations. $BBS1^{M390R}$ is predicted to be highly disruptive due to the introduction of a positive charge into the hydrophobic core of the folded protein. We use the zebrafish to understand the functional properties of BBS1 and the disease mechanism of $BBS1^{M390R}$. Analysis of BBS1 and $BBS1^{M390R}$ subcellular localization shows that $BBS1^{M390R}$ fails to localize to the centrosome. We also find that $BBS1^{M390R}$ maintains interaction with some, but not all, components of the BBSome complex, thereby likely disrupting its cellular function in cilia transport. To evaluate functional properties, suppression of knockdown defects (reduced Kupffer's vesicle cilia and intracellular transport delays) was tested. We also examined the extent to which the interaction of BBS1 with BBS4, a component of the BBSome, influences stability and localization as well as describe recently generated BBS1 genetic lines.

Z6177C Establishing PXE disease model in zebrafish. *J. Sun*[1,2,3], Tao Zhong[1,2,3]. 1) School of Life Sciences, Fudan University, Shanghai, CN; 2) State Key Laboratory of Genetic Engineering,Fudan University, Shanghai, CN; 3) Collaborative Innovation Center of Genetics and Development, Fudan University, Shanghai, CN.

Abstract:Pseudoxanthoma elasticum (PXE) is an autosomal recessive multi-system disease, manifesting pathologic mineralization of connective tissues, including the skin, eyes and cardiovascular system. The prevalence of PXE in population is about 1/50000. PXE is mainly caused by mutations in *abcc6*/*mrp6*, which encodes a member of the sub-family C of ATP-binding cassette (ABC) transport proteins. However, the roles of *abcc6* for organogenesis and mechanisms remain largely unknown. We have constructed *abcc6a* mutant with the same conserved domain substitution of PXE disease (G1302R) using CRISPR/Cas9-mediated knock-in system in zebrafish. We observed similar symptoms of human PXE disease in *abcc6a* mutants. The establishment of PXE disease model in zebrafish provides insights into pathological mechanisms of

PXE disease and opens novel avenues for developing potential therapy.

Keywords: PXE, ABCC6, disease model, zebrafish.

Z6178A The down-regulation of pank2 gene in zebrafish as a model of Pantothenate Kinase Associated Neurodegeneration. *N. Tiso*[1], D. Zizioli[2], G. Busolin[1], D. Khatri[2], R. Giuliani[2], G. Borsani[2], E. Monti[2], F. Argenton[1], D. Finazzi[2]. 1) University of Padova, Padova, IT; 2) University of Brescia, Brescia, IT.

The increased iron deposition is a hallmark of many neurodegenerative diseases, but its pathogenic role is still unclear. A strong link between iron and neurodegeneration is evident in a set of heterogeneous neurological disorders, known as Neurodegeneration with Brain Iron Accumulation (NBIA). The most common form of inherited NBIA is associated with mutations in the human *PANK2* gene (PKAN disease). Pank2 is the rate-limiting enzyme in CoA biosynthesis and its down-regulation in mammalian cells leads to perturbation of cellular iron homeostasis. In our work we have explored the Pank2 biological function in zebrafish (*Danio rerio*), proposing this system as an important new tool for the study of PKAN disease.

The zebrafish Pank2 protein shows 65% identity with the human ortholog. By qRT-PCR analysis on total RNA from embryos and adult tissues we have found that the expression of *pank2* transcripts is detectable in embryos from early stages to 72 hours post-fertilization, and that the brain is the tissue with the highest expression level of *pank2*. The whole-mount *in situ* hybridization (WISH) technique confirms the qRT-PCR results, showing high *pank2* expression in different brain structures, in the main vessels and in the venous plexus. The microinjection of *pank2*-specific morpholino oligos results in a clear-cut phenotype, with perturbation of CNS structures and vascular system development, suggesting the relevance of *pank2* expression for the normal nervous and vascular developmental process in zebrafish. Both the co-injection of *pank2* mRNA and the addition of pantethine 30 mM at the gastrula developmental stage can restore the wild type phenotype with high efficiency. The effects induced in the CNS and vascular structures have been characterized by WISH with different neuronal and vascular markers and by injecting *pank2* morpholino oligos in different transgenic lines. The results indicate a clear effect on the development of the forebrain, where also the nuclei corresponding to the human globus pallidus are located. The vascular arborization is also drastically perturbed, with severe fenestration of the main vessels and reduced connections of the inter-somitic vessels. Altogether these data indicate that the transient down-regulation of *pank2* gene expression in zebrafish represents an interesting model of PKAN disease, potentially amenable for high-throughput screening of molecules with therapeutic potential.

Z6179B Real-time Quantitative Assessment of Oxidative Stress as a Marker for Differential Nanoparticle Toxicity. *K. N. Wallace*, Rifat Emrah Ozel, Xiaobo Liu, Silvana Andreescu. Clarkson University, Potsdam, NY.

Rapid progress of nanotechnology and advanced nanomaterials production over the past decade offer significant opportunities for a wide range of applications in many fields ranging from medical diagnostics, imaging and drug delivery to sensing, catalysis and environmental remediation. While many engineered nanomaterials are commonly used in commercial products, their interactions with biological systems, their transport, kinetic, toxicity and accumulation in living organisms as well as their environmental and health effects are largely unknown and their use has recently become of particular concern. Several studies have shown that there is a direct relationship between the nanomaterial's structure and physicochemical properties and their impact in biological systems. The effect of NPs on biological systems varies broadly, and some reported results are contradictory, even in the case of the same type of materials. One of the key nanotoxicity mechanisms is the potential for induction of oxidative stress by generating nitrogen (RNS) species. However, assessing the extent of NPs induced oxidative stress has been a challenge as most RNS are highly reactive and short lived and therefore difficult to detect. We have developed electrochemical sensors for detection by direct real-time assessment of RNS species at the NPs accumulation site in living zebrafish embryos.

Z6180C Transcriptional Disease Signatures of Zebrafish Models of Fanconi Anemia. *C. Wilson*[1], W. C. Warren[2], J. H. Postlethwait[1]. 1) Institute of Neuroscience, University of Oregon, Eugene OR, USA; 2) McDonnell Genome Institute, Washington University, St Louis, MO, USA.

Fanconi Anemia (FA) is a rare pediatric disease caused by biallelic mutations in any of 19 different genes acting in a common DNA-crosslink repair pathway. FA involves bone marrow failure, hypogonadism, and high risk of hematopoietic and squamous cell cancers. Patient cells exhibit increased chromosome breakage when challenged with a DNA-crosslinking agent such as diepoxybutane (DEB) and show depressed stem cell renewal even in the absence of exogenous DNA damage. To better understand the mechanisms of FA and to facilitate the search for therapeutics, we used insertional mutagenesis and TILLING to generate mutant lines for the FA core-complex genes *fancc* and *fancl*, and the downstream gene *fancd1*(*brca2*). Zebrafish mutants for all three *fanc* genes exhibited increased cell death in response to DEB, as well as female-to-male sex reversal and gonadal dysgenesis. While the sex-reversal phenotype is caused by the death of meiotic oocytes in juvenile gonads, little is known about transcriptional changes underlying FA phenotypes during development of whole organisms. Tissues relevant to FA, including hematopoietic tissue, gonads, and the adaptive immune system, all develop in zebrafish in the first month post-fertilization. We used RNA-seq to compare gene expression between FA mutants and wild-type siblings in larval and juvenile zebrafish. We generated strand-specific cDNA libraries from 3-5 replicates of mutant and wild-type zebrafish at 4, 10, 14, 18, 22, 26, and 30 days post-fertilization and sequenced them at an average depth of 20 million reads on an Illumina HiSeq. Differential expression was found in genes involved in mitochondrial function and oxidative stress. These results provide a fuller understanding of the mechanisms of FA disease and may help identify new target genes for human therapies.

Z6181A Myelination deficiencies and pharmacological treatments in a zebrafish model for psychomotor retardation. *D. Zada*, A. Tovin, L. Appelbaum. Bar-Ilan University, Ramat-Gan, IL.

The letter preceding the number is the community. A, B, C after the number is presentation time.
W – *C. elegans*, C – Ciliates, D – Drosophila, M – Mouse, P – PEQG, Y – Yeast, Z – Zebrafish

Allan Herndon Dudley syndrome (AHDS) is a severe psychomotor retardation disorder characterized by neurological impairments and abnormal thyroid hormone (TH) levels. THs regulate metabolism, embryonic development and neurogenesis. Mutations in the TH transporter, monocarboxylate transporter 8 (MCT8), are associated with AHDS; however, the function of this gene and the mechanism of the disease remain elusive. Similar to human patients, MCT8-knockout mice exhibit impaired TH levels; however, they lack neurological defects. We utilized the zebrafish model to study MCT8 function and psychomotor retardation. This transparent vertebrate has emerged as a promising model to study neurobiology and development because it combines the advantage of high-throughput genetics of invertebrates with mammalian-like conserved genome and brain structure. Importantly, in contrast to mice, MCT8 mutant (*mct8*-/-) zebrafish exhibit impaired neurogenesis and altered behavioural performances. Here, we studied the development of myelination in *mct8*-/- zebrafish. We used the *myelin basic protein* (*mbp*) as a marker for mature oligodendrocytes in the CNS. The levels of expression of *mbp* mRNA were reduced in *mct8*-/- larvae. Furthermore, time-lapse live imaging of *mbp:EGFP* transgenic fish showed a decrease in the number of oligodendrocytes in different brain regions of *mct8*-/- larvae during development. In order to test potential treatments, the effect of a few drugs on myelination was determined during several developmental stages in live *mct8*-/- larvae. These treatments resulted in partial to full recovery of myelination. These results suggest that, similar to humans, loss of MCT8 affects the development of myelin in zebrafish larvae. It also suggests a putative pharmacological treatment for AHDS patients. Altogether, the *mct8*-/- zebrafish provide a model to study the mechanism and treatment of psychomotor retardation, and may help to understand other myelination disorders such as multiple sclerosis.

Z6182B Gene miles-apart is required for formation of otic vesicle and hair cells in zebrafish. *Jing-pu Zhang*, Zhan-ying Hu, Qing-you Zhang, Wei Qin, Jun-wei Tong, Bo Chen. Institute of Medicinal Biotechnology, Chinese Academy of Medical Sciences. Beijing, China.

Hearing loss is a serious burden to physical and mental health worldwide. Aberrant development and damage of hearing organs are recognized as the causes of hearing loss, the molecular mechanisms underlining these pathological processes remain elusive. Investigation of new molecular mechanisms involved in proliferation, differentiation, migration and maintenance of neuromast primordium and hair cells, will contribute to better understanding of hearing loss pathology. This knowledge will enable development of protective agents and mechanism study of drug ototoxicity. In this study, we demonstrate that the zebrafish gene *miles-apart*, a homolog of sphingosine-1-phosphate receptor 2 (s1pr2) in mammals, plays an important role in the development of otic vesicle, neuromasts and survival of hair cells. Whole mount *in situ* hybridization of embryos showed that *miles-apart* expression occurred mainly in the encephalic region and the somites at 24 hpf, in the midbrain/hindbrain boundary, the brainstem and the pre-neuromast of lateral line at 48 hpf in a strict spatiotemporal regulation. Both up- and down-regulation of *miles-apart* led to abnormal otoliths and semicircular canals, excess or few hair cells and neuromasts, and their disarranged depositions in the lateral lines. Miles-apart dysregulation also caused abnormal expression of hearing associated genes, including *hmx2*, *fgf3*, *fgf8a*, *foxi1*, *otop1*, *pax2.1* and *tmieb* during zebrafish organogenesis. Moreover, in larvae *miles-apart* gene knockdown significantly up-regulated proapoptotic gene *zBax2* and down-regulated prosurvival gene *zMcl1b*; in contrast, the level of *zBax2* was decreased and of *zMcl1b* enhanced by *miles-apart* overexpression. Collectively, miles-apart activity is linked to organization and number decision of hair cells within a neuromast, also to deposition of neuromasts and formation of otic vesicle during zebrafish organegenesis. At larva stage miles-apart as an upstream regulator of bcl-2 gene family, plays a role in protection of hair cells against apoptosis by promoting expression of prosurvival gene *zMcl1b* and suppressing proapoptotic gene *zBax2*.

Z6183C Fer1L-6 is a calcium signaling membrane protein that plays a critical role in skeletal muscle and heart development. *C. P. Johnson*, Chelsea Holman, Trisha Chau, Robert Tanguay. Oregon State University, Corvallis, OR.

The ferlin protein family are group of membrane proteins composed of multiple C2 domains with emerging roles in calcium regulated membrane trafficking and vesicle fusion events. Ferlin mutations are associated with muscular dystrophy and deafness, as well as infertility in Caenorhabditis elegans and Drosophila. Ferlin genes appear early in eukaryotic evolution and members are found in all eukaryotic kingdoms. Despite their prevalence, several vertebrate ferlins remain completely uncharacterized.

We present results of studies conducted on Fer1L-6, one of the uncharacterized vertebrate ferlins, in zebrafish. Fer1L-6 expression occurred early in zebrafish development and peaked 48 hpf, with greatest expression levels in muscle and brain. Knockdown of Fer1L-6 expression resulted in defects in skeletal muscle patterning, as well as cardiac chamber development and heart valve formation. We conclude that Fer1L-6 plays a critical role in the development of skeletal muscle and the heart.

Z6184A A dynamic anesthesia system for long-term imaging in adult zebrafish. *R. Y. Kwon*, B. M. Wynd, K. Patil, C. J. Watson, G. E. Sanders. University of Washington, Seattle, WA.

Long-term in vivo imaging in adult zebrafish (i.e., 1-24 hours) has been limited by the fact that regimens for long-term anesthesia in embryos and larvae are ineffective in adults, with respiratory arrest occurring within ~10-50 mins using MS-222 or MS-222 cocktails [1]. Here, we report the potential for dynamic administration of benzocaine to enable long-term anesthesia of up to 24 hours in adult zebrafish. We developed a computer-controlled perfusion system comprised of a 3D printed imaging chamber coupled to programmable peristaltic pumps that enabled automatic exchange between anesthetic and system water. Continuous administration of benzocaine in adult zebrafish resulted in a mean time to respiratory arrest of 5.0 hours and 8-hour survival of 14.3%. We postulated that an intermittent regimen consisting of ~100% of the average time to sedation and ~50% of the average time to recovery would prolong time to respiratory arrest compared to continuous administration. We measured characteristic sedation and recovery times in response to benzocaine, and used them to devise an intermittent dosing regimen consisting of 14.5 min of benzocaine followed by 5.5 min of system water. Intermittent benzocaine administration in adult zebrafish resulted in a mean time to respiratory arrest of 7.6 hours and 8-hour survival of 71.4%. To examine the potential for this regimen to extend anesthesia

beyond an 8-hour period, we performed a single 24-hour trial and found that intermittent dosing maintained anesthesia in an adult zebrafish over the entire period, with respiratory rates comparable to those observed in fish that survived to 8 hours in intermittent benzocaine trials. In summary, our studies demonstrate the potential for dynamic administration of benzocaine to significantly extend anesthetic periods in adult zebrafish, expanding the potential for imaging in adult physiologies that unfold over 1-24 hours.

Z6185B Identification of skeletal disruptor compounds through *in vivo* screening in zebrafish. *SAVINI THRIKAWALA*[1], Rachna Sachanandani[1], Sanat Upadhyay[2], Clifford Stephan[3], Nghi Nguyen[3], Mary Sobieski[3], Richard Judson[4], Jan-Åke Gustafsson[1], Maria Bondesson[5]. 1) Department of Biology and Biochemistry, Center for Nuclear Receptors and Cell Signaling, University of Houston, Houston, TX; 2) Department of Computer Science, University of Houston, Houston, TX; 3) Center for Translational Cancer Research, Texas A&M Health Science Center, Institute of Biosciences and Technology, Houston, TX; 4) National Center for Computational Toxicology, Office of Research and Development, US Environmental Protection Agency, Research Triangle Park, NC; 5) Department of Pharmacological and Pharmaceutical Sciences, University of Houston, Houston, TX.

Exposure to teratogens during embryonic development may lead to skeletal birth defects, including cranio-facial and limb malformations. We have used zebrafish as a model organism to identify skeletal disruptors. Transgenic zebrafish expressing fluorescent markers in bone or cartilage tissues were used to visually monitor the development of the cleithrum and craniofacial cartilage structures under normal and perturbed conditions. Next, transgenic skeletal embryos were used in a primary high-throughput screen of 309 compounds of the ToxCast phase I chemical inventory, primarily consisting of pesticides and antimicrobials. We found that exposure to 82 compounds perturbed normal development of the cleithrum. The compounds causing an effect in the primary screen were further analyzed across a wider dose range. From this we identified 38 skeletal disruptors; 29 of them caused malformations in the cleithrum and 9 caused a short cleithrum. By further analysis in cartilage transgenic fish, we found that exposure to some, but not all, of the compounds caused perturbed development of both skeleton and cartilage.

Univariate analysis was performed to identify ToxCast *in vitro* assays that significantly correlated with the identified *in vivo* zebrafish skeletal disruptors. Ten assays were identified and were used to create ToxPi profiles for the skeletal disruptors and rank them based on the AC_{50} values of the ToxCast assays. A number of the corresponding molecular pathways to the ToxCast assays were further confirmed to be altered by exposures to skeletal disruptors in zebrafish. Additionally, RT-PCR was used to show that the expression of skeletal marker genes, such as Sox9 and Runx2, were affected by exposure to several of the skeletal disruptors. In conclusion, our results show that several environmental pollutants have skeletal disrupting capacity and that the developing zebrafish embryo is an efficient *in vivo* model that can be used for identification of skeletal disruptors and the molecular pathways that are affected by these chemicals.

Z6186C Multi-Modal High-Content Imaging Reveals Relationships Between Cell Signaling and Mineralization in Zebrafish. *Claire Watson*, Edith Gardiner, Werner Kaminsky, Ronald Kwon. University of Washington, Seattle, WA.

The generation of new bone requires activation of specific signaling cascades in a temporally and spatially distinct manner. However, until recently, a direct comparison between the dynamics of these signaling events and the formation of mineralizing bone has been precluded by the lack of strategies to simultaneously visualize these relationships *in vivo*. The optical clarity of the zebrafish caudal fin allows for high-content imaging of cell signaling in real time using fluorescent reporter strains. Previously, we demonstrated the potential to measure crystalline mineral accrual during fin regeneration using quantitative birefringence imaging (Rotopol microscopy [1]). Building on these findings, in this study, we developed a high-content, multi-modal system for tandem imaging of fluorescent transgenic reporters and bone mineralization within the same tissue. The system consisted of a motorized rotating polarizer integrated into a fully motorized Zeiss Axio Imager.M2 high-content fluorescence microscope, with custom software enabling interfacing between systems. We applied this imaging strategy to directly examine the relationships between canonical Wnt signaling and *sp7* (osterix) expression (using the Tg(7xTCF-Xla.Siam:GFP)ia4 and Tg(sp7:EGFP) reporter fish, respectively) with changes in cell metabolism (indicated by NADH autofluorescence) and mineralization (via Rotopol acquired birefringence) during bone formation and maturation in the regenerating zebrafish fin.

A custom mapping approach was developed to register images from different imaging days onto one another by creating landmarks of fixed pixel distances along each ray. Mapped images permitted the analysis of signaling events at any location in the regenerate, even before bony tissue was detectable. During the initial outgrowth phase, we find that acute activation of NADH is followed by Wnt signaling and subsequent expression of *sp7*. Interestingly, step-wise increases in mineralization coincide with second and third peaks in NADH autofluorescence. Furthermore, we find that mineralization is not complete even at 26 dpa in some fish. Using Rotopol imaging in concert with high resolution fluorescent imaging for the first time, we demonstrate that this system can be used to examine relationships between core bone formation events and maturation into fully mineralized bone.

Z6187A Myomesin-1 stabilises sarcomeric structure acting as a shock absorber in skeletal muscle. *M. ZHAO*[1], A. Costin[2], C. Williams[1], G. Ramm[2], R. Bryson-Richardson[1]. 1) Monash Universtiy, Melbourne, Victoria, Australia; 2) The Clive and Vera Ramaciotti Centre for Structural Cryo-Electron Microscopy, Monash University, Melbourne, Victoria, Australia.

Skeletal muscle consists of bundles of myofibrils that act in concert to generate movement. Each myofibril is composed of repeating

contractile units, known as sarcomeres, which produce force by the sliding of the myosin-rich thick filaments along the actin-rich thin filaments. Thin filaments are anchored to the Z-disks that flank the sarcomere, whereas thick filaments anchor to the M-band at the centre of the sarcomere. In contrast to the extensive research into Z-disks and the identification of skeletal myopathies that result from their disruption, little is known about the M-band.

Myomesins (MYOMs) are a family of M-band-restricted proteins that crosslink thick filaments with MYOM1, MYOM2, and MYOM3, each occupying distinct locations within the M-band. MYOMs contain repeats of highly elastic domains and is able to reversibly stretch to 2.5 times of its original length under force, and thus MYOMs are predicted to act as molecular springs at the M-band. To investigate the roles of Myoms and the M-band, we used mutant lines and morpholino injections in combination to examine myomesin function in the zebrafish. Electron microscopic analysis showed the absence of Myom1 leads to contraction-dependent loss of the M-band and thick filament misalignment, showing that Myom1 is essential for sarcomeric integrity. We also show that loss of Myom1 does not affect maximal force generation but significantly decreases swimming activity. Our results suggest the M-band act as a shock absorber at the centre of the sarcomere, and demonstrate for the first time, Myomesin-1 is crucial in maintaining structural stability of the muscle.

Z6188B Defective Migration of Facial Branchiomotor Neurons Affects Jaw Movements and Food Intake in Zebrafish. *E. Asante*[1], J. Allen[1,2], B. Almadi[1], A. Chandrasekhar[1]. 1) University of Missouri, Columbia, MO; 2) Washington University School of Medicine, St. Louis, MO.

Migration of neuronal cell bodies from their birthplace to their final destination is a crucial step in brain development. Proper organization and function of neurons circuits depends on developmental processes such as neuronal specification and migration, axon guidance and maturation of synapses. Improper neuronal migration may play a role in human diseases such as schizophrenia, mental retardation, and autism. Despite its importance, the consequences of abnormal neuronal migration on circuit organization and behavioral function are poorly understood. To investigate migration of neurons we study the facial branchiomotor (FBM) neurons in zebrafish as a model system. In the zebrafish hindbrain, FBM neurons migrate caudally in the hindbrain from rhombomere 4 to their final destination rhombomeres 6/7, and innervate jaw and gill muscles. In order to examine the behavioral consequences of defective migration in FBM neurons, we characterized the maturation and function of the neural circuits controlling jaw movement in zebrafish larvae between 3-7 days post fertilization (dpf) by time-lapse imaging and quantitative analysis. At 3 dpf larvae exhibited little or no jaw movement and minimal gape activity (opening and closing of the lower jaw). At 5 dpf, larvae exhibited rhythmic jaw movements such that gape increases in amplitude and frequency. By 7 dpf jaw movement are very robust and rapid, with a doubling of frequency over 5 dpf larvae. These data indicate that jaw movements develop and mature between 3- 7 dpf**,** 24-36 hours after FBM neurons have completed caudal migration and 72 hours after completed axon projection to the jaw muscle. To study the consequences of defective neuronal migration, we measured the gape activity of *off limits* (*fzd3a-/-*) mutant larvae where FBM neurons fail to migrate out of rhombomere 4. Mutant larvae exhibited a small increase in gape activity from 3-7 dpf, resulting in very low gape frequency at 5 and 7 dpf compared to wild type siblings. These data suggest that a failure of FBM neuron migration leads to defects in motor circuits, resulting in a failure of jaw movement to be established properly. Given the defects in jaw movements in *off limits* mutants, we wondered whether another functional output of the branchiomotor circuits, namely food intake, was also affected in mutants. As expected, *olt* mutants exhibited a significant decrease in food intake. These results demonstrate that misslocation of the FBM neurons can lead to deficits in the functional output of the branchiomotor circuits. Our studies establish a foundation for dissecting the neural circuits driving a motor behavior essential for survival.

Z6189C Do fish itch: identifying mechanisms of pruritigen transduction and behavior in *Danio rerio*. *L. Condon*[1], K. Esancy[1], J. Feng[2], C. Kimball[1], A. Curtright[1], H. Hu[2], A. Dhaka[1]. 1) University of Washington, Seattle, WA; 2) Washington University, St. Louis, MO.

Chronic itch is a debilitating condition that affects a large portion of the population. It is a symptom of many illnesses including cancer, kidney failure, liver cirrhosis, MS, and shingles. Finding treatments for chronic itch would greatly improve many peoples' lives. The first step in developing effective treatments is to determine the cellular and molecular mechanisms responsible for itch. Using the zebrafish (*Danio rerio*) model system, we are exploring whether zebrafish experience pruritus as a discrete sensation from nociception and whether the itch transduction pathways identified in mammals are present in zebrafish. We expect that the advantages of the zebrafish model system, including rapid genetic manipulation, in vivo calcium imaging, and high throughput behavioral screening, will allow us to expand our knowledge of the cellular and molecular mechanisms that allow for the separation of nociception and this novel sensation. The Dhaka Lab is interested in determining what forms of itch, if any, exist in zebrafish so that we may leverage the advantages of the zebrafish model system to characterize the properties of itch stimuli transduction, thus expanding our knowledge of itch pathways and potentially gaining insight into the evolutionary origin of itch in vertebrates. We have been exploring whether compounds that induce itch in mammals, such as agonists of histamine receptor 1, protease-activated receptor 2, and toll like receptor 7, evoke a behavioral and somatosensory response in zebrafish. Our behavioral data shows that imiquimod produces both locomotive behavior in larval zebrafish and a novel lip rubbing behavior in adult zebrafish. Additionally when fish were exposed to imiquimod we observed activity in neurons of the trigeminal ganglion, an exclusively somatosensory cluster of neurons, which indicates that this compound elicits a somatosensory response in zebrafish. We plan to continue characterizing these pathways to increase our understanding of itch, which may aid in the development of novel therapies to treat itch.

Z6190A Photoreceptor development and regeneration examined by automated analysis of behavior. *Robbert Creton*, Danielle Clift, Robert Thorn, Emily Passarelli, Ruth Colwill. Brown University, Providence, RI.

Visual impairments affect 285 million people worldwide: 39 million people are blind and 246 million people have low vision. Several lines of evidence suggest that it may be possible to restore vision by regenerating photoreceptors and neural connections. However, as novel

methodologies are developed, a critical question will need to be addressed: how do we monitor in vivo for functional success? One approach to monitor for functional success in animal model systems is the analysis of behavior, since behavioral analyses can reveal subtle functional defects, even if the visual system appears normal by morphological criteria. The current study is focused on the automated analysis of behavior in response to visual stimuli, using zebrafish larvae as a model system. Zebrafish larvae are ideally suited for such studies, since high-throughput analyses of behavior can be combined with genetics, high-resolution imaging and experimental manipulations. We developed a novel behavioral assay using colored visual stimuli and found that 5-7 day-old zebrafish larvae display distinct responses to the visual stimuli. These behavioral responses were inhibited by photoablation of photoreceptors, but recover over time as the eye regenerates. The developed tools may be used in future research to screen small molecule libraries for novel treatments of blindness and low vision.

Z6191B Evaluation of the circadian biology of the neurohypophyseal hormones and their relationship with aggressive behavior in a vertebral model: Zebrafish. *L. A. Diaz-Arias*[1], S. A. Valencia[1], T. Manrique[2], V. Akle[1]. 1) Laboratory of neuroscience and circadian rhythms, School of Medicine, Universidad de los Andes, Bogota, DC, Colombia; 2) Brain and Behavior Laboratory, Pshycology department, Universidad del Rosario, Bogota, DC, Colombia.

The circadian rhythm is a physiological period of about 24 hours that coordinates the activity of different biological processes such as reproduction cycles, tissue regeneration, epigenetic, metabolism and behavior. Despite the fact that many studies have shown that aggressive behaviors as well as the expression of "social neuropeptides" follow a circadian pattern in different species, the relationship between aggression and the expression of the neurohypophyseal peptides has not been studied systematically. The objective of this study is to evaluate the role of the circadian system in aggressive behaviors of zebrafish and its relationship with the hormones isotocin (IT) and vasotocine (VT). For this purpose, we used a battery of behavioral tests that consisted of: Open Field test, Mirror test and Opponent test to assess aggression in the fish at specific time points during the light cycle. In subsequent experiments, using RT-PCR and immunohistochemistry the levels of IT, VT and its receptors at different times of day will be evaluated. Also, the receptors will be blocked to establish a possible mechanism of action of these neuropeptides. Preliminary results revealed that the mirror and predator assays acquire different kind of information. While the mirror test is appropriate as a measure of aggression, the encounter with the natural predator evaluates exploratory behavior or "shyness" more effectively. In general, there is a high variability in the behavior of individual fish, probably as a result of their social hierarchy. The behavior of males and females is statistically different in the Open Field test, while that difference is not evident in the Mirror test and Opponent test. Finally, even though there is a tendency toward more aggressive behaviors during the morning hours, the differences did not reach statistical significance. However, further tests are needed to clarify whether there are circadian differences in the aggressiveness of the zebrafish and between genders. This study represents the first step in exploring the role of the endogenous clock in the manifestation of aggression and neurohypophyseal expression of hormones in the vertebrate model zebrafish.

Z6192C Zebrafish: Lead and Learning. *M. A. Haasch*, Richard Sear, Simon Ng, Max Ho, Josephine Brenner, Alec Lau, Jeremy Kaine. Wauwatosa West High School, Wauwatosa, WI.

Zebrafish: Lead and Learning

Authors: Josephine Brenner, Maxmilian Ho, Jeremy Kaine, Alec Lau, Simon Ng, Richard Sear **Adviser:** Mary Haasch, Wauwatosa High School

Purpose: Adult zebrafish exposed to lead as embryos will exhibit lower learning and memory performance than adult zebrafish which were not exposed to lead as embryos.

Experiment: In collaboration with the Children's Environmental Health Sciences Center (CEHSC) at the University of Wisconsin-Milwaukee, students have tested the learning and memory capabilities of adult zebrafish exposed to 10uM lead as embryos, and adult zebrafish not exposed to lead as embryos. Using a simple T-maze, the number of trials needed for fish to learn to turn right (max. of 20 trials) and then learn the reverse by turning left (max. of 20 trials), was measured on three consecutive days and then 1 week after the initial day. Learning was measured by the number of trials needed to achieve 5 correct turns out of 6 consecutive trials. Memory was measured at 1 week using the same criteria.

Results: Adult zebrafish exposed to 10uM lead as embryos needed more trials to learn the right turn behavior compared to adult zebrafish not exposed to lead as embryos. Memories of learning the right turn in adult zebrafish exposed to 10uM lead as embryos needed a couple more trials compared to the adult zebrafish not exposed to lead as embryos.

Adult zebrafish exposed to 10uM lead as embryos needed more trials to learn the left turn behavior compared to the adult zebrafish not exposed to lead as embryos. Memory of learning the left turn at 1 week needed more trials by the adult zebrafish exposed to 10uM lead as embryos compared to the adult zebrafish not exposed to lead as embryos.

Conclusion: Lead exposure of zebrafish as embryos negatively affects learning as adults. Based on observations, students would like to compare the learning abilities of long finned to short finned zebrafish. Students would also like to pursue research into the affect of varying lengths of adult lead exposure on learning.

Z6193A Zebrafishbrain.org: developing a community neuroanatomical resource. *Thomas A. Hawkins*[1], Kate Turner[1], Andy Symonds[2], Mónica Folgueira[3], Jon Clarke[2], Stephen W. Wilson[1]. 1) UCL, London, London, UK; 2) King's College London, London, UK; 3) Universidade A Coruña, A Coruña, Spain; 11) Universidade A Coruña.

This poster will present an update on the development of zebrafishbrain.org and is intended to invoke a discussion on the best way forward for neuroanatomical atlasing resources for the zebrafish. Our objective with zebrafishbrain.org has been to create a web-based repository to communicate – in a user-friendly manner – information about the zebrafish brain.

Zebrafishbrain.org consists of annotated 2D projections of confocal data from transgenic and immunohistochemically stained larval zebrafish specimens. Many of these annotated images have also been incorporated into image and video-enriched tutorials about particular structures in the brain. The annotations and tutorials follow the standard ontology provided by ZFIN.org.

Recently, several brain data-registration systems have been independently developed by other groups and most are directed towards mapping expression or activity data to common anatomical frameworks.

We believe it is timely for these various resources to be brought together using one or few standardised approaches to ease the analysis of future anatomical, neuronal activity, and gene expression datasets. We present here some ideas about how best to achieve this through strengthening links between these disparate resources.

In addition, we will also present ideas about how best to generate high-throughput neuronal morphology data for incorporation into a standardised framework in order to build circuit information.

Z6194B A Zebrafish Model for Identifying Common Biological Mechanisms and Pharmacological Pathways in Autism Spectrum Disorders. *S. Ijaz*[1], E. Hoffman[1], M. Ghosh[2], J. Rihel[2], S. Wilson[2], M. State[1,3], A. Giraldez[1]. 1) Yale University, New Haven, Co; 2) University College London, London, UK; 3) University of California, San Francisco, CA.

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by deficits in social interaction and communication and restrictive, repetitive behaviors. ASD is considered one of the most heritable of neuropsychiatric disorders. Whole-exome sequencing has led to a growing list of genes that are strongly associated with ASD through the identification of an increased rate of de novo loss of function mutations in these genes in affected individuals. However, we are in need of model systems to identify common neurodevelopmental mechanisms that are affected by risk gene disruption. To address this, we are capitalizing on the advantages of zebrafish as a model system to investigate how disrupting these risk genes affects brain development and simple behaviors. First, we generated loss of function mutations in the zebrafish orthologs of nine ASD risk genes using CRISPR/Cas9 technology. These genes include: CHD8, SCN2A, POGZ, TBR1, GRIN2B, DYRK1A, KATNAL2, CUL3, and ANK2. For genes that are duplicated in zebrafish, we generated double mutant lines. Next, we are utilizing high-throughput behavioral analysis and high-resolution brain imaging to assess how disruption of these genes affects simple behavioral phenotypes and the development of excitatory and inhibitory neuronal populations. We are beginning to identify unique pharmaco-behavioral phenotypes among mutant lines. Next, our goal is to compare the behavioral profiles across mutant lines to identify pharmacological suppressors of abnormal behavioral fingerprints in mutants. Together, these studies have the potential to identify pharmacological pathways with relevance to ASD.

Z6195C Targeted knockout of a chemokine-like gene increases anxiety and social cohesion. *Y. Jeong*, J. Park, K. Ariyasiri, K. Lee, T. Kim, D. Jeong, K. Hong, C. Kim. Chungnam National University, Daejeon, KR.

Emotional responses such as fear and anxiety are essential for decision-making and survival. The habenula (Hb) is a structure in the epithalamus highly conserved during vertebrate evolution. It mediates behavioral responses to stress, anxiety, and fear. Dysfunction of Hb is associated with depression, post-traumatic stress disorder, and schizophrenia in humans. Furthermore, the ablation of Hb has been shown to profoundly alter fear and anxiety responses in fish and mice. However, the molecular mechanisms underlying the emotional responses and functional regulation of Hb remain largely unknown. Here we report the critical function of a novel chemokine-like protein, *samdori-2* (*sam2*), in anxiety and fear-related behaviors. We found that *sam2* is predominantly expressed by neurons in the dorsal Hb of adult zebrafish. Targeted knockout (KO) of the *sam2* gene by zinc finger nucleases in zebrafish did not affect viability, fertility, or general morphology. Furthermore, *sam2* KO fish showed normal development of neural circuits including Hb to interpeduncular nucleus (IPN) pathways. However, *sam2* KO fish exhibited robustly elevated anxiety-like behaviors in the novel tank and scototaxis tests, and showed increased social cohesion. In addition, nicotine-induced *c-fos* expression in the dorsal Hb-IPN pathway was significantly inhibited in the *sam2* KO fish. Consistent with these findings, Sam2 was found to strongly attenuate inhibitory synaptic function in neurons. These results establish a crucial role of *sam2* in regulating anxiety and social cohesion, and delineate a potential function of novel chemokine-like proteins in controlling neuronal circuit activity and behavior.

Z6196A Using larval zebrafish as an *in vivo* model system to study otoferlin, a protein expressed in the sensory hair cells and essential for hearing. *Colin Johnson*, Paroma Chatterjee, Murugesh Padmanarayana, Robert Tanguay. Oregon State University, Corvallis, OR.

Sensory hair cells convert mechanical motion into chemical signals. Otoferlin, a six-C2 domain transmembrane protein linked to deafness in humans, is hypothesized to play a role in synaptic vesicle exocytosis at hair cell ribbon synapses. To date however, otoferlin has been studied almost exclusively in mouse models which are technically challenging due to the inaccessibility of their hair cells and reluctance to genetic manipulation, and no rescue experiments have been reported. To overcome these challenges, we have developed zebrafish as a model for studying otoferlin function, and report the first otoferlin rescue experiments. We found that larval zebrafish have two otoferlin genes, otoferlin a and otoferlin b that are expressed early in development and are restricted to sensory hair cells and the midbrain. Knockdown of the otoferlin genes resulted in hearing and balance defects, and a phenotype associated with a looping and circular swimming pattern. Otoferlin morphants also had uninflated swim bladders. Microscopy revealed that otoferlin localized to both the apical and synaptic basolateral side of the cell and that knockdown resulted in abnormal presynaptic structures; namely changes in synaptic ribbon distribution and synaptic vesicle VGlut3 localization. Fluorescent mCLING dye loading experiments suggest that the loss of otoferlin also results in defective synaptic vesicle exocytosis and recycling. RNA-seq studies we have conducted provide a “big picture” view of otoferlin’s impact on zebrafish, and implicate otoferlin-related signaling in a variety of physiological processes extending beyond hearing. Rescue experiments conducted with mouse otoferlin

completely restored hearing, balance, and inflation of the swim bladder. Remarkably, truncated forms of otoferlin retaining the C-terminal C2F domain also rescued the otoferlin knockdown phenotype, while the individual N-terminal C2A domain did not. We conclude that otoferlin plays an evolutionarily conserved role in vertebrate hearing and that truncated forms of mouse otoferlin can rescue hearing and balance.

Z6197B Epidermal growth factor signaling regulates normal levels of sleep in zebrafish. *D. A. Lee*, J. Liu, D. A. Prober. California Institute of Technology, Pasadena, CA.

Sleep is an essential phylogenetically conserved behavioral state, whose regulation remains poorly understood. Several lines of evidence suggest that epidermal growth factor (EGFR) signaling may play an evolutionarily conserved and important role in regulating sleep. Genetic studies in *Drosophila* and *C. elegans* have demonstrated that EGFR signaling is required for invertebrate sleep. However, vertebrate studies have been inconclusive. To address this, we use the diurnal zebrafish to test the hypothesis that EGFR signaling is required for vertebrate sleep. We reveal that heat shock-induced overexpression of the EGFR ligand transforming growth factor alpha (TGFa) decreases locomotor activity and increases sleep, and that this phenotype is abrogated by small molecule inhibitors of MAPK, an EGFR effector pathway. We further observe that zebrafish containing mutations in EGFR ligands exhibit a dose dependent decrease in sleep. Corroborating this, animals with pharmacological inhibition and genetic loss-of-function of EGFR, demonstrate increased locomotor activity and decreased sleep during the day and night. Moreover, site of action analysis demonstrate that TGFa-induced sleep is centrally mediated. Similar to rodents and humans, EGFR is expressed in cells lining the brain ventricle of zebrafish. Following TGFa overexpressing, *c-fos* coexpresses with these *egfra* cells, suggesting that neural activity in this cell population is critical in mediating TGFa/EGFR-induced sleep. Taken together, these results indicate that EGFR signaling is both necessary and sufficient for normal vertebrate sleep, suggesting it participates in an ancient and central aspect of sleep control.

Z6198C The Role of Neurotensin Neuronal Networks in Zebrafish. *T. Levitas-Djerbi*, L. Appelbaum. Bar-Ilan University, Ramat Gan, IL.

Neurotensin (NTS) is a 13 amino acid neuropeptide that is expressed in the hypothalamus. In mammals, NTS-producing neurons that express leptin receptor (LepRb) regulate the function of hypocretin/orexin (HCRT) neurons. Thus, the hypothalamic leptin/NTS/HCRT neuronal network orchestrates key homeostatic output, including sleep, feeding and reward. However, the intricate mechanisms of the circuitry and the unique role of NTS-expressing neurons remain unclear. We studied the NTS neuronal networks in zebrafish and cloned the genes encoding the NTS neuropeptide and receptor (NTSR). Similar to mammals, the ligand is expressed primarily in the hypothalamus, while the receptor is expressed widely throughout the brain. A portion of hypothalamic *nts*-expressing neurons are inhibitory and some co-express leptin receptor (LepR1). As in mammals, NTS and HCRT neurons are localized adjacently in the hypothalamus. In order to track the development and axonal projection of NTS neurons, a partial NTS promoter sequence was isolated. Transgenesis and double labeling of NTS and HCRT neurons showed that NTS axons project toward HCRT neurons, some of which express *ntsr*. To determine the genetic, neuroanatomical, and behavioral role of NTS, we generated a CRISPR-based mutant zebrafish line (*nts*-/-). Using a video-tracking behavioral system, we studied the neurological and behavioral phenotype of the *nts*-/- fish. These findings suggest structural and functional circuitry between leptin, NTS and hypocretinergic neurons, and establish the zebrafish as a model to study the role of NTS in the regulation of key behavioral states such as feeding, sleep and wake.

Z6199A Statistical morphometric analysis and annotation of brain microstructure defects in larval zebrafish. *G. D. Marquart*[1,2], S. Pajevic[3], A. Heffer[1], T. Mueller[4], I. B. Dawid[1], H. A. Burgess[1,2]. 1) NICHD, Bethesda, MD; 2) UMD, College Park, MD; 3) NIH, Bethesda, MD; 4) KSU, Manhattan, KS.

Transgenic lines provide excellent tools to target defined groups of neurons within the developing nervous system. However, whole mount visualization frequently lacks the context to adequately align and annotate transgene expression. To address this we previously adapted volumetric registration techniques to align patterns from 109 transgenic lines into a common reference space and generated software to survey expression patterns at any point within the brain. This alignment allows us to better characterize expression, predict overlap and identify lines with expression in target regions. Without detailed anatomical annotation, however, the value of the data remains limited. While manual labeling addresses this, it is laborious, highly subjective, and constrained by our understanding of neuroanatomy, especially early in development when many primordial structures lack clear nuclear organization. However, we reasoned that local correlations in transgene expression might delineate emerging structures and allow us to computationally derive neuroanatomical annotations. Using spatially constrained data clustering of 112 transgenic lines, we were able to extract regions corresponding strikingly with previously identified neuroanatomical structures. These data-based annotations are less subjective than those manually defined and may allow identification of regions that would otherwise be impossible to reliably segment. Brain alignment also provides a framework for voxel-based morphometric comparisons, a statistically rigorous method for analyzing brain microstructure. As a proof of principle for the use of voxel-based morphometry in identifying discrete neuromorphological differences, we tested for differences in 10 wildtype brains and their left-right flipped counterparts. We speculated that if the analysis was both sensitive and selective, we should only pull out brain asymmetries. All statistically significant pixels that were found were in fact found in the habenula, the only asymmetric brain structure identified in larval zebrafish. Next, to test whether this analysis could locate novel brain abnormalities in mutant zebrafish, we aligned brains of kctd15a/b knockouts and compared them to their wildtype cousins. While kctd15 has been linked to human obesity, knockout larvae show no gross behavioral or morphological abnormalities yet lag behind wildtypes in their growth into adulthood. However, based on voxel-wise analysis of aligned brains, we identified a midbrain tegmental nucleus, the torus lateralis, that was absent in mutants. This finding was confirmed in six-month old mutants zebrafish using conventional histology. Together these results show that brain alignment can provide a powerful tool to screen for subtle neuroanatomical defects in mutants as well as to segment the larval brain into well-defined anatomical regions.

Z6200B Evaluating Pitch Perception via Acoustic Startle Behavior. *G. Ordiway*, R. Jain. Haverford College, Haverford, PA.

Interpreting auditory stimuli and triggering the appropriate physical responses are key biological processes through which individuals navigate their environment. A wide variety of acoustic frequencies are presented by the environment, and the relationship between frequencies can characterize complex hearing, and in part, predict responses to specific types of auditory stimuli. Due to the physics of sound waves, sound vibrations occur not only at the fundamental frequency (n) of that sound, but also double that frequency, or the first harmonic (2n). Perception across a variety of frequencies, as well as this idea of harmonics, we can more effectively test nuanced aspects of zebrafish hearing and interpretation. Since zebrafish use auditory hair cells for audition, characterizing their capacity for complex hearing will better relate them to mammalian and other higher order auditory models. Using habituation to measure non-associative learning, and prepulse inhibition to measure acoustic precision and sensitivity, assays normally designed to observe startle response modulation can now be used to evaluate pitch perception and interpretation. This study measures the baseline responsiveness for a variety of frequencies, and we hypothesize that if harmonics are interpreted as more similar than unrelated tones, habituation to a fundamental frequency (n), will accelerate the rate of habituation to a harmonic frequency (2n) more than to a frequency unrelated to the fundamental. Using high-speed recording at millisecond resolution and FLOTE tracking software, we analyzed the responses of five dpf zebrafish larvae. Frequencies of 200-2000Hz were used to test baseline response levels, as well as harmonic relationships (ie 200Hz vs 400Hz). Future studies could use the acoustic environment of an organism to rationalize aspects of complex hearing, including sounds that might indicate danger or predators. In addition, this study suggests a characterization of complex hearing that can be applied across species and animal models.

Z6201C Deciphering the role of Tmie in the mechanotransduction in sensory hair cells. *I. V. Pacentine*, R. Maeda, T. Nicolson. Vollum, Portland, OR.

The **t**rans**m**embrane **i**nner **e**ar (TMIE) protein is required for the function of auditory and vestibular hair cells in the inner ear. Mutations in *TMIE* cause deafness in humans (DFNB6) and previous work in mice suggests a role for TMIE in mechanotransduction (i.e. the conversion of mechanical energy into electrical signals). While we know that TMIE is essential for the mechanotransduction process, it is not clear whether it is more of an accessory protein of the mechanotransduction complex or whether it plays a more central role in this process. To address questions about the function of Tmie, we characterized two zebrafish *tmie* mutants: a previously published null mutant (*ru1000*) and an uncharacterized mutant expressing a truncated version of Tmie (*jp060*). In addition we examined Tmie's relationship with other known components of the mechanotransduction complex in hair cells (Lhfpl5a, Pcdh15a, Tmc2b), and we examined the function of various motifs that are present in Tmie. Both *tmie*^{ru1000} and *tmie*^{jp060} mutants have normal hair-cell morphology and Lhfpl5a, Pcdh15a and Tmc2b are present in hair bundles where transduction takes place. Tmie itself localizes independently of other transduction proteins. However, our preliminary evidence using a yeast two-hybrid assay suggests that Tmie can interact directly with the tip-link protein Pcdh15a. In *jp060* mutants, the truncation of Tmie, which eliminates the C-terminus of Tmie, results in a hypomorphic phenotype, with scant yet residual activity in hair cells. Consistent with the requirement of this region for the normal function of Tmie, the absence of the C-terminus abolishes the interaction with Pcdh15a in the two-hybrid experiments. Aside from potential interactions with Pcdh15a, we suspect that the lysine-rich C-terminus also interacts with phospholipids in the plasma membrane. Further inspection of other motifs in Tmie revealed that the first transmembrane domain, which is not conserved between fish and mammals at the amino acid level, is non-essential. However, the highly conserved second transmembrane is critical for stability and localization of Tmie at the site of mechanotransduction. Future experiments will include additional structure-function analysis to identify regions and residues critical to function, and yeast two-hybrid experiments to confirm and identify interacting partners of Tmie.

Z6202A Isolation and molecular characterization of a spinal interneuron that modulates swimming behavior. *Andrew Prendergast*[1], Urs Böhm[1], Lydia Djenoune[1,2], Laura Desban[1], Pierre-Luc Baradet[1], Claire Wyart[1]. 1) Institut du Cerveau et de la Moelle épinière, Inserm U1127, CNRS Université Pierre et Marie Curie UMR 7225, Campus Hospitalier Universitaire Pitié-Salpêtrière, Paris, France; 2) Evolution des Régulations Endocriniennes, UMR 7221 CNRS, Muséum National d'Histoire Naturelle, Paris, France.

Vertebrate locomotion relies on precisely timed output of motor neurons. Spinal cord circuits are known to autonomously produce locomotor rhythms following sensory stimulation or descending commands from the brain. In a changing environment, it is necessary to modulate CPG activity with external and internal sensory information. CSF-contacting neurons (CSF-cNs) project a ciliary tuft into the central canal of the spinal cord and make projections throughout the motor column. Consequently, these cells have been hypothesized to act as an internal sensory cell detecting cues from the CSF that modulate locomotor activity. We previously showed that CSF-cNs modulate locomotion in zebrafish larva. Here, we demonstrate that CSF-cNs detect curvature of the spinal cord during active and passive locomotion. However, the sensory mechanisms underlying CSF-cN function remain elusive. We have developed a transgenic line to label differentiated CSF-cNs in zebrafish. In order to identify novel candidate receptors underlying their sensory function, we isolated CSF-cNs by FACS enabling us to proceed to a transcriptome analysis. After identifying candidate molecules, we will disrupt their function and assess defects on CSF-cN activity *in vivo* and on innate locomotion. All together, this project will characterize the role of sensory information carried by the CSF and relayed to spinal circuits. In the future, our effort in zebrafish will be ported to mammalian studies.

Z6203B Ntrk2b expression and function in developing brain of zebrafish. *M. P. Sahu*, Pertti Panula, Eero Castren. Neuroscience Center, University of Helsinki, Helsinki, FI.

Brain-derived neurotrophic factor (BDNF), a member of the neurotrophin family, plays an important role in neuronal network plasticity by promoting differentiation and survival of neurons during development and in adult brain. BDNF signals by activating its cognate receptor

tyrosine kinase B, NTRK2 and has trophic effects on the serotonergic system. The exact role of NTRK2 in the behavioral effects of serotonin remains poorly understood. Alterations in the BDNF-NTRK2 signaling and/or in 5-HT neurons have been implicated in the pathophysiology of psychiatric or mood disorders. This study pursues to interrogate the role of NTRK2 in brain development and more specifically the effects on the serotonergic system. The aim of this study is to understand the developmental effects of TrkB in the zebrafish model. The TrkB receptor has two forms in zebrafish Ntrk2a and Ntrk2b. The Ntrk2a is not found in significant amounts therefore the focus has been mostly on Ntrk2b.

The mRNA expression of Ntrk2b was assessed by in-situ hybridization in the larval stages and adult brain of zebrafish. Wide distribution of the mRNA was observed in the CNS such as dorsal telencephalon, diencephalon, in the parvocellular pre-optic nucleus, hypothalamus, positive radial glial cells lining the mesencephalic ventricle, cerebellum and dispersed positive fibers in the medulla oblongata. The expression of mRNA for BDNF complemented with specific Ntrk2b expression pattern. The morpholino oligonucleotides against Ntrk2b was designed and validated by western blotting using Trk specific antibody. The Ntrk2b morphants had no major gross phenotype and the motor behavior did not change significantly as compared to the controls. There was a significant difference in the monoamines levels of dopamine and serotonin observed in the Ntrk2b morphants. Immunoreactivity using antibodies for serotonin, GABA1H and tyrosine hydroxylase was reduced in the morphants as compared to the controls. The expression level of serotonin transporter (*serta*), and tyrosine hydroxylase (*th1*) was reduced in the morphants. The transient loss could be rescued by over expression of full length Ntrk2b mRNA. No major change in cell death in the Ntrk2b morphants was observed by TUNEL staining method. These results reveal potential role of NTRK2 during development and its effect on the monoaminergic system. The results establish that zebrafish Ntrk2b has wide spread distribution throughout development and loss of Ntrk2b plays an important role in monoamines mainly the serotonergic and the dopaminergic system.

Z6204C Effects of neurostimulation of the habenula in serotonergic and dopaminergic systems in zebrafish. *L. M. Sanchez-Lasso*[1], S. A. Valencia[1], H. Oliva[1], N. Prieto[1], J. C. López[1], G. Monsalve[1,2], A. Ávila[1], V. Akle[1]. 1) Universidad de los Andes, Bogotá, CO; 2) Hospital universitario de la Fundación Santafe de Bogotá, Bogotá, CO.

Neurostimulation is a therapy based in the chemical or electrical stimulation of the brain nuclei, which can generate variations in the production of neurotransmitters. The habenula is part of a conserved brain circuit, which has been considered as a target for the treatment of severe depression. However, studies evaluating the effects of electrical stimulation in the habenula are scarce. The object of the present study is to assess the effect of electrical stimulation of the habenula at different frequencies on the dopaminergic and serotonergic systems in zebrafish. Adult zebrafish were anesthetized, paralyzed and intubated during the deep brain stimulation procedure with frequencies of 20Hz and 130Hz. The stimulation is made with one of two types of microelectrodes: carbon fiber with a diameter of 7±0.6 µm and a resistivity of 2±0.3 10^{-5}Ω m and 30 µm diameter gold wire with a tip of 7±2 µm and a resistivity of 1.6±0.1 10^{-7}Ω m. Gold microelectrodes were fabricated by an electrochemical process in 0.5 M NaCl in DI water and the resistivity was determined by 4-point probe. After the stimulation, the fish are evaluated with immunohistochemistry procedures to identify the changes in the expression of tyrosine hydroxylase and tryptophan hydroxylase, the rate limiting enzymes in the production of dopamine and serotonin, respectively. Also, the receptors zD1 and zSER will be studied across the entire brain. Preliminary results show that zebrafish can be paralyzed at a dose of 1.5µg/g of rocuronium and the effects last for about 4 hours. Fish are anesthetized, paralyzed, intubated using a custom-made system and received a craniotomy of 1mm of diameter above the habenular region. The maximum restrictive amplitude voltage in the zebrafish brain is 4V. This study tests the hypothesis that stimulation of the habenula results in changes in expression on the enzymes and receptors of the serotonergic and dopaminergic systems. Studying the mechanisms of the neurostimulation of the habenula is a step toward understanding the effect of neuromodulator that may be beneficial as an adjuvant therapy against neuropsychiatric disorders.

Z6205A From drug discovery to mechanism: comparison of nicotine-induced locomotor activity in freely swimming and embedded zebrafish larvae. *H. Schneider*, J. M. Abarr, K. Y. Chen, E. E. Clor, B. Edwards, R. Fantus, S. India-Aldana, B. F. Kopecky, R. Miller, C. A. O'Brien, S. Owiredu, M. Pogue, S. Ramayadan, N. J. Snyder. DePauw University, Greencastle, IN.

Potential new pharmacotherapeutics for smoking cessation therapy can be identified in simple neurobehavioral assays using zebrafish larvae. Recording the activity of neural networks or individual neurons in individual larvae could ultimately lead to a better understanding of underlying neuronal mechanisms of drug action thus augmenting drug discovery. Certain adjustments of nicotine dosage and application are required as behavioral experiments on freely swimming larvae are translated into experiments that record nicotine-induced changes of neuronal activity in agarose-embedded larvae. Embedding larvae does not seem to change the overall response to nicotine. However, an increase in locomotor activity occurs with a 10 to 15 min delay after addition of nicotine to embedded larvae compared to the immediate onset in freely swimming larvae. Higher dosage of nicotine used in short behavioral assays of freely swimming larvae, is not suitable for monitoring neural activity in embedded larvae for several hours as nicotine appears to cause irreversible changes in locomotor activity. Lower nicotine dosage allows repeated application of the drug that alternates with "rinse" phases during which locomotor activity can recover. Initial experiments demonstrate that chemicals that reduce the nicotine-induced locomotor activity in freely swimming larvae also reduce recorded muscle activity in embedded larvae. Focal application of chemicals to the head region or injection into the brain can provide further evidence of the specific action of a drug. Establishing nicotine-response assays for embedded zebrafish larvae represents the first step towards measuring nicotine-induced neuroadaptations of larval brain activity using methods such as calcium-imaging.

Z6206B Development of an assay to identify novel modulators of spinal motor activity from the venom of the fish-hunting cone snail *Conus catus*. *J. R. Schulz*, K. Medina, J. Sasaki, N. Leung. Occidental College, Los Angeles, CA.

The zebrafish model is rapidly being developed for use in neurophysiological studies. Here we describe the development of a novel small-

volume assay utilizing larval zebrafish to identify novel modulators of spinal motor activity in parallel. The assay is able to quantify the amount motility as well as distinguish the types of movements made in the absence of supraspinal inputs.

Using this assay we have identified novel modulators of spinal motor activity from the collected venom of the fish-hunting cone snail *Conus catus*. We have also utilized this approach to identify active synthetic neuroexcitatory peptides based on novel sequences identified through deep amplicon sequencing of products specific to the A-superfamily of *Conus* venom peptides. This assay, in conjunction with *in situ* and single cell recordings, extends the utility of the zebrafish model system for venom peptide research and pharmacology. We foresee that the approaches described here will be enhanced by the growing complement of genetic resources available to the zebrafish community.

Z6207C Molecular-genetic analysis of simple decision-making in larval zebrafish. *Hannah Shoenhard*[1], Roshan Jain[2], Marc Wolman[3], Kurt Marsden[1], Michael Granato[1]. 1) University of Pennsylvania; 2) Haverford College, PA; 3) University of Wisconsin-Madison.

Decision-making requires animals to integrate information from the environment with their experiences and their internal state in order to select appropriate behaviors. Although animals continuously make decisions critical for their survival, the genetic and molecular pathways underlying the assembly and function of decision-making circuits in vertebrates are not well understood. We recently developed an assay of larval zebrafish that measures in response to an acoustic stimulus the behavioral choice between a rapid escape behavior and a reorientation-like behavior (Jain et al., in preparation). We will present data demonstrating that this assay fulfills key criteria of decision-making, including dynamic biasing in response to stimulus quality, stimulus history, and internal state.

Using this assay, we conducted a forward genetic screen to identify genes required for this simple decision behavior. This screen yielded nine mutant lines in which decision-making is disrupted. While overall responsiveness is largely unaffected in these mutants, their response bias is shifted such that stimuli that preferentially result in an escape response in wild type instead preferentially elicit a reorientation-like behavior. We will present ongoing efforts to identify the causative mutations, as well as progress in applying whole-brain imaging (Randlett et al. Nature Methods 2015) to identify neurons selectively active during reorientation-like behaviors. Together, these approaches will yield new understanding of how the circuits involved in simple vertebrate decision-making develop and function.

Z6208A Role of Autism Susceptibility gene *Topoisomerase 3B* (*top3b*) in neural and behavioral development in Zebrafish larvae. *Vinoth Sittaramane*, Sydney Doolittle, Danielle Lott, Kori Williams, Paul Lascuni. Georgia Southern University, Statesboro, GA.

Autism Spectrum Disorder is a class of developmental disabilities characterized by social, communication, and behavioral impairments that has a wide range of severity between individuals. Studies have shown these defects stem from abnormal brain development during crucial developmental stages during early development. The underlying genetic cause of these impairments is not well understood but is believed to be a combination of a complex pairing of genetic and environmental factors. Several papers have indicated that topoisomerase 3B (top3b) plays a role in phenotypic defects in mice and fruit flies role indicating a defect in synaptic formation, a key component in developing verbal and social skills. These hindered neural circuits could potentially be the cause of the cognitive deficits characteristic in Autism. Our current research aims to better understand the specific roles of top3b in early neurological development though an *in vivo* study using zebrafish embryos as a vertebrate model system. We used a technique called RNA in situ hybridization and identified the regions of zebrafish nervous system where top3b is present during early neural development. We identified top3b is present in the forebrain, notochord, and visual neural pathways. Further, we used anti-sense nucleotides and created top3b deficiency in zebrafish embryos. Top3b deficient zebrafish embryos revealed defects in spinal motor nerves in the trunk and visual neural pathways in the head. We labeled the motor nerves and their muscle targets (Acetylcholine receptors) using molecular labeling techniques and identified that top3b deficient embryos lack connectivity of nerves and their target muscles. Further, when we re-introduce top3b RNA into deficient embryos, the defects were largely reduced and the embryos develop with normal spinal and visual neural pathways and are able to make connections to their muscle targets. Activation of Acetylcholine receptors have been shown to produce a variety of behavioral and physiological effects such as cognitive performance, vigilance, locomotor activity, respiration, and cortical blood flow. Location of top3b regions and the defect patterns seen in the deficient embryos implicate top3b plays a role in visual neural pathways and neuromuscular connectivity. Developing and analyzing the *top3b* deficient zebrafish model would enable us to use this model to identify potential drug targets against human neurological disorders such as autism.

Z6209B Developing an inducible gene regulation system with spatiotemporal precision at cellular resolution. *Mahendra Wagle*, Zhiqiang Dong, Annam Jayabhargav, Seema Niddapu, Su Guo. University of California San Francisco, San Francisco, CA.

The ability to regulate gene expression with saptiotemporal precision is highly desirable to study various biological phenomena. There has been considerable development in tools and methods available for controlling gene expression in zebrafish. Morpholino knockdown and CRISPR knockouts are most widely used methods for downregulating genes of interest, but have limitations with respect to controlling it to desired cells. RNAi mediated gene knockdown has been successfully demonstrated in zebrafish. We further develop this technique by combining GAL4-UAS and drug inducible TetON system to efficiently knockdown genes of interest. By using tissue specific promoters or available enhancer trap lines to drive Gal4 in specific cell types, it will be possible to restrict gene knockdown in desired cell types at various time points during the development. To achieve such regulation at single cell level, we are currently developing light inducible GAL4 system for gene expression and knockdown.

Z6210C The Role of Non-Neuronal SNAREs on Synaptic Transmission in Zebrafish Hair Cells. *Mike Waltman*[1], Suna Li[2], Katie Kindt[1]. 1) NIH/NIDCD, Bethesda, MD; 2) University of Pennsylvania School of Veterinary Medicine, Philadelphia, PA.

Mechanosensitive hair cells and their associated ribbon synapses are required for hearing and balance. Hair cells have a unique presynaptic

structure called a ribbon body which functions to tether glutamatergic vesicles near adjacent presynaptic L-type calcium channels. The ribbon body is believed to be important for encoding vestibular and auditory information by maintaining fast, sustained exocytosis. Despite their similarity to neuronal synapses, previous work suggests that hair cells do not require the classical neuronal soluble NSF attachment protein receptors (SNAREs) VAMP1 and VAMP2 for vesicle release (Nouvian et al., 2011). Therefore, the SNARE machinery functioning in hair cells is not known.

To determine the SNARE machinery required in hair cells we utilize the genetically tractable zebrafish model. The zebrafish has hair cells in their inner ear as well as in rosettes of hair cells that compose the lateral-line system. The zebrafish is an excellent model to investigate the molecular basis of ribbon synapse function as previous work has shown that ribbon synapses are structurally conserved amongst vertebrates (reviewed in Nicolson., 2015). Due to this level of conservation, combined with CRISPR-Cas9 advances in zebrafish, have enabled us to use the zebrafish to investigate what VAMP family member or members are required for hair-cell exocytosis.

We are currently examining CRISPR-Cas9 generated knockouts of the v-SNAREs (vesicle SNAREs/VAMPs). We are currently screening all VAMP family members. As of yet, no single VAMP has been directly linked to a complete loss of exocytosis or endocytosis in the hair cell. This suggests that no single VAMP subfamily plays a role in hair-cell synaptic transmission, but may require redundant VAMPS or an interaction with the complimentary subfamily of SNARES: t-SNARES (target SNAREs/SNAPs). We are exploring both possibilities now and continue to examine our current mutant *vamp* strains.

Lastly, in order to quantify alterations to synaptic vesicle release between wildtype and mutant strains, we are utilizing a transgenic line that expresses synaptophluorin in hair cells to measure vesicle release using swept-field confocal microscopy. In the future we plan on expanding our analysis to include electrophysiological studies in order to further examine alterations to neuronal function based on deficiencies in hair-cell release. An update of this research will be presented.

Z6211A Roles of *per1b*, *per2* and *rev-erbα* in zebrafish circadian behaviors. *H. Wang*[1]. 1) Center for Circadian Clocks, Soochow University, Suzhou, Jiangsu, China; 2) School of Biology & Basic Medical Sciences, Medical College, Soochow University, Suzhou 215123, Jiangsu, China.

Zebrafish are an important model for investigating vertebrate circadian clocks. However, scarce of zebrafish genetic circadian mutants has hindered further advancement of the zebrafish circadian field. We set out to dissect molecular genetic mechanisms underlying zebrafish circadian clocks. Using retroviral insertional mutagenesis, TALEN or CRISPR-Cas9, we have generated a library of zebrafish circadian mutants. Here we report characterization of zebrafish *per1b*, *per2* and *rev-erbα* mutants. Behavioral assays showed that under light/dark (LD) condition, *per1b* mutant larvae are approximately three times more active than their wild-type counterparts and the amplitude of *rev-erbα* mutants increases more than 40% during the whole duration of a 24-hour day and night, while *per2*mutant larvae have approximately 30% reduced activity amplitude in comparison with wild types; under constant darkness (DD) condition, locomotor activity of *per1b* mutant larvae is phase advanced by two hours, while locomotor activity of *per2* mutant larvae is phase delayed by two hours, and *rev-erbα* mutants display 0.5-hour phase delay and 0.25-hour shortened period. Under DD condition, *per1a*, *per2* and *per3* were all significantly up-regulated in *per1b* mutants, indicating that Per1b serves as a negative regulator in the zebrafish circadian system. Under LD condition, *bmal1a* and *annat2* were significantly up-regulated but *per1a*, *per1b* and *bmal1b* were significantly down-regulated in the *per2* mutant fish. *In Vitro* cell transfection assays showed that Per2 not only acts through E-boxes to repress E-Box-containing genes but also acts through RRE-boxes to activate RRE-box-containing genes. Under DD condition, both *bmal1b* and *bmal2* are significantly up-regulated in *rev-erbα* mutant larvae. We also found that zebrafish *per1b* mutants display hyperactive-, impulsive-, and attention deficit-like behaviors and low levels of dopamine, reminiscent of human Attention Deficit Hyperactivity Disorder (ADHD) patients. Rev-erbα modulates autophagy rhythms directly via controlling expression of autophagy and autophagy-related genes, and also plays regulatory roles in stress response, metabolism, signal transduction and posttranslational modification. Taken together, our findings demonstrate that Per1b, Per2 and Rev-erbα are essential for the zebrafish circadian clock and also play regulatory roles in numerous fundamental life processes, and highlight zebrafish as an attractive model for investigating vertebrate circadian rhythmicity.

Z6212B Retinal patterning and saccadic eye movements in Zebrafish require Down Syndrome Cell Adhesion Molecule-Like 1. *Tong Wang*[1], Manxiu Ma[1], Avirale Sharma[1], Christopher Kuang[1,7], Rachel Roberts[1,8], James A. Gagnon[2], Andrea Pauli[2], Steve Zimmerman[2], Shengdar Q. Tsai[3,4], Deepak Reyon[3,4], J. Keith Joung[3,4,5], Alexander F. Schier[2], Y. Albert Pan[1,6]. 1) Department of Neuroscience and Regenerative Medicine, Medical College of Georgia, Augusta Univ., Augusta, GA; 2) Department of Molecular and Cellular Biology, Harvard Stem Cell Institute, Center for Brain Science, Harvard Univ., Cambridge, MA; 3) Molecular Pathology Unit, Center for Computational and Integrative Biology, and Center for Cancer Research, Massachusetts General Hospital, Charlestown, MA; 4) Department of Pathology, Harvard Medical School, Boston, MA; 5) The Broad Institute of Massachusetts Institute of Technology and Harvard, Cambridge, MA; 6) Department of Neurology, James & Jean Culver Vision Discovery Institute, Medical College of Georgia, Augusta Univ., Augusta, GA; 7) Medical Scholars Program; 8) Graduate Program in Neuroscience.

Down syndrome cell adhesion molecule (Dscam) family genes play diverse roles across many species. The *Drosophila dscam* is alternatively spliced and serves as intra- and intercellular recognition cues for repulsive interactions between axons and dendrites. In mice and chicken, *Dscam* and *Dscam-like 1* (*Dscaml1)* are involved in promoting cell death, maintain cellular spacing, and laminar targeting of neurites in the developing visual system. The functional and behavioral importance of *Dscam* and *Dscaml1*, however, are less clear. In this study, we generated a TALEN-mediated *dscaml1* mutant in Zebrafish (*Danio rerio*) and investigated how loss of *dscaml1* affects visual system development and visual behaviors. The small size, translucent brain, powerful genetics, and robust visual behaviors of zebrafish make it an ideal vertebrate model system. Consistent with *dscaml1*'s function in mammals, we found significant aggregation and misplacement of retinal cell types, particularly the serotonergic amacrine cells and muller glia. The mutant brain was narrower, with increased neuropil thickness and

reduced width. Despite these abnormalities, *dscaml1* have normal light-on and light-off induced locomotor response and can respond to moving vertical bars while performing the optokinetic response (OKR), suggesting that perception of visual stimulus is grossly normal, though light sensitivity is reduced. However, when challenged with a faster or more prolonged moving stimulus, the *dscaml1* mutants display severe deficits in saccadic (fast-resetting) eye movements and the eyes eventually become fixated at eccentric positions. These results suggest that *dscaml1* is required for the development or function of the motor systems downstream of saccade generation centers. Work is currently in progress to investigate the neural correlates of the saccade deficits and the temporal requirements of *dscaml1*.

Z6213C Comparative analysis of cart peptide expression and function. *Ian Woods*, Emily Conklin, KathyAnn Lee, Haley Coleman, Andrew Rodenhouse, Anastasia Koulopoulos. Ithaca College, Ithaca, NY.

Neuropeptidergic modulation of neuronal signaling facilitates context-dependent differences in neuronal circuit activity, and can thus generate profound differences in behavior. We study Cart (Cocaine- and Amphetamine-Regulated Transcript), a neuropeptide with proposed roles in the regulation of several behaviors, including arousal, anxiety, appetite, and reward. In mammals, a single Cart gene exhibits complex expression in many brain regions. In contrast, Cart is encoded in zebrafish by seven separate genes, each with a relatively simple expression pattern. The genetic tractability of zebrafish, along with its optical transparency and wide range of experimentally validated behavioral assays, provides an unparalleled system to link functions of Cart in specific brain regions with specific behaviors. First, we are pinpointing regions of Cart expression in zebrafish larvae via colocalization with markers of conserved neurotransmitter and peptidergic systems. Second, we are working to elucidate the development and targeting of Cart neurons using transgenic larvae that express GFP driven by cis-regulatory sequences of each Cart gene. Third, we are working to analyze the behavioral functions of each zebrafish Cart gene. Specifically, we have generated fish with loss-of-function mutations in four Cart genes, and transgenic lines that enable inducible overexpression of four Cart genes. Analogous reagents for the other Carts are in progress. We and others have established behavioral assays that are especially suited for analyzing behaviors relevant to Cart function, including arousal, sensory responsiveness, anxiety, and appetite. Hierarchical clustering of behavioral outcomes will elucidate the roles of each Cart gene in regulating specific behaviors. Finally, to explore the significant difference in Cart peptide family representation between species, we are using computational tools to model patterns of gene gain and loss in all neuropeptide families across a panel of vertebrate species.

Z6214A Origin and Functional Heterogeneity of Zebrafish Lateral-line Hair Cells. *Q. Zhang*, C. Wong, J. He, K. Kindt. National Institutes of Health, NIDCD, Bethesda, MD.

Hair cells are the sensory receptors required for proper hearing and balance. In hair cells, function is shaped by summation of local calcium signals that ultimately trigger vesicle release in order to encode a sensory stimulus. We studied calcium signals and vesicle release in neuromast hair cells of the lateral-line system. We observed that calcium signals were extremely heterogeneous within a neuromast cluster, with a subset showing a more robust and persistent calcium influx. It was only in this later subset of hair cells that we observed vesicle release. The purpose of this study is to understand the basis for this functional heterogeneity and to understand why a sensory organ would be organized to function in this manner.

We have developed several transgenic lines that express calcium indicators (GCaMP6s, GCaMP3, RGECO or GGECO) that allow us to stimulate and monitor calcium signals in hair cells or postsynaptic afferents. In addition, we use SypHy, an indicator to monitor hair-cell vesicle release. Overall, this is a very powerful system, where we can continuously record larvae over multiple days to understand how activity of a neuromast or a single hair cell changes over time or during development. This long-term functional imaging, combined with mutant analysis and pharmacology have allowed us to better understand the basis of hair-cell functional heterogeneity.

Our long term imaging experiments indicate that hair cells located around the periphery of the neuromast are most likely to have robust calcium signals and release vesicles. The periphery of the neuromast is where new hair cells are generated. Our data shows that as hair cells mature at the periphery, they have robust calcium signals. Whether they continue to release vesicles ultimately depends on location within the neuromast and whether additional cells are added to the neuromast. Damage to hair cells with robust calcium signal enables other hair cells to release vesicles, indicating all hair cells are primed and competent to encode stimuli. Using genetics, we have found that the functional heterogeneity of hair cells does not result from afferent or efferent modulation. Lastly, our pharmacological results suggest that instead, connections between hair cells or supporting cells may facilitate functional heterogeneity. From these results we hypothesize that not all hair cells may be required to encode sensory signals. In addition, the heterogeneity within the neuromast may play an important role in development and maintaining a healthy balance for encoding sensory information.

Z6215B Pharmacological reprogramming of lateral line neuromast support cells to a migratory progenitor state. *Paige Brooks*, Anastasiya Yandulskaya, Hannah Akre, Jason Meyers. Colgate University, Hamilton, NY.

The lateral line is a collection of small sensory organs called neuromasts that run along the body of fish and amphibians, and consists of sensory hair cells homologous to the hair cells within the inner ear. Each neuromast consists of sensory hair cells surrounded by support cells with a ring of mantle cells at the outer edge of the neuromast. Between 24-48 hours of development, protoneuromasts are deposited by a migratory primordium with Wnt positive mesenchymal-like cells proliferating at the leading edge and FGF positive cells forming into epithelial rosettes at the depositing end. Although the role of Wnt and FGF signaling has been well studied in the migratory primordium, the on-going roles of those signals in the deposited neuromasts is less clear. Given this, and the interaction between Wnt and FGF signaling in initial patterning of the primordium and protoneuromast deposition, we have examined the effects of Wnt and FGF manipulation to neuromasts after the migratory primordium has completed neuromast deposition. When we pharmacologically block FGF signaling, the neuromasts become

elongated as mantle cells begin to stream away from the neuromasts anteriorly and posteriorly. During FGF inhibition, the mantle cells begin expressing Wnt reporter genes, suggesting that one of the functions of FGF might be to limit Wnt signaling in deposited neuromasts. The upregulation of Wnt signaling in the mantle cells paired with the migration of these mantle cells along the horizontal midline suggests that Wnt signaling in the absence of FGF signaling promotes a migratory state similar to that in the leading edge of the migratory primordium. Consistent with this, when we couple the inhibition of FGF signaling with a pharmacological activation of Wnt signaling, driving Wnt reporter expression in all cells of the deposited neuromasts, all of the supporting cells adopt a migratory mesenchymal-like fate, leading to dissolution of the neuromasts and streaming of the cells both anteriorly and posteriorly along the lateral midline. This reversion of the epithelial cells to a migratory state is coupled with loss of cadherin expression and flattening of the cells. Remarkably, following washout of the drugs, the migratory cells re-epithelialize and reconstitute neuromasts. Many more neuromasts reform after washout than were present initially, and each reconstituted neuromast reforms sensory hair cells. We also show that these signals are utilized during neuromast regeneration following tail amputation to promote migration and reformation of neuromasts. Together, these data suggest that Wnt signaling may promote a reversion of supporting and mantle cells to a migratory state capable of reconstituting full neuromasts, but that this is normally repressed by FGF signaling working to maintain the cells in an epithelial state.

Z6216C Regulation of neural stem cell division modes in the developing zebrafish brain. *R. Choi*, X. Zhao, Z. Dong, S. Guo. University of California San Francisco, San Francisco, CA.
Zhao X[1,2] Choi R[1,2] Dong Z[1], Guo S[1*]
[2]Co-first author
[*]Corresponding author
Asymmetric cell division (ACD) is a conserved and fundamental process in neurogenesis for generating cellular diversity across both invertebrates and vertebrates. As the principal neural stem cells (NSCs), radial glia progenitors (RGP) undergo ACD to generate self-renewing and differentiating daughter cells in the developing central nervous system. Until now, the cellular and molecular mechanisms of ACD and subsequent daughter fate choice is not well understood in vertebrates.
By using zebrafish, we have identified that the cortical polarity regulator Partitioning defective protein-3 (Par-3) plays a crucial role in the establishment of ACD through localizing the ubiquitin E3 ligase Mindbomb (Mib), which activates Notch by ubiquitinating the Notch ligand unequally in the apical daughter. Using immunocytochemistry, in vivo imaging, and other molecular genetic and biochemical methods, we are elucidating the nature of Mib asymmetry and the underlying mechanisms that orchestrate such asymmetry.

Z6217A Hereditary cerebellar ataxia and the role of CAMTA1, a zebrafish study. *c. cianciolo cosentino*[1], p. ender[1], j. loffing[2], s. neuhauss[1]. 1) Institute of Molecular Life Sciences, University of Zurich, Zurich, CH; 2) Institute of Anatomy, University of Zurich, Zurich CH.
Hereditary cerebellar ataxias are a wide and heterogeneous group of neurological disorders characterized by motor incoordination, instability and developmental delay, with cerebellar neuron degeneration as a common hallmark. The genetic cause and the underlying pathophysiological mechanisms for many forms of ataxias are still unclear and, currently, there are no effective therapies. Recent studies have shown that loss-of-function mutations in the calmodulin-binding transcription activator 1 (CAMTA1), a calcium responsive transcription factor, are associated with childhood cerebellar ataxia and intellectual deficiency in humans. Zebrafish have been successfully used to model a range of neurological and behavioral abnormalities. In an attempt to establish a zebrafish model of hereditary cerebellar ataxia, we characterized the zebrafish CAMTA1 orthologue *camta1a* and its transcription pattern, and by making use of morpholino-mediated gene inactivation and the CRISPR/Cas9 genome editing tools, we analyzed the phenotype induced following zebrafish *camta1a* depletion. The amino acid sequence of *camta1a* display a 73% overall similarity with the human protein, and, like in mice and humans, expression analyses showed brain-enriched expression, with highest levels of transcript in the cerebellar granule cells and Purkinje cells. The injection of *camta1a* antisense morpholino oligonucleotides recapitulated salient features of ataxia. In particular, *camta1a* morphants presented abnormal movement pattern, with increased spontaneous contractions and shorter swimming path. Moreover, *camta1a* MO larvae showed a loss of Purkinje neurons. To confirm the phenotype obtained with *camta1a* knock-down experiments, we have generated *camta1a* genetic mutants by CRISPR/Cas9 genome editing, targeting the DNA binding domain of the protein. The analysis of *camta1a* homozygous mutant zebrafish (camta1a $^{-/-}$) is under way, together with the identification and characterization of genes transcriptionally regulated by *camta1a* in the cerebellum. Our results so far validate zebrafish as a valuable model organism in which to investigate the molecular mechanism leading to the cerebellar neuron degeneration responsible for the ataxic phenotype in humans with CAMTA1 mutation.

Z6218B Screening for genetic interactions in the blood-brain barrier *in vivo* in the zebrafish, *Danio rerio*. *Thomas Clements*[1], Shinya Hirota[2], Sam Kwiatkowski[2], Cecilia Guerra[1], Aryeh Warmflash[1], Joseph McCarty[2], Daniel Wagner[1]. 1) Rice University, Houston, TX; 2) University of Texas M. D. Anderson Cancer Center, Houston, TX.
In the blood-brain barrier (BBB), glial cells interact with vascular endothelial cells (ECs) to control blood vessel development and formation.

However, the molecular mechanisms of these interactions remain mostly uncharacterized. In order to screen for genetic interactions amongst genes of interest, we used MOs to repress the translation of the zebrafish homologs of these genes *in vivo.* Morpholinos (MOs) are an established reverse genetic technique that prevents splicing of pre-RNA or translation of mRNA by binding to complementary regions of RNA *in vivo*. Using MOs allows us to titrate the single doses down to the lowest effective levels and then screen combinations for more drastic effects, which cannot be done using traditional gene knockout methods. The zebrafish is ideal for studying genetic interactions in the blood-brain barrier because fertilization is external and the embryo is transparent, thus allowing for easy visualization of neural development.

It is hypothesized that an uncharacterized signaling network controls gene expression to regulate cerebral blood vessel development mediated by *αVβ8* integrin-activated (*Igtβ8, IgtαV)* TGF-*β*s. Thus, it is our goal is to confirm crosstalk and coordinated regulation of specific genes in this pathway using conditional systems in mice (done by our collaborator), MO as well as CRISPR-Cas knockouts in zebrafish, and the use of endothelial specific Smad-4 GFP transgenic line. Here we report a synergistic relationship between *Igtβ8* and Neuropilin1a (Nrp1a) *in vivo* as ascertained through the use of MOs, which was done by quantifying loss of transcript through observable brain hemorrhages and RT PCR.

Z6219C Molecular mechanisms of Schwann cell development and function in the peripheral nerve system. *M. R. D'Rozario*[1], S. D. Ackerman[1], A. Mogha[1], S. Giera[2], R. Luo[2], X. Piao[2], K. R. Monk[1]. 1) Washington University School of Medicine, St. Louis, MO; 2) Boston Children's Hospital and Harvard Medical School, Boston, MA.

Schwann cells (SCs) are the myelinating glia of the peripheral nervous system (PNS) that associate with and wrap around axons to form the insulating myelin sheath. During development, immature SCs select appropriately sized axons (a process termed radial sorting) and repeatedly wrap their membranes around their selected axon. The importance of SC myelin is best underscored in diseases in which SC dysfunction leads to peripheral neuropathies such as Charcot-Marie-Tooth Disease; importantly, defects in radial sorting are frequently observed in human PNS disease. Advances in identifying growth factors and signaling molecules expressed by SCs reveal the myriad roles of glial cells in the nervous system and their interaction with each other, neurons, and the surrounding extracellular matrix (ECM). We have previously identified the adhesion G protein-coupled receptor (aGPCR) GPR56/ADGRG1 as a critical regulator of PNS myelination. Loss of *Gpr56* function in zebrafish and mouse mutants results in delayed radial sorting. Consistent with the ability of aGPCRs to transduce extracellular stimuli into intracellular signals, we demonstrate that GPR56 signals through RhoA to promote SC radial sorting prior to myelination. Despite delays during early development, radial sorting in *Gpr56* mutants recovers with time. However, the mature myelin ultrastructure is disorganized and we observe increased outfoldings with age. In spite of these key functions, it is unclear what developmental cues activate GPR56 in the PNS. In other contexts, GPR56 has two known binding partners, the ECM proteins collagen III and tissue transglutaminase 2, and our efforts to define the roles of these potential GPR56 interactors in the PNS will be discussed. Interestingly, however, an unbiased proteomics screen has identified additional candidate binding partners for GPR56 in the PNS. Currently, we are using CRISPR/Cas9-mediated genome editing to generate zebrafish mutants for these candidate genes in order to define their role in radial sorting as well as perform genetic interaction studies to test whether these mutants enhance *gpr56*$^{stl13/stl13}$ phenotype. Together, our studies define the role of GPR56 PNS development, and our work has important implications for human neuropathies and myelin diseases.

Z6220A Genetic regulation of photoreceptor specification in zebrafish as a model for understading photoreceptor variation in diurnal species. *J. M. Fadool*, M. Sotolongo-Lopez. Florida State University, Tallahassee, FL.

The visual system is highly adapted to convey detailed ecological and behavioral information essential for survival of a species. The retinas of the majority of vertebrates are dominated by 4 cone subtypes sensitive to UV, blue, green and red wavelengths of light. However, much of our understanding of photoreceptor development is based on findings from mammalian models which are highly adapted to dim light conditions with rods vastly outnumbering the sparse and less diverse cone subtypes and thus fail to explain the tremendous diversity of cone subtypes and variation of rod and cone numbers in many species. The spatial patterning of zebrafish photoreceptors combined with classical genetics and emerging gene-targeting technologies, offer unprecedented opportunities to investigate photoreceptor biology. In the larval zebrafish retina the four cone subtypes grossly outnumber the far fewer, assymetrically distributed rods. Previously, we showed that loss-of-function and hypomorphic alleles of *tbx2b* result in an increase in the number of rods across the retina and a decrease in the number of UV-sensitive cones. Subsequently we showed that knockdown of *six7* results in a nearly identical rod phenotype, and knockout alleles result in the additional loss of the green-sensitive cone subtype. We report that hypomorphic alleles of *six7* and *tbx2b* are additive in their effects upon the number of rods. In wildtype larvae, cones outnumber rods 20:1, but in double mutants, the rods account for approximately 40% of the total number of photoreceptors. Furthermore, spatial pattern analysis indicates that the rods are uniformly distributed across the mutant retinas. Genome sequence analysis of the hypomorphic allele identified the deletion of a putative *cis*-regulatory module that may underlie the photoreceptor alterations. Lastly, additional gene knockdown approaches show the potential of epistatic interactions to drive further changes in rod and cone ratios. These data demonstrate the effects of subtle alteration of gene expression upon photoreceptor patterning, and the potentail for alterations in the gene-regulatory network as a driving forces underlying variation in rod and cone numbers across species.

Z6221B A Novel Developmental Requirement for NMDA Receptors in Axon Guidance is Disrupted by Hypoxic Injury. *J. Gao*, T. Stevenson, J. Bonkowsky. Department of Pediatrics, University of Utah School of Medicine, Salt Lake City, UT.

Hypoxic injury in the developing human brain is a major cause of chronic neurodevelopmental impairments in part through loss of normal connectivity although the mechanisms are poorly understood. Here we found that hypoxic injury down-regulates N-methyl-D-aspartate receptors (NMDAR) expression in the developing brain. NMDARs are glutamate-gated heteromeric ion channels widely expressed in the CNS

that play key roles in excitatory synaptic transmission in the adult brain and in synapse stabilization. We found that commissural pathfinding is disrupted by pharmacological inhibition of NMDARs. We demonstrate that the NMDAR NR1 subunit is expressed in commissural axons, and that *vglut1*, the biosynthesis enzyme for glutamate, is expressed in neurons adjacent to the commissural axons. We further show that NMDAR agonist can rescue the hypoxic-induced commissural neuron pathfinding defects. In summary, we report an unexpected developmental role for NMDARs in axon pathfinding, and show that disruption of normal NMDAR function by hypoxia contributes to connectivity disruption.

Z6222C Zebrafish Rfx4 is required for neural tube morphogenesis. *Y. Grinblat*, I. Sedykh, A. Keller. Univ Wisconsin, Madison, WI.

Rfx family of wing-helix transcription factors are key regulators of the core ciliogenesis program in vertebrates. Recently, Rfx genes have been shown to function independently of ciliogenesis, e.g. during brain ventricle morphogenesis. To better understand the mechanism of Rfx gene function during neural tube development, we have generated frame-shift alleles in the zebrafish *rfx4* locus using CRISPR/Cas9. Rfx4 mutant embryos develop with a curvature characteristic of disrupted ciliogenesis, as do Rfx4 morphants. However, transcriptome analysis of Rfx4 mutant vs sibling embryos suggests that the primary role of Rfx4 is to promote expression of neural tube roof plate markers, e.g. *zic2a*, and floor plate markers, e.g. *fox2a*. Further, transcriptome analysis suggests that zebrafish Rfx4 is essential for Hh signaling but does not play a major role in ciliary gene transcription during embryogenesis. These findings are consistent with a recent mouse study that identified a cilia-independent role for Rfx4 as a transcriptional regulator of *foxa2 i*n the floor plate and *zic2* in the roof plate. Notably, curvature reminiscent of the *rfx4* phenotype has been reported in *foxa2/monorail* mutant zebrafish. Collectively, these data shed light on an important, yet incompletely understood conserved node in the gene regulatory network that controls patterning and morphogenesis of the neural tube.

Z6223A Distinct roles for the adhesion molecule Contactin2 in the development and function of neural circuits in zebrafish. *S. Gurung*, E. Asante, A. Chandrasekhar. University of Missouri, Columbia, MO.

During development, newborn neurons frequently migrate before assembling into neural networks that control complex motor and cognitive functions. In addition, neuronal growth cones must mediate precise axon pathfinding to generate functional neural circuits. Cell adhesion molecules play important roles during development, including in neuronal migration and axon guidance. Contactin2 (Cntn2)/Transiently-expressed Glycoprotein 1 (Tag1), a glycosylphosphatidylinositol anchored cell adhesion molecule of the immunoglobulin superfamily, is expressed in specific neuronal types during vertebrate nervous system development. In zebrafish, the facial branchiomotor (FBM) neurons, a subset of the hindbrain motor neurons, express *cntn2* while migrating caudally from rhombomere 4 to rhombomeres 6 and 7. Our previous studies using morpholinos suggested that *cntn2* is necessary for FBM neuron migration, and that it genetically interacts with the planar cell polarity gene *vangl2* during FBM neuron migration. To validate these data, we generated loss-of-function mutations in *cntn2* using CRISPR/Cas9, and identified three alleles including two frameshift mutations generating premature stop codons (*zou20* and *zou22*) that exhibited identical phenotypes. *cntn2* expression was reduced in $cntn2^{zou20}$ *and* $cntn2^{zou22}$ homozygotes, and Cntn2 protein was undetectable in both cases, suggesting these identified alleles are null. In contrast to the morphant phenotype, zygotic and maternal-zygotic (MZ) $cntn2^{-/-}$ mutants exhibited normal FBM neuron migration, suggesting either that the morphant phenotype may be non-specific or that there is genetic compensation from related genes in MZ mutants. Consistent with the latter, FBM neurons failed to migrate caudally in a significant fraction of $cntn2^{+/-}$*; vangl2*$^{+/-}$ embryos obtained from $cntn2^{-/-}$ mothers, supporting the genetic interaction observed using morpholinos.

Previous studies showed that morpholino-mediated *cntn2* knockdown generated defasiculation defects in midbrain nucMLF and spinal cord Rohon-Beard (RB) axons. However, MZ $cntn2^{-/-}$ mutants exhibited no nucMLF defects. To assay for defects in the sensorimotor circuits of RB neurons in *cntn2* mutants, touch-evoked escape responses was evaluated. Wild type and mutants larvae exhibited normal escape responses when touched on the head. In contrast, mutants were significantly less responsive when touched in the trunk consistent with putative defects in RB circuits. Together, these data support distinct roles for Cntn2 in the development and function of neural circuits in zebrafish.

Z6224B Before Neural Circuit Formation: A Role for Semaphorins on Retinal Progenitor Cells. *R. Halabi*[1,2,4], S. McFarlane[1,2,3,4]. 1) Hotchkiss Brain Institute; 2) Department of Neuroscience; 3) Department of Cell Biology and Anatomy; 4) University of Calgary, Calgary AB Canada.

Coloboma is a congenital ocular malformation caused by the failure of the choroid fissure to close during development. Although mutations in a number of genes have been identified, the cellular and molecular mechanisms in the pathogenesis of the disease remain poorly understood. Here we identify the secreted guidance molecule, Semaphorin3f (Sema3f), as a novel factor involved in retinal development. We used embryonic transgenic (Tg) zebrafish injected with antisense morpholino or CRISPR interference RNA to block Sema3fa production, and analyzed embryos throughout retinal development. Histological sections, in situ hybridization for retinal polarity markers and analysis of the retinal ganglion cells (RGCs) using the Tg(isl2b::GFP) reporter line were used to characterize the Sema3fa deficient embryos. We find that *sema3fa* is expressed around the choroid fissure and temporal retina prior to fissure closure and RGC axonal exit in wildtype embryos. Sema3fa deficient embryos present with coloboma of the eye at 48 hours post fertilization, defective patterns in the expression of retina polarity markers, and proliferation deficits in the temporal retina. During RGC axonogenesis, embryos present with aberrant axonal sprouts into the neural retina from the ganglion cell layer and optic nerve. Overall, these data suggest Sema3f as a novel factor involved in eye and choroid fissure morphogenesis, progenitor behaviour and neural retina development.

Z6225C *actr10* is a regulator of myelinating glial cell development. *A. L. Herbert*[1], K. Drerup[2], B. L. Harty[1], S. D. Ackerman[1], R. S. Gray[3], T. O'Reilly-Pol[1], S. L. Johnson[1], A. Nechiporuk[2], K. R. Monk[1]. 1) Washington University in St. Louis, St. Louis, MI; 2) Oregon Health and Science University, Portland, OR; 3) University of Texas at Austin, Austin, TX.

Myelin is the lipid rich sheath that surrounds axons and promotes rapid action potential propagation in the vertebrate nervous system.

Myelin is made by specialized glial cells called oligodendrocytes (OLs) in the central nervous system (CNS) and Schwann Cells (SCs) in the peripheral nervous system (PNS). Loss of or disruption to the myelin sheath can result in debilitating human conditions including multiple sclerosis and Charcot-Marie-Tooth disease, and understanding glial cell development is critical for development of therapies to treat myelin diseases. Our lab therefore performed a large-scale forward genetic screen in zebrafish to look for novel regulators of myelination and identified a mutant, *stl83*, that exhibits both axon and myelin defects. Using whole genome sequencing, it was determined that the *stl83* phenotype results from a missense mutation in the gene *actr10,* which encodes the protein Arp11. This was confirmed by a complementation cross using a previously identified mutant *actr10* allele, *llg22*, which results in a point mutation in the start site. Arp11 is a component of the dynactin complex, which is necessary for retrograde transport by the molecular motor dynein. *In-situ* hybridization (ISH) for *myelin basic protein* (*mbp*) mRNA to mark mature glial cells showed that both $actr10^{stl83/stl83}$ and $actr10^{llg22/llg22}$ mutants have drastically reduced *mbp* expression in the CNS and PNS at 5 dpf. Transmission electron microscopy analysis revealed that many fewer axons are myelinated in the CNS and PNS of both mutants. In addition, those axons that are myelinated have a thinner myelin sheath. We are currently teasing out the mechanism resulting in reduced *mbp* expression and transport by marker analysis for different molecular makers of oligodendrocyte and Schwann cell development, cell death and cell proliferation assays, live imaging using fluorescent transgenic reporter lines, and chimera analysis to determine autonomy of the myelin defects.

Z6226A *ZC4H2*, an XLID gene, is required for the generation of GABAergic interneurons. *K. Hwang*, T. Choi, M. Thiruvarangan, S. Lee, S. Hyung, H. Hwang, K. Lee, C. Kim. Chungnam National University, Daejeon, KR.

X-linked intellectual disability (XLID) is a well-known form of intellectual disability which is specifically associated with X-linked recessive inheritance. To investigate the function of XLID gene, *ZC4H2*, we generated zebrafish mutant for *ZC4H2* homologue gene using TALEN methodology. Zebrafish *zc4h2* homozygous mutant larvae exhibited abnormal swimming, stationary eye movement, and hyperactivity of jaw and pectoral fin. Because of the behavioral defects were consistent with hyperactivity, we focused on underlying neuronal defects. Through various molecular markers, we observed a striking reduction in GABAergic interneurons. Analysis of cell type specific markers showed a specific loss of V2 interneurons in the midbrain tegmentum and spinal cord. Also, we found that loss of Zc4h2 function affects in misexpression of *dbx2*/*nkx6.1* boundary. To restore the Zc4h2 function in the mutant, we microinjected human and zebrafish mRNAs in *zc4h2* mutant embryos, and examined *gad1b*-positive neurons. As a result, human and zebrafish mRNAs rescued the mutant phenotype. However, mutant zebrafish microinjected with human p.L66H or p.R213W mRNA failed to be rescued, while the p.R18K mRNA was able to rescue the interneuron defect. In this studies clearly support *ZC4H2* as a novel XLID gene with a required function in V2 interneuron development. Loss of function of ZC4H2 thus likely results in altered connectivity of many brain and spinal circuits.

Z6227B Goosecoid regulates a Spemann organizer-like function for neurogenesis in the inner ear. *H. Kantarci*, A. Gerberding, B. Riley. Texas A&M University, College Station, TX.

In all vertebrates hearing and balance related information is transmitted from the ear to the brain by the neurons of the Statoacoustic Ganglion (SAG). SAG neuroblasts originate in the inner ear epithelium, undergo epithelial-mesenchymal transition, then leave and migrate to a region between the ear and the hindbrain to subsequently differentiate into mature neurons. Locally expressed Fgf sources initiate cell fate specification of SAG neuroblasts by inducing expression of Ngn1 in the ear epithelium. However, there are no proposed mechanisms to explain how transition to mesenchymal state is induced during SAG development. Here, we report Goosecoid (Gsc) as a key regulator of this process, a gene famous for inducing the formation of the Spemann organizer and initiating the migratory movements that define the future embryonic axes. In zebrafish, Fgf signaling co-regulates expression of *gsc* and *ngn1* in partially overlapping domains. Loss of Gsc function impairs the ability of SAG neuroblasts to leave the ear and results in a significant loss of mature SAG neurons, whereas overexpression of Gsc increases the number of mesenchymal cells. Our analysis also reveals that Gsc induces transition to mesenchymal state without affecting the size of the neurogenic domain in the inner ear. Thus, Gsc and Ngn1 regulate epithelial-mesenchymal transition and neuronal specification as two distinct outputs of Fgf signaling. Furthermore, we discovered that medially expressed transcription factor Pax2a completely blocks Gsc function in the non-neurogenic regions of the developing inner ear, spatially restricting epithelial-mesenchymal transition to ventrolateral regions. The role of Gsc in SAG neurogenesis, together with its regulation of cell movement in the Spemann organizer and promotion of tumor metastasis indicates that Gsc might have a more widespread role in epithelial-mesenchymal dynamics than previously thought.

Z6228C A zebrafish model of vanishing white matter disease. *Matthew D. Keefe*. Department of Neurobiology, University of Utah, Salt Lake City, UT.

Vanishing white matter disease (VWMD) is an inherited leukodystrophy, causing CNS demyelination and high rates of morbidity and mortality. VWMD is autosomal recessive, and is caused by mutations in the five subunits of the eukaryotic translation initiation factor 2B (eIF2B) complex. eIF2B is the guanine nucleotide exchange factor for eIF2, and together they govern the rate of global protein synthesis. VWMD is characterized by reduced numbers of oligodendrocytes and astrocytes, as well as the progressive loss of myelinated axons. How mutations in eIF2B, a complex universally required for protein synthesis, disproportionately affects oligodendrocytes and astrocytes is not known. In yeast, null mutations in *eIF2B(2-5)* are non-viable which may indicate why in humans, mutations that prevent the expression of full-length *EIF2B* subunits have only been reported in the compound heterozygous state with a missense mutation as the second mutation. Because null mutations are most likely lethal in humans, this will limit the severity of phenotypes observed in individuals that survive to birth, making it difficult to determine the effects of *EIF2B* mutations in development. Importantly, mutations that severely compromise the function of eIF2B have not been studied in a vertebrate model system. The goal of our study is to develop a model of VWMD in zebrafish that

recapitulates the clinical features of the disease, and to discover developmental defects associated with impaired function of eIF2B.

We have generated mutant alleles in the zebrafish *eif2b* subunits 2 and 5. Our characterization of these mutants has revealed a diversity of phenotypes that range in phenotypic severity from mild growth defects to early lethality. The *eif2b5* alleles alter somatic growth rates in development, while only some alleles impact survival. To date, a point mutation in *eif2b2* is the most severe allele characterized. *eif2b2* mutants appear to develop normally, but by 5dpf are smaller in size compared to their siblings and display increased apoptosis in the fore-and-mid-brain, followed by early lethality by 10dpf. Our current study represents an essential step in the study of eIF2B related leukodystrophies, specifically by testing the function of several *eif2b* alleles in a vertebrate model organism. The genetic and developmental toolbox in the zebrafish field makes it a good candidate to develop disease models for the study of how developmental defects impact disease progression.

Z6229A Development of a Novel Pharmacological Model of Okadaic Acid-induced Alzheimer's Disease in Zebrafish. *D. Koehler*, F. Williams, Z. Shah. University of Toledo, Toledo, OH.

The present study aimed at establishing a new pharmacologically-induced Alzheimer's (AD) model in zebrafish by administering okadaic acid (OKA). This model involves most of the pathophysiological conditions predominant in AD while also cutting down time constraints and cost which hinder previously established AD models. Zebrafish were divided into 5 groups containing 5-6 fish per group. Each group was exposed to a respective concentration of OKA of 10nM, 100nM, 500nM, and 1µM along with a control group. Each exposure lasted for 9 days with a learning and memory test performed at the end. Fish were tested individually in a spatial alternation task in order to assess learning and memory capabilities. Fish were placed in a 10 L aquarium that was divided into two equal sections by a white divider that allowed for adequate room for the fish to swim from one side of the aquarium to the other. Each trial was initiated with a light tap at the center of each aquarium. After the light tap, there is a 5 second delay followed by food presentation on one side of the tank. In 20 minutes intervals, food presentation continued on alternating sides for a total of 28 trials (14 on each side). A response was considered correct if the fish was present on the side of food presentation during or shortly after food presentation. Each trial ended 5 seconds after the food was presented. Zebrafish are deemed to have learned the task when 75% or more of the responses are correct. After completing the learning and memory tests, fish were euthanized and their brains were further analyzed by conducting immunohistochemistry analysis for phospho-glycogen synthase-3 α/β (p-GSK-3 α/β), GSK-3 α/β, Aβ, p-tau, and tau. All parameters of expression of p-GSK-3α/β, GSK-3α/β, Aβ, p-tau, and tau were analyzed using a student's t-test. A value of $p<0.05$ was considered to be significant. It was observed that brain hemorrhages and higher mortality rates were caused in fish with increasing concentration of OKA. The 500nM and 1µM exposure groups observed the highest mortality rates of 60%-70%. The control group demonstrated rapid learning with maximal learning shown to be between 75%-80%. The exposed groups never demonstrated learning with their probabilities of correctness continuously staying around 50%. OKA exposure resulted in the increased phosphorylation of GSK-3 α/β, increased phosphorylation of tau, Aβ deposition, and the formation of Aβ plaques. These experiments were able to establish an AD model that incorporates most of the hallmarks of AD pathophysiology. This model can now be used to study drug discovery for AD and the molecular mechanisms involved in AD without the time and cost constraints that other AD models entail.

Z6230B Regulation of the cell cycle and cell fate by TGFβ signaling in larval and adult zebrafish. *J. R. Lenkowski*, M. Downey, K. Brandt, D. Meir-Levi. Goucher College, Baltimore, MD.

Several studies indicate that the TGFβ signaling pathway plays an important role in regulating proliferation of progenitors and cell differentiation during mammalian retinal development and zebrafish retinal regeneration. We are using chemical genetics and genetic approaches in zebrafish to manipulate TGFβ signaling in order to study how the signaling pathway regulates the cell cycle and cell differentiation during retinal development, which has not yet been described, and regeneration of the adult retina. Specifically, TGFβ signaling has been shown to promote Müller glial cell fate, inhibit proliferation, and increase differentiation into photoreceptors during rodent retinal development, and in the regenerating adult zebrafish retina, proliferation and regeneration are impaired when canonical TGFβ signaling is mis-regulated. Our preliminary studies of retinal development in zebrafish using fluorescence immunohistochemistry suggest that the CMZ may be expanded when TGFβ signaling is inhibited. In the adult damaged retina, the initial damage response by Müller glia is extremely similar between mammals and zebrafish, but the zebrafish is able to achieve robust regeneration of destroyed neurons while mammals are limited. In the zebrafish retina, Müller glial cells respond to damage by dedifferentiating and generating a neurogenic progenitor that goes on to regenerate lost neurons. Ongoing experiments are clarifying whether manipulating TGFβ signaling in the adult zebrafish retina promotes a more mammalian-like response to acute retinal injury.

Z6231C Making Functional Neuronal Circuitry: Interneuron specification in the spinal cord. *K. E. Lewis*. Syracuse University, Syracuse, NY.

CNS damage caused by abnormal development, injury or disease profoundly impacts quality of life. For example, spinal cord injuries are relatively common, but strategies to repair or regenerate damaged sites remain elusive. To develop more effective treatments it is essential that we understand the molecular mechanisms that produce functional spinal cord circuits. In addition, if we are to understand the genetic basis of neuro-developmental and behavioral disorders we need to understand how specific genes regulate the development of neuronal circuitry and hence enable particular behavioral repertoires. A particularly tractable model system for this research is spinal cord circuitry. This is partly because the development and functions of this circuitry can be studied in simpler vertebrates such as zebrafish and partly because the spinal cord is a much simpler structure than the brain. Specification of distinct types of neurons with particular functional properties is a crucial step in circuit formation. Interneurons constitute most of the neurons in the CNS and they function in almost all neuronal circuits. However, there are significant gaps in our knowledge of how spinal interneurons with specific functional characteristics develop and form appropriate neuronal circuitry. All of the evidence so far, suggests that the properties of distinct interneurons are determined by the transcription factors

that these cells express as they stop dividing and start to differentiate. However, in many cases, it is still unclear which transcription factors specify particular properties, at least partly because we do not yet know the full complement of transcription factors expressed by any population of spinal interneuron.

To address these critical gaps in knowledge we have expression-profiled different spinal interneurons using transgenic zebrafish lines that specifically label these cells. Using these data, we have identified transcription factors that are candidates for specifying particular interneuron properties and we are currently testing the functions of these using mutations. Notably we have already identified several families of transcription factors that are required to specify and/or maintain the neurotransmitter properties of particular spinal interneurons. For example, we have shown that Pax2 & Pax8 are required for the inhibitory fates of many distinct spinal neurons and Evx1 & Evx2 are required for the excitatory fates of V0v neurons. We have also identified additional transcription factors that are required either for the inhibitory fates of distinct ventral neurons or the excitatory fates of specific dorsal neurons or to maintain the glutamatergic fates of some excitatory neurons.

Z6232A Telomere-Dependent and -Independent Functional Roles of A Telomeric Factor TRF2 in Early Vertebrate Development and Neurogenesis. *S. Lian*[1], A. Khan[1], T. Sasaki[1], M. Rebagliati[2], L. Bally-Cuif[3], H. Sirotkin[4], S. Kishi[1]. 1) The Scripps Research Institute, Jupiter, FL; 2) Institute of Genetics and Molecular and Cellular Biology, France; 3) Institute of Neurobiology Alfred Fessard, France; 4) Stony Brook University, Stony Brook, NY.

Telomere repeat-binding factor 2 (TRF2) is critical for telomere integrity in dividing stem and somatic cells, and its role is essential for vertebrate early development because animals carrying a null *terf2* mutation have early embryonic lethality due to an unknown molecular mechanism. Besides telomeric homeostasis by protecting telomere ends, it has been shown that TRF2 can interact with the neuronal gene-silencer repressor element 1-silencing transcription factor (REST), whose instability via TRF2 affects neuronal cell differentiation *in vitro*. However, the mechanism that couples TRF2-mediated features to cellular differentiation programs has yet to be elucidated *in vivo*. Loss of TRF2 in zebrafish embryos recapitulates key aspects of telomere attrition, including the DNA-damage response and cell-cycle arrest, as well as neurodegeneration. Intriguingly, TRF2-deficient animals develop similar but more severe neuromuscular defects observed in spinal muscular atrophy, a genetic disorder characterized by a loss of alpha motoneurons in the spinal cord. Using *terf2* zebrafish embryos that carry the concurrent triple- or quadruple-defects of the *rest, tert, tp53 and/or terf1* genes with the expression of the various transgenic reporter genes including the zebrabow system, we show motor axon-specific pathfinding/guidance abnormalities that could be linked to aberrant Wnt and Hedgehog pathways in parallel with telomere fusion/attrition. Our results show for the first time, *in vivo*, that TRF2 functions in motor axon development and suggest that *terf2* mutation leads to early developmental senescence and motoneuron defects in both telomere-dependent and -independent manners.

Z6233B The Role of the CoREST Family in Early Neurodevelopment. *C. M. Monestime*, Andrew Taibi, C. R. Milano, Neal Bhattacharji, Esha Chebolu, Ibrahim Elmaghrbi, H. I. Sirotkin. Stony Brook University, Stony Brook, NY.

Neurogenesis is a highly regulated process that results in the emergence of diverse neural cell types from progenitor and stem cell pools. The RE 1-silencing transcription factor (REST) has been proposed to play a role in regulating neurogenesis, fine-tuning expression of neural genes, and suppressing expression of target genes in non-neural tissues. REST is a part of a neuronal macro-repressor complex. REST acts by binding to a highly conserved DNA element, the RE1 site; once bound, it recruits co-repressors Sin3 to its N-terminal domain and the CoREST family to its C-terminal domain, which subsequently recruit chromatin modifiers to form the repressor complex. Initially, CoREST was identified in association to the REST complex, but it is now recognized that CoREST also works independent of REST. In vertebrates, the CoREST family contains three members, RCOR1, RCOR2, and RCOR3; distinct activities and roles have yet to be established for each of these proteins. To tease apart the REST-dependent and REST-independent roles of the CoREST family in neural development, we used transcription activator-like effector nucleases (TALENS) to disrupt all three CoREST genes in zebrafish. The three single mutants and all three double mutant combinations are viable. qPCR analysis revealed that expression levels of RE1- containing genes differs between the CoREST mutants, suggesting unique roles for each protein. In addition, analysis of larval locomotor behavior of each of the mutants revealed distinct behaviors were produced in the absence of each CoREST gene. These results show that members of the CoREST family differentially mediate gene expression and larval behavior and suggest both redundant and unique functions for zebrafish CoREST family members during development.

Z6234C Dissecting the Endocannabinoid System using the zebrafish model. *F. Oltrabella*[1], B. Nguyen[2], S. Guo[1]. 1) UCSF, San Francisco, CA; 2) UC Berkeley, Berkeley, CA.

Recent trends in marijuana legislation have been a topic of significant public attention. Legalization of the drug in many US and overseas countries will increase its daily usage, which in turn will necessitate the need to understand the fundamental mechanisms underlying marijuana's effect *in vivo*, as it remains rudimentary. Δ9-tetrahydrocannabinol (THC), the main psychoactive ingredient in marijuana interferes with the endogenous cannabinoid system (eCBs), which includes cannabinoid receptors, endogenous ligands, and enzymes involved in the synthesis and metabolism of these ligands. The eCBs modulate various cognitive and physiological processes associated with addiction including reward, stress responsiveness and appetite stimulation. Limited functional studies of eCBs have been carried out in zebrafish, which have relied on the use of morpholinos and THC treatment but little is known regarding the role of eCBs on brain development. Through genomic analysis we identified components of eCBs in the zebrafish genome, which include:

- orthologous receptors (Cb1 and Cb2)
- synthesis enzymes (Abdh4, Daglα and Daglβ)
- catabolic enzymes (Faah and Mgll)

• cannabinoid receptor 1 interacting proteins (Cnrip1A and Cnrip1B)

Here we show expression analysis of eCBs genes in the zebrafish in different embryo time points and within tissue types in adults. To further characterize the molecular mechanisms by which endocannabinoid system works we targeted and disrupted eCBs associated genes using CRISPR/Cas9 technology. We successfully generated F1 hets with indels for all the eCB genes and obtained F2 for the majority of them. Here I am presenting the preliminary characterization of these mutants revealing new insights into the mechanism of action of eCBs on neurodevelopment, physiology and behaviour.

Z6235A Gene Expression Changes during Brain Regeneration in Adult Zebrafish. *Kanagaraj Palsamy*, Jack Parent. Department of Neurology, BSRB, University Of Michigan, Ann Arbor, MI, USA.

In the mammalian brain, neural stem cells and neurogenesis persist into adulthood mainly in the subependymal zone-olfactory bulb pathway and hippocampal formation. Adult neurogenesis is proposed to play an important role in learning and memory, but it also offers the potential for replacing injured or diseased brain tissues through regeneration by neural stem cells. Despite the persistence of neurogenesis, mammals have limited brain regenerative capacity. Zebrafish, however, display robust regeneration in many different brain regions and can make mature, functional neurons after injury. We use adult zebrafish to explore the molecular networks induced by traumatic brain injury and quinolinic acid (QA)-induced neurotoxicity. We performed RNA sequencing on telencephalic tissue collected 24 or 48 hours after brain injury, with or without QA lesioning, and identified many interesting candidate genes involved in various biological processes. Our gene ontology and pathway analysis study confirms upregulation of immune response, tissue regeneration, wound healing, cell migration, angiogenesis processes, and Jak-Stat, interleukins, inflammatory-induced chemokines and cytokines, notch, and B cell and T cell activation pathways respectively. Based upon expression level changes and their known roles in neuroprotection or stem cell function, we selected 8 candidate genes to explore their potential involvement in different cellular and molecular pathways necessary for brain regeneration. We first confirmed the RNAseq expression changes of the candidates after injury using real-time RT-PCR. Work is ongoing to examine cellular expression changes by in situ hybridization, and to generate loss-of-function models to examine how alterations in the candidate genes influence brain injury and the regenerative process. We are also using the QA excitotoxicity model in mouse striatal lesioning with the goal of comparing gene expression changes with the zebrafish model. Our eventual aim is to shed light on mechanisms underlying the limited regenerative capacity of the mouse brain with the goal of improving brain repair.

Z6236B A Zebrafish Screening Platform for *In Vivo* Pro-Myelinating Drug Discovery. *M. A. Preston*, L. Finseth, W. B. Macklin. University of Colorado Anshutz Medical Campus, Aurora, CO.

Myelin is produced by oligodendrocyte lineage cells in the central nervous system. Numerous extracellular and intracellular molecules influence myelination, but how these diverse cues are integrated at the level of transcription to control myelination remains poorly understood. Nuclear Receptors (NRs) are transcription factors that bind a wide variety of lipophilic molecules and activate or repress transcriptional programs that control differentiation and maturation of cells. One NR signaling cascade important for myelination is mediated by Retinoid X Receptors (RXRs), which dimerize with other NR family members, potentially influencing multiple NR signaling cascades. Signaling interactions between RXRs and other NRs have been tested with *in vitro* cell assays, which fail to replicate the complex intercellular relationships and signaling interactions that occur *in vivo*. The zebrafish embryo is an excellent model to study myelination *in vivo* as embryos develop *ex utero,* myelination of the spinal cord occurs during the first week of life and each pair of zebrafish produce hundreds of embryos, allowing multiple drugs or combinations of drugs to be tested simultaneously for their impact on myelination. As such, we have developed a novel zebrafish model which quantifies the promoter response of a critical myelin gene, myelin protein zero (*mpz*), to RXR and NR ligands using a fluorescent or nanoLuciferase-based reporter system.

The *mpz* reporter embryo responds to known positive and negative regulators of myelination, consistent with changes in myelin mRNAs as quantified by qPCR. Initial studies of known RXR agonists and antagonists indicate that endogenous ligands such as 9-cis retinoic acid (9cRA) or Docosahexaenoic acid (*DHA*) have no significant effect on myelination *in vivo*, while synthetic molecules such as Fluorobexarotene, SR11237, UVI3003, PA 452, HX 630 and HX 531 can have significant dose-dependent effects on *mpz* promoter activity. These studies suggest that RXR-mediated signaling *in vivo* is more complicated than previously predicted and that investigating RXRs in an *in vivo* context will be essential for understanding the underlying mechanisms of action. Future experiments will use the *mpz* reporter to identify RXR and NR-mediated signaling interactions using an *in vivo* screening approach with the goal of identifing other pro-myelinating signaling interactions.

Z6237C N-cadherin is required cell-autonomously for the collective migration of facial branchiomotor neurons. *J. K. Rebman*, G. S. Walsh. Virginia Commonwealth University, VA.

Neuronal migration is a key mechanism during neural development, as it allows cells to reach their final destination, establishing the basis for the subsequent wiring of neural circuitry. Collective cell migration, the coordinated migration of a cell population through cell–cell contact, is a recognized mode of migration for a variety of cell types, but its role in neuronal migration has been poorly characterized. We have recently published that facial branchiomotor (FBM) neurons, that migrate from rhombomere (r)4 to r6 in the developing hindbrain, use a collective mode of migration in which one FBM neuron can influence the migration of neighboring FBM neurons presumably through cell-cell contact. Here, we examined whether N-cadherin is a candidate cell adhesion molecule mediating the collective migration of FBM neurons. To accomplish this, we generated stable transgenic fish expressing a dominant-negative N-cadherin, lacking the extracellular domain (*ncadhDEC*), specifically in cranial branchiomotor neurons using the *islet1* promoter. We find that caudal migration of FBM neurons is blocked in *Tg(isl1: ncadhDEC)* fish, as they fail to exit r4. Timelapse imaging revealed that loss of N-cadherin function does not block cell motility as FBM neurons

migrate randomly and dorsally within r4. To determine whether N-cadherin is required for collective migration, we generated mosaic embryos in which some FBM neurons expressed *ncadhDEC* adjacent to wild-type FBM neurons. We found that few, if any, *ncadhDEC*-expressing FBM neurons could be rescued via collective migration by neighboring wild-type neurons. Taken together, our data suggest that N-cadherin plays an essential cell-autonomous role in mediating the collective migration of FBM neurons.

Z6238A Paclitaxel-induced epithelial damage and ectopic MMP-13 expression promotes neurotoxicity in zebrafish. *S. Rieger*[1], T. Lisse[1,2], L. Middleton[1], A. Pelegrini[1], P. Martin[1], E. Spaulding[1], O. Lopes[1], E. Brochu[1], E. Carter[1], A. Waldron[1]. 1) MDI Biological Laboratory, Salisbury Cove, Maine; 2) The Jackson Laboratory, Bar Harbor, Maine.

Paclitaxel is a microtubule-stabilizing chemotherapeutic agent that is widely used in cancer treatment and in a number of curative and palliative regimens. Despite its beneficial effects on cancer, paclitaxel also damages healthy tissues, most prominently the peripheral sensory nervous system. The mechanisms leading to paclitaxel-induced peripheral neuropathy remain elusive and therapies that prevent or alleviate this condition are not available. We established a zebrafish *in vivo* model to study the underlying mechanisms and to identify pharmacological agents that may be developed into therapeutics. Both adult and larval zebrafish displayed signs of paclitaxel neurotoxicity, including sensory axon degeneration and the loss of touch response in the distal caudal fin. Our studies in zebrafish larvae further showed that paclitaxel promotes epithelial damage and decreased mechanical stress resistance of the skin prior to induction of axon degeneration. Epithelial damage correlates with rapid accumulation of fluorescein-conjugated paclitaxel in epidermal basal keratinocytes, but not axons, and upregulation of the collagenase matrix-metalloproteinase 13 (MMP-13, collagenase 3) in basal keratinocytes. Intriguingly, pharmacological inhibition of MMP-13 largely rescued paclitaxel-induced epithelial damage and neurotoxicity. Thus our studies provide evidence that the epidermis plays a critical role paclitaxel neurotoxicty, and we provide a new candidate for therapeutic interventions.

Z6239B Integration of multiple signaling pathways in habenular development. *S. Roberson*[1,2], M. E. Halpern[1,2]. 1) Carnegie Institution for Science, Baltimore, MD; 2) Johns Hopkins University, Baltimore, MD.

The habenulae are paired nuclei of the epithalamus, which have been implicated in a number of behaviors, such as sleep, fear/anxiety and reward, as well as in neurological diseases such as bipolar and major depressive disorder. Despite the importance of the habenulae, relatively little is known about their development. Wnt and Fgf signaling pathways have been implicated in the formation of the dorsal habenular (dHb) nuclei, but their interaction during dHb development has not been explored. Both pathways are necessary for the generation of habenular progenitors, which are recognized by their expression of the homeodomain transcription factor *dbx1b* (Dean et al., 2014, Vue et al., 2007). This progenitor population is dramatically reduced in *fgf8* and *wntless* mutants. Using lineage tracing, we confirmed that *dbx1b*-expressing progenitors contribute to the entire dHb of larval and adult zebrafish. The *dbx1b*-expressing progenitors were also found to persist past 12 days post fertilization. It was previously suggested that the chemokine receptor Cxcr4b was also produced in habenular progenitors or early habenular neurons. Our data indicate that *cxcr4b* is not transcribed in habenular progenitors; rather, *cxcr4b* expression increases as *dbx1b* expression decreases, supporting the hypothesis that *cxcr4b* demarcates newly born habenular neurons. Wnt and Fgf signaling both regulate the spatial domain of expression of chemokine pathway components in the dorsal diencephalon, with Wnt acting upstream of Fgf8. We will present new findings on both the function of the chemokine signaling pathway in habenular development and the role of Wnt and Fgf signaling in this pathway.

Z6240C Bsx in Neuroendocrine and Pineal Complex Development. *Theresa Schredelseker*, Wolfgang Driever. Developmental Biology, Biology I, University of Freiburg, DE.

By releasing secreted factors to the blood upon receiving neuronal input neuroendocrine cells represent the main integrators connecting nervous and endocrine systems. The pineal gland is a small neuroendocrine structure in the dorsal diencephalon crucial for the regulation of circadian rhythm, partially via secretion of melatonin. Several nuclei at the base of the diencephalon form the hypothalamus, a master gland from which various factors controlling body temperature, hunger, thirst, fatigue and reproduction are released.

The highly conserved homeodomain factor *brain specific homeobox* (*bsx*) is expressed in both the developing pineal complex and hypothalamus. Using TALEN-mediated targeted mutagenesis in zebrafish, we generated the *bsx*^{m1376} mutant allele, in which a truncated Bsx protein lacking a functional DNA-binding domain is translated. In the rodent hypothalamus the orexigenic neuropeptide AGRP has previously been described as being significantly downregulated upon loss of functional Bsx. In *bsx*$^{m1376/m1376}$ larvae we observed drastically reduced *agrp* expression in the hypothalamus, suggesting a similar Bsx function in zebrafish.

Very little is known about the role of Bsx in the pineal complex. *In situ* hybridization revealed pineal gland expression of *tph2,* a key enzyme in melatonin synthesis, to be missing in *bsx*$^{m1376/m1376}$. Loss of Tph2 suggests absence of melatonin in *bsx*$^{m1376/m1376}$ and thus disturbed activity regulation during dark cycles. Reduction of *irbp* and *gngT1* expression further indicates disturbed photoreception via the pineal complex in *bsx*$^{m1376/m1376}$.

The teleost pineal complex more recently has also been implicated in background adaptation as well as the establishment of both anatomical and functional asymmetries in the epithalamus. We analyzed expression of *agrp2*, a neuropeptide crucial for melanocyte contraction, which we found to be significantly reduced in *bsx*$^{m1376/m1376}$. Furthermore, bsx$^{m1376/m1376}$ larvae display abnormalities in epithalamus asymmetry as revealed by absence of parapineal *otx5* expression as well as symmetrical expression of *lov* in the habenula. Through epistasis analysis including *floating head* and *one-eyed pinhead* mutants as well as injections of *otx5* and *crx* morpholinos, we seek to integrate Bsx into a comprehensive model of pineal complex development. Detailed knowledge about the mechanisms by which Bsx regulates neuroendocrine

development or differentiation in not only one but two neuroendocrine brain areas could contribute to a better understanding of numerous diseases associated with the neuroendocrine system.

Z6241A Pard3c, an unconventional zebrafish Par-3 ortholog for organogenesis: important for cell survival and proliferation but not for apicobasal polarity. *Z. Shi*, W. Fang, C. Guo, X. Wei. University of Pittsburgh, Pittsburgh, PA.

Vertebrate homologs of *Caenorhabditis elegans* Par-3 have versatile biological functions, including the prototypical role in cell polarization; such functional versatility may be partly explained by the variety of vertebrate Par-3 homologs. Thus, revealing the similarities and differences among individual Par-3 homologs is a prerequisite for a thorough understanding of their biology in vertebrates. Here, we identified and characterized Pard3c, one of the four zebrafish Par-3 orthologs. The Pard3c sequence is most closely related to that of Pard3, a zebrafish Par-3 ortholog that has been studied extensively. Surprisingly, unlike Pard3, Pard3c does not restrictively localize apically nor is it required for epithelial apicobasal polarity; instead, Pard3c localizes broadly to the cell membranes and is required for proper levels of cell survival and proliferation during the morphogenesis of the retina, lens, midbrain-hindbrain boundary, pharynx, and pectoral fin. Thus, despite the loss of the hallmark function of regulating apicobasal polarity as other Par-3 homologs do, Pard3c yet plays indispensable roles in zebrafish organogenesis.

Z6242B The role of microglia in neurogenesis and repair following telencephalic lesion in adult zebrafish. *Kaia Skaggs*. University of Findlay, Findlay, OH.

Zebrafish represent an attractive system for the study of neurogenesis following injury because, unlike mammals, they regenerate damaged neurons. After stab lesioning, initial cell death is followed by a robust inflammatory response 1-2 days post-injury and a marked increase in proliferation of radial glia-like progenitors that peaks 3-4 days post-injury. In order to study the role of the early inflammatory response on neurogenesis, we ablated microglia that responded to injury though concurrent injection of liposomes containing Clodronate at the injury site. Phagocytosis and subsequent degradation of the liposomal membrane releases Clodronate and causes microglial apoptosis. In the absence of microglia, proliferation and neurogenesis were markedly reduced. These effects persisted over time, resulting in incomplete repair in Clodronate-treated, lesioned brains compared to control liposome-treated, lesioned brains. These results indicate that the early inflammatory response following telencephalic lesioning is an important signaling event that stimulates neurogenesis and repair of adult zebrafish brain injury. A significant limitation of Clodronate treatment is that the critical time period during which microglia crucially affect regeneration cannot be determined. Microglia are dependent on colony-stimulating factor receptor 1 (CSFR1) for viability in other organisms. We used a small molecule inhibitor of CSFR1 to determine the effects of non-invasive microglial ablation on regeneration following brain injury and to further determine with increased precision the time period during which microglia are required to stimulate the neurogenic response following injury.

Z6243C Characterization of two protein repair enzymes in Zebrafish and their influence on the motor system. *Remon F. Soliman*, M. L. Cordero Maldonado, S. Perathoner, A. Crawford, C. Linster. LCSB, Belvaux, LU.

Most neurodegenerative diseases are associated with protein aggregation which in turn could be due to protein damage. One kind of protein damage results from the spontaneous isomerization of aspartyl and asparaginyl residues leading to structural alterations and potentially loss of function of the protein. A protein repair enzyme, namely Protein L-Isoaspartyl Methyltransferase (PIMT), specifically recognizes isoaspartyl residues and repairs them, restoring the original structure of damaged proteins. PIMT knock-out mice die at early stages due to fatal epileptic seizures. Better understanding the physiological role of PIMT may therefore enable us to modulate the progress of epilepsy. Due to limitations in using mouse models to investigate the molecular mechanisms involved in epilepsy, zebrafish (Danio rerio) emerges as a good alternative model organism to pursue this aim. There are two homologues of human PIMT in zebrafish: Pcmt and Pcmt-like. We found that both of them are ubiquitously expressed in many tissues, with the highest expression levels in the brain. We were able to show that both enzymes catalyse the same biochemical reaction as human PIMT. Both genes could successfully be knocked down using morpholino technology. Morphants showed a developmental delay and accumulated isoaspartyl-containing proteins. Preliminary results indicate that the morphants are prone to developing seizures and display disturbed calcium signalling, as observed in the transgenic zebrafish line GCaMP6. As calmodulin was previously found to be a major substrate of PIMT, our results suggest that PIMT is important to sustain normal brain activity, at least partially by supporting calmodulin-mediated calcium signalling.

Z6244A Wnt signaling and mediator 12 control development of the hypothalamus and pituitary. *E. D. Spikol*, E. Glasgow. Georgetown University, Washington, DC.

The brain is a complex structure composed of several distinct tissue types, the patterning of which requires the confluence of multiple signaling networks. The neuroendocrine system represents a vital connection between the brain and body that regulates homeostasis, metabolism, mood and sexual behaviors. Disruptions in the development and regulation of this system are associated with congenital abnormalities and neuropsychiatric disorders. Here, the role of Wnt signaling in the differentiation of neuroendocrine cells in the hypothalamic-pituitary axis is investigated. We examine the effect of the *apc* and *med12* mutations, and treatment with a Wnt-inhibitor compound on zebrafish embryos. Wnt signaling is upregulated in the *apc* mutant and putatively downregulated in the *med12* mutant. We analyzed morphology and used *in-situ* hybridization to detect neuroendocrine gene expression in the pre-optic area, anterior hypothalamus, and pituitary. Our morphology data are consistent with the hypothesis that *med12* acts downstream of *apc* to modulate transcription of Wnt-responsive genes, but suggest that this requirement is not absolute in all tissues. Our studies of brain development indicate that Med12 is

required and Wnt-signaling must be suppressed for normal development of hypothalamic and pituitary cells. However, it appears that Med12 acts independently of Wnt to control the development of the cell populations investigated. Mapping the impact of Wnt signaling and the role of Med12 contributes to a better understanding of the development of neuroendocrine cells, and in what ways alterations in this pathway harm the developing organism.

Z6245B The Retinoic Acid signaling pathway temporally influences enteric neural crest cell migration and differentiation during early phases of enteric nervous system formation in vivo. *R. A. Uribe*, S. Hong, M. E. Bronner. Caltech, Pasadena, CA.

The enteric nervous system (ENS), also known as the "gut brain", is an autonomous network of thousands of interconnected ganglia located within the walls of the digestive tract that regulates peristalsis, gut secretion and water balance. During development, the ENS is derived from "vagal" neural crest cells that emigrate from the hindbrain and, in response to environmental cues, migrate ventrally toward and caudally along the primitive gut. Once reaching their final destinations along the gut, they differentiate into distinct types of enteric neuron or glia. Whereas the migration of neural crest cells along the gut has been extensively studied, little is known about vagal neural crest migration toward the gut and the extrinsic signaling factors regulating their gut entry. Using FACS sorting, transcriptome and perturbation analyses, we have discovered that Retinoic Acid (RA) signaling pathway components are expressed in the zebrafish gut endoderm concomitant with invasion of the gut. Exogenous treatment with RA prior to and during vagal neural crest gut entry enhanced migratory progress, increased the number of gut resident neural crest cells and later of differentiated enteric neurons. Conversely, temporal attenuation of the RA pathway using Tg(*hsp70*:dnzRAR) heat-shocked embryos led to delayed gut entry by neural crest cells and live imaging revealed altered neural crest migratory behavior and progress along the gut. RA treatment was sufficient to expand *meis3* and *shha* expression domains, while its attenuation led to diminished *meis3* and *hoxb5b* expression. Together, these results suggest that the RA signaling pathway plays a key temporal role during the early phases of ENS development, thus enhancing our understanding of the genesis of the ENS *in vivo*.

Z6246C Role of local neurogenesis in functional recovery post spinal cord injury . *Deeptha Vasudevan*, Lisa Briona, Richard Dorsky. University of Utah, Salt Lake City, UT.

Successful treatment for human spinal cord injury (SCI) is currently an insurmountable goal. The biggest obstacle is the inability of severed axons and neurons to regenerate. Adult mammals have a conspicuous inability to regenerate post SCI, but zebrafish show full functional recovery throughout life due to axon regrowth, rewiring of existing circuits and/ or local neurogenesis. Our aim is to understand the role of local neurogenesis in functional recovery. Studies from our lab have shown that resident radial glia undergo a change in morphology, and actively make neurons post injury. To test the hypothesis that neurons born after SCI integrate into existing circuits and are required for recovery of sensorimotor behavior, we are using two approaches. In the first approach, we are genetically ablating neurons that arise from a radial glial lineage post injury to evaluate their specific requirement in swimming behavior. The second approach is to express a calcium reporter specifically in neurons arising from radial glia after injury, to determine whether they exhibit physiological activity during a defined escape behavior. We are also tracing the lineage of radial glia to test whether specific cell identities with known physiological properties are restored.

Z6247A Planar cell polarity components control anterior-posterior guidance of spinal commissural axons. *G. S. Walsh*, J. P. Miano, A. M. Purdy. Virginia Commonwealth University, Richmond, VA.

Spinal commissural neurons are an attractive model to investigate how multiple guidance cues control growth cone navigation along the dorso-ventral (D-V) and anterior-posterior (A-P) axes by both pre- and post-midline crossing axons. Commissural axons extend toward the floorplate, cross the midline, and turn anteriorly toward the brain. In the zebrafish, the earliest born spinal commissural neuron to navigate the midline and turn rostrally is termed CoPA (**C**ommissural **P**rimary **A**scending). We show an evolutionarily conserved role for planar cell polarity (PCP) components as essential for the anterior turning of CoPA axons in the zebrafish spinal cord. Specifically, we show that CoPA axons make randomized turns in *fzd3a* and *vangl2* mutants, with half of CoPA axons executing the correct rostral turn and the other half projecting posteriorly inappropriately. All other guidance decisions along the dorsal-ventral axis are unaltered in PCP mutants. We extend these findings to reveal a role for additional PCP components, *celsr3*, *scribble* (*scrib,*) and *protein tyrosine kinase 7 (ptk7),* in the anterior guidance of commissural axons. Specifically, we find randomized A-P guidance of CoPA axons in *celsr3* morphants, zygotic *scrib* mutants and maternal-zygotic *ptk7* mutants. We observe CoPA axons extend for long distances even after turning the wrong direction in PCP mutants, suggesting that PCP proteins are not required for axon growth *per se,* but appear to establish a "compass" within the growth cone from which directional pathfinding can be executed. Finally, we show that c-jun-N-terminal kinase (JNK) is an effector of PCP signaling in axon guidance. Embryos treated with the JNK inhibitor, SP600125, from 16-24 hpf, display a similar defect in A-P guidance of CoPA axons as seen in PCP mutants. Taken together, our data establish CoPA commissural axons as a model system to elucidate how planar cell polarity controls axon guidance decisions along the anterior-posterior axis. .

Z6248B A genomic approach to investigate the interactions between somatosensory neurons and skin. *Fang Wang*[1], Shawn Cokus[2], Maricruz De La Torre[1], Stacy Nguyen[1], Jueun Kim[1], Alvaro Sagasti[2]. 1) California State University, Dominguez Hills, Carson, CA; 2) University of California, Los Angeles, CA.

Somatosensory neurons detect mechanical, thermal, and chemical stimuli, which is crucial for animals to sense their environment and respond appropriately. Many studies have suggested that the interactions between somatosensory neurons and skin cells not only play an important role during development but also may be critical for neuron function. Thus, we have undertaken a genomic approach to investigate

the interactions between touch-sensing neurons and skin cells.

Peripheral axons of somatosensory neurons first arborize between the two epithelial layers (periderm and basal cells) that compose larval zebrafish skin, starting at the ~18 somite stage. Electron microscopy has revealed that the free endings of somatosensory axons become ensheathed by basal cells between 54 and 78 hours post fertilization (hpf). To identify genes that may be involved in axon/skin interactions, we examined the gene expression profiles of skin cells in zebrafish at three different stages: 20 hpf, 52 hpf, and 72 hpf. To accomplish this goal, periderm cells, basal cells, and non-skin cells were purified with fluorescent activated cell sorting of krt4:DsRed krt5:GFP transgenic fish that express DsRed in both epithelial layers, but only express GFP in periderm cells. mRNAs isolated from these cells were used for RNA-Seq. This method provides comprehensive and quantitative gene expression data. RNA-Seq was also performed on skin cells in wildtype fish as well as fish lacking somatosensory neurons to gain a genomic view of transcriptional changes in skin cells as they respond to axon innervation.

Currently, we are using molecular and cellular methods to verify the expression pattern of genes that are enriched in a specific skin layer and/or at a specific developmental stage. Loss-of-function studies will be conducted to unveil the functions of these genes.

Z6249C Lineage Tracing of Neuronal Progenitor Cells Expressing *dlx* Genes in the Zebrafish Brain. *H. C. Weinschutz Mendes*, C. M. Solek, S. Feng, E. Mahoney, M. Ekker. Department of Biology, University of Ottawa, Ottawa, ON, CA.

During development, the proper specification and migration of GABAergic interneurons is essential to the establishment of appropriate synaptic connections. Abnormal establishment of these neuronal types are often related to neurological and behavioral disorders. The *Dlx* homeobox gene family and the transcription factors they encode are involved in the proper specification of GABAergic interneurons in vertebrates. In the forebrain, the expression patterns of the *dlx1a/dlx2a* and of the *dlx5a/dlx6a* bigene clusters presents extensive overlaps and the functional specificity of the four *dlx* paralogs still remains elusive. The purpose of this research is to trace the lineage of *dlx*-expressing cells in the zebrafish brain, from early development to adulthood, and to compare the fate of cells expressing genes from the *dlx1a/dlx2a* and *dlx5a/dlx6a* clusters. We have produced a transgenic line that express the $CreER^{T2}$ recombinase under the control of *dlx1a/2a* or *dlx5a/6a* regulatory sequences and bred them with zebrafish that express a floxed GFP gene followed by the mCherry gene under the control of an ubiquitin promoter. These double transgenic lines allow us to permanently label *dlx*-expressing cells by introducing tamoxifen in the embryo medium and to observe the tracing of these cells on a time-related manner at different time points during early stages of development. We followed the migration and differentiation of these cells throughout the life of the zebrafish. Our findings indicate that, as predicted, the majority of labeled cells give rise to GABAergic neurons, although a small number of cells in the ventral telencephalic area are not immunoreactive for GABA or neuronal markers. The *dlx1a/dlx2a*-expressing cells labeled at 24 hours post-fertilization (hpf) seem to give rise to a relatively larger number of mCherry-positive cells when examined in older animals, compared to similar labeling of *dlx5a/dlx6a* fish. Furthermore, the *dlx1a/dlx2a*-labeled cells give a higher proportion of cells that remain close to the neurogenic zones, compared to *dlx5a/dlx6a*-labeled cells. Interestingly, a number of *dlx5a/6a*-expressing cells, labeled at 5 dpf, give rise to a large number of cells that populate the dorsal telencephalon, the periventricular grey zone and the hypothalamus, something that is not seen with *dlx1a/2a*-labeled cells nor when induction of *dx5a/6a*-driven Cre is performed earlier. This lineage tracing system can also be used to characterize the development of new GABAergic neurons in adult zebrafish both in conditions of homeostasis and during regeneration following injury. Supported by the Canadian Institutes of Health Research.

Z6250A Zebrafish Models for Parkinson's Disease. *J. Wint*, A. DellaPenna, E. Okoye, H. Sirotkin. Stony Brook University, Stony Brook, NY.

Parkinson's disease is the second most common neurodegenerative disorder. The majority of cases are idiopathic, having no identifiable cause. Approximately 5-10% of cases are due to inherited genetic mutations that provide a gateway to understand the mechanistic causes of this disease. The overt symptoms of Parkinson's disease are movement related and include shaking, rigidity, slowness of movement and difficulty with walking. These symptoms arise due to the death of dopaminergic neurons in the substantia nigra. About 70% of human protein-coding genes have homologs in zebrafish, thus allowing this model organism to provide a platform to fully elucidate and understand the mechanisms of these mutations. We are employing the CRISPR/Cas9 system to develop zebrafish models for the disease by altering zebrafish homologues of genes linked to the disease including LRRK2 (Leucine Rich Repeat Kinase 2) and PARK2. LRRK2 is a large multidomain protein with GTPase and kinase activity. The GTPase regulates kinase activity. We created mutations in the GTPase domain of LRRK2 as well as a single nucleotide change in the kinase domain. The single nucleotide change corresponds to the most commonly reported mutation of LRRK2, G2019S, which enhances the kinase activity of the protein. PARK2 is an E3 ubiquitin ligase and we have created a deletion mutation that is predicted to impair its activity. We are employing behavioral studies to screen through the various mutants and evaluate their locomotor defects. We will also analyze changes to dopaminergic neurons through staining with tyrosine hydroxylase. Zebrafish models would not only empower mechanistic and gene interaction studies, but enable behaviorally based small molecule screens to identify compounds that alleviate Parkinson's related phenotypes.

Z6251B Functional Genomics of Somatosensory Neuron Signaling And Morphology. *Victoria Wright*, Ian Woods. Ithaca College, Ithaca, NY.

The somatosensory system detects mechanical, thermal and chemical stimuli; abnormalities in somatosensory signaling can lead to migraine and chronic pain. Neurons within the somatosensory system are specialized to detect different types of sensory stimuli, via expression of various cell surface receptors, development of diverse branching morphologies, and appropriate targeting to the central nervous system. To uncover the molecular mechanisms that generate these differences, we employed genome-wide transcriptional profiling in purified subpopulations of somatosensory neurons. From our list of differentially-expressed candidate genes, we are focusing on secreted peptides, transmembrane proteins, cytoskeletal regulators, and transcription factors for follow-up studies, as these gene families likely

regulate development, morphogenesis, and function of somatosensory neurons. We are working to confirm enrichment of these genes in sensory neurons via fluorescence expression analyses, and to identify the neuronal subtypes in which these genes are expressed. Potential functions for the most promising candidates are being identified with genetic gain- and loss-of-function approaches. Specifically, neuronal outgrowth and branching morphology are quantified in embryos in which each candidate gene is overexpressed simultaneously with a fluorescent marker, driven by subtype-specific enhancer sequences. These embryos are also tested for changes in sensory responsiveness via high-throughput videotracking analysis. Similarly, CRISPR-generated knockouts will be analyzed for mutant phenotypes using assays of neuronal morphology and behavioral response to sensory stimuli of various modalities..

Z6252C Eyes shut homolog is localized near connecting cilia/transition zone and is required for cone photoreceptor survival in zebrafish. *Miao Yu*, Yu Liu, Jing Li, Brianna Natale, Jeffrey Amack, Huaiyu Hu. Upstate Medical University 750 E. Adams Street Syracuse, NY 13210.

Mutations in the extracellular matrix protein eyes shut homolog (EYS), also known as spacemaker or spam, make up a large number of autosomal recessive cases of retinitis pigmentosa (retinitis pigmentosa 25, RP25). Drosophila EYS protein is located in and required for the formation of the inter-rhabdomeral space. Vertebrate EYS is thought to be located in the analogous extracellular space of the outer segment layer. Because the mouse genome lacks an EYS locus, we have chosen zebrafish to study the roles of EYS in photoreceptor survival. Our results showed that EYS protein was not located at the outer segment layer. EYS immunostaining exhibited a punctate pattern on the basal end of the outer segment reminiscent of connecting cilia/transition zone (CC/TZ). Double immunostaining revealed that EYS protein was located on the basal end of acetylated a-tubulin but apical to g-tubulin, indicating that EYS was localized near CC/TZ. Using CRISPR/Cas9 technology, we generated several zebrafish EYS mutant lines. Although EYS deficiency did not cause any apparent retinal defect up to 40 days post-fertilization (dpf), progressive loss of cones became apparent at 4-, 6-, and 8-months post-fertilization (mpf). Guanine nucleotide binding protein (G protein) alpha transducin activity polypeptide (GNAT) 2 in the mutant retina, as well as the numbers of red-, green-, blue-, and UV-opsin positive cones progressively decreased. TUNEL-positive nuclei were also observed in the outer nuclear layer of cone photoreceptors. Contrary to the cones, rod markers Zpr3 and GNAT1 immunostaining and GNAT1 real-time RT-PCR did not reveal any significant changes in rod photoreceptor survival. Our results indicate that EYS is located near CC/TZ and is required for cone photoreceptor survival in zebrafish.

Z6253A Regulation of neural stem cell division modes in the developing zebrafish brain. *X. Zhao*, R. Choi, Z. Dong, S. Guo. Department of Bioengineering and Therapeutic Science, University of California, San Francisco, San Francisco, CA.

Asymmetric cell division (ACD) is a conserved and fundamental process in neurogenesis for generating cellular diversity across both invertebrates and vertebrates. As the principal neural stem cells (NSCs), radial glia progenitors (RGP) undergo ACD to generate self-renewing and differentiating daughter cells in the developing central nervous system. Until now, the cellular and molecular mechanisms of ACD and subsequent daughter fate choice is not well understood in vertebrates.

By using zebrafish, we have identified that the cortical polarity regulator Partitioning defective protein-3 (Par-3) plays a crucial role in the establishment of ACD through localizing the ubiquitin E3 ligase Mindbomb (Mib), which activates Notch by ubiquitinating the Notch ligand unequally in the apical daughter. Using immunocytochemistry, in vivo imaging, and other molecular genetic and biochemical methods, we are elucidating the nature of Mib asymmetry and the underlying mechanisms that orchestrate such asymmetry.

Z6254B Committed stem cells derived from the somites supply the osteoblasts during adult bone homeostasis and regeneration. *K. Ando*[1], E. Shibata[1], A. Kudo[1], G. Abe[2], K. Kawakami[2], S. Hans[3], M. Brand[3], A. kawakami[1]. 1) Tokyo Institute of Technology, Yokohama, JP; 2) National Institute of Genetics, Mishima, JP; 3) DFG-Center for Regenerative Therapies Dresden, Germany.

Calcified bone is a characteristic feature of vertebrates that is indispensable for maintaining their terrestrial lives. Since the bone matrix needs to be actively renewed and repaired throughout the animal life, a constant supply of osteoblasts is essential. It is thought that the progenitor cells of osteoblast, the osteoprogenitor cells (OPCs), which are derived from the mesenchymal stem cells (MSCs) in the bone marrow in the case of mammals, produce the osteoblasts in post-developmental stages; however, the identity, function and developmental origin of OPCs in adult vertebrates are unclear.

Here, from the analysis of transgenic (Tg) zebrafish of *matrix metalloproteinase 9* (*mmp9*), we identified a stem cell that produces the osteoblasts during adult zebrafish fin regeneration. In the *mmp9* BAC Tg, the EGFP localization was associated with bony tissues, and in particular a strong fluorescence was seen in the joints of adult fin. The Cre-loxP-mediated cell lineage tracing showed that *mmp9*-positive cells migrate from the nearby joints after fin amputation and produce the osteoblasts and new *mmp9*-positive joint cells as well, indicating that *mmp9*-positive cells are the committed stem cells, osteoblast stem cells (OSCs). The genetic ablation of *mmp9*-positive cells by nitroredutase and prodrug exhibited a significant decrease of the number of regenerating osteoblasts and the regenerating bone, indicating that the OSCs indeed play a role in bone regeneration, although they are not an only source of osteoblasts during fin regeneration.

To investigate the developmental origin of OSCs, we conducted the somite transplantation analysis. Donor somites from the *Tg(mmp9:eGFP; beta-actin:DsRed2)*, which ubiquitously expresses DsRed2, not only produced the osteoblasts in the caudal fin, but also gave rise to the *mmp9*-expressing OSCs, indicating that the OSCs were originated from the somites. However, the early OSCs labelled by the Cre-loxP recombination at 4 weeks post fertilization neither produced osteoblasts nor new OSCs in the fin, suggesting that *mmp9*-negative precursors produce the BSCs and osteoblasts during infant stage. On the other hand, at later stages after 3 months, the OSCs at the fin joints gave rise to the fin ray osteoblasts by the homeostatic cell turnover. These observations suggest that the OSCs are a reserved population of stem cells that are dedicated to the homeostasis and regeneration of calcified bones.

Z6255C Melanocyte stem cell dynamics in wound healing. *Christina D. Carnevale*, David M. Parichy. University of Washington, Seattle, WA.

Humans cannot regenerate lost or damaged appendages and organs, with all of their complexity, whereas several ectothermic organisms, such as salamanders and teleost fishes, can. After severe cutaneous injuries resulting from burns or other trauma, humans develop discolored scars due to the failure of melanocytes to regenerate at the pre-wound density; such discoloration of scar tissue can be psychologically debilitating even after the acute injury has healed. By contrast, zebrafish can regenerate their melanocyte complement perfectly, even after full-thickness skin wounds. Here, we use high resolution imaging with photo-convertible fluorophores to document the dynamics of individual melanocyte progenitors as they migrate into the wound and populate regenerative tissue, as well as assess roles for candidate pathways in these events. Understanding melanocyte stem cell behavior in an organism that does not develop discolored scars may suggest novel ways to stimulate pigment regeneration in human patients.

Z6256A Regeneration after zebrafish traumatic brain injury is dependent upon microglia. *J. Y. Chen*[1], K. Skaggs[2], Y. Qadeer[1], D. Goldman[1], J. M. Parent[1]. 1) University of Michigan, Ann Arbor, MI; 2) University of Findlay, Findlay, OH.

Unlike mammals, adult zebrafish are capable of virtually full restoration of damaged brain tissues after injury. This repair is characterized by the lack of glial scar formation and the ability of adult-born neurons to establish long-distance projections to the contralateral hemisphere. The remarkable regenerative capacity of zebrafish allows for exploration of the cell types and molecular pathways necessary for effective regeneration. Brain injury induces a widespread neuroinflammatory response that recruits activated microglia to damaged regions. This is followed by proliferation of telencephalic ventricular zone (VZ) radial glia, whose neural progenitor cell progeny migrate to areas of injury and give rise to new neurons – a process that is complete in roughly 21 days post lesion (dpl). We generated a right telencephalic stab lesion in adult zebrafish using a 30-gauge Hamilton syringe. To determine the role of microglia in the injury response, we ablated these cells by injecting liposomal clodronate at the time of stab lesioning. The loss of microglia after injury was associated with a pronounced decrease in regenerative potential, as clodronate-treated animals displayed persistent tissue damage even at 90 dpl when compared to controls, suggesting that microglial signaling plays a key role in the regenerative process. Using EdU pulse labeling of proliferating cells, we found that peri-injury clodronate-induced microglial ablation significantly reduced proliferation in the parenchyma, but not the VZ. In separate experiments, we performed RNAseq to examine a brain injury model, quinolinic acid (QA)-induced excitotoxic lesioning, with even more robust regeneration than stab wound alone. Comparing injured, with and without QA, and uninjured brains allowed us to identify stab lesion-induced altered expression of many genes, a subset of which were further upregulated in response to QA injury. We have chosen candidates known to be secreted by microglia for further analysis. These findings highlight a microglial-dependent repair mechanism in the zebrafish brain that may provide strategies for promoting mammalian brain repair.

Z6257B A novel role for miR-9 and Argonaute proteins in balancing quiescent and activated neural stem cell states. *M. Coolen*[1], S. Katz[1], D. Cussigh[1], N. Urban[2], I. Blomfield[2], F. Guillemot[2], L. Bally-Cuif[1]. 1) NEUROPSI CNRS, Gif-sur-Yvette, FR; 2) Francis Crick Institute, London, UK.

Adult neurogenesis is the process by which adult neural stem cells (NSCs) produce new neuronal and glial cells throughout an animal life. Over the past two decades, studies in vertebrate animal models have unveiled the crucial importance of this phenomenon for neural tissue homeostasis and proper brain function. Fundamentally, this process is a balance between maintaining a quiescent NSC pool and recruiting them into the neurogenesis cascade. Using the adult zebrafish telencephalon as a model, we aim at deciphering the molecular mechanisms governing this balance. We place special focus on microRNA-9 (miR-9), which we previously showed to control the transition between commitment states in embryonic neural progenitors. Our recent work shows that miR-9 expression in the adult telencephalon is restricted to NSC residing in a quiescent state (qNSCs) and is anchoring them in this state, at least in part through maintaining high levels of active Notch signaling. Moreover miR-9 expression highlights a striking heterogeneity within qNSCs, which we could link to the division history of the cells. Unexpectedly, we also could observe that miR-9 concentrates into the nucleus of qNSCs together with Argonaute proteins, effector proteins of microRNAs. Manipulating the subcellular localization of miR-9/Ago complexes impacts the quiescent vs activated state of NSCs, thus implying that miR-9 is regulating quiescence through a non-canonical nuclear activity. Interestingly, miR-9/Ago nuclear localization is a specificity of adult NSCs, as opposed to embryonic and juvenile NSCs, where we find it exclusively in the cytoplasm; it thus reveals and highlights a marked age-dependent change in NSCs properties and microRNA regulation.

Z6258C Development and Regeneration in the Zebrafish Lateral Line System. *Ivan Cruz*, David Raible. University of Washington, Seattle, WA.

The zebrafish lateral line system is an excellent model system to investigate tissue development, as well as tissue regeneration. The lateral line system is composed of external sensory organs called neuromasts that are located on the head and trunk of the fish. Each neuromast has centrally located mechanosensory hair cells that are surrounded by non-sensory support cells. These hair cells are structurally and functionally similar to the hair cells located within mammalian ears that detect fluid fluctuations caused by sound. However, unlike their mammalian counterparts, zebrafish are able to replace lost hair cells by symmetric divisions of underlying support cells. Our lab has previously shown that adult zebrafish replace hair cells and support cells after multiple ototoxin-induced hair cell deaths. Currently, the mechanism preserving hair cells and support cells during regeneration and development is unknown. Using the Zebrabow transgenic line, we are able to permanently and mosaically label different support cell populations to perform lineage tracing of support cells under different conditions. We observe that neuromasts, initially of a multicolored support cell arrangement, drift towards clonality over an extended period of time. This suggests that neuromasts are maintained by a small long-lived population of progenitor support cells to produce all the support cells in the neuromast.

Z6259A Leukocyte Itga4 Signaling Regulates Heart Regeneration in Zebrafish. *J. Diao*[1], D. Li[2], X. Zhu[1], W. Pan[2], JW Xiong[1]. 1) Institute of Molecular Medicine, Peking University, Beijing, Beijing, CN; 2) Shanghai Institute of Biological Sciences, Shanghai, China.

Different from the human heart, zebrafish are capable of fully regenerating its damaged heart after ventricular resection, cryoinjury or genetic ablation of cardiomyocytes, but the underlying mechanisms are not completely understood. In this study, we report that Itga4, a subunit of integrin heterodimer, is necessary for adult zebrafish heart regeneration. Both mRNA and protein of Itga4 were dynamically expressed during heart regeneration. Homozygous Itga4 mutants showed deficiency in the recruitment of leucocytes and angiogenesis in the injury site, and therefore had severe cardiac fibrosis and compromised myocardial regeneration. Itga4 was found to mainly colocalize with Lcp1-positive and coronin1a-EGFP-positive inflammatory cells, suggesting Itga4 regulates heart regeneration mainly through its function in leucocytes. Taken together, our study has obtained novel insights of Itga4-mediated leukocyte signaling into zebrafish heart regeneration.

Z6260B Defining the Progenitor Population in Adult Zebrafish Jaw Bone Regeneration. *D. Giovannone*, S. Paul, S. Schindler, F. Mariani, G. Crump. University of Southern California, Los Angeles, CA.

Approximately 8 million bone fractures occur annually and 10% of these are delayed and nonunion fractures which fail to heal despite therapeutic intervention. Current therapeutic strategies are severely hindered by the limited supplies of autograft bone and the poor mechanical properties of artificial materials. Zebrafish are masters of regeneration, and I have found that adult zebrafish can rapidly regenerate up to half of its lower jawbone after resection. Craniofacial bone development is highly conserved between zebrafish and humans, and hence understanding large-scale bone regeneration in zebrafish may lead to novel treatments in patients. A unique feature of zebrafish jawbone regeneration is the involvement of an unusual bone-producing chondrocyte population. In this proposal, I aim to identify the progenitor population that generates these ossifying chondrocytes during large-scale bone regeneration, as well as the role of macrophages in stimulating this progenitor population. Utilizing Cre-based transgenic lineage tracing strategies, I will test that a Runx2+/Sp7- population of pre-osteolasts in the periosteum generate the cartilage callus during regeneration. Using a genetic ablation strategy, I will then test that macrophages are required for the earliest events in bone repair, namely the shift of periosteal cells from making bone during homeostasis to making cartilage during repair. Lastly, I propose to utilize a *RUNX2*:GFP transgene to isolate these periosteal cells for deep sequencing of expressed mRNAs, which will help identify macrophage-dependent genes activated in periosteal cells after injury. Together, positive findings will illuminate the role of the immune system in shifting the fate of periosteal cells from bone to cartilage during bone repair, with knowledge gained in the zebrafish model being used in the future to develop new bone repair strategies in patients.

Z6261C Zebrafish fin fold regeneration requires proper control of inflammation via macrophage. *T. Hasegawa*[1], C. Hall[2], P. Crosier[2], A. Kudo[1], A. Kawakami[1]. 1) Tokyo Institute of Technology, Yokohama, Japan; 2) University of Auckland, Auckland, New Zealand.

Elucidation of tissue regeneration mechanism is necessary for the realization of regenerative medicine. Analysis of its mechanism in regenerative animal models such as zebrafish is one of important approaches.

We have adopted the larval fin fold regeneration model and found that the *cloche* (*clo*) mutant, which lacks the hematopoietic and endothelial cells, displays a unique phenotype that apoptosis is induced in the regenerative blastema cells. Our analysis suggested that the blastema cells are normally maintained by a factor from the myeloid cells.

Here, we firstly examined which type of the myeloid cell is crucial for blastema maintenance. Knockdown of macrophage differentiation by the morpholino antisense oligo (MO) against *interferon regulatory factor 8 (irf8)* showed an increase of apoptosis during regeneration. On the other hand, knockdown of neutrophil differentiation by the colony stimulating factor 3 receptor *(gcsfr)* MO didn't effect survival of blastema cells. These results suggested that macrophage may play crucial role in the maintenance of blastema.

Next, we performed a transcriptome analysis and found that *interleukin1b (il1b),* a molecule that plays a central role in inflammatory response, is highly expressed in the *clo* for a prolonged time. Furthermore, treatment with dexamethasone, an anti-inflammatory reagent, or the *il1b* knockdown by MO significantly decreased the apoptosis in the *clo* mutant, suggesting that an excessive and prolonged inflammation is actually a cause for apoptosis in the *clo*.

Together, our study suggests a scenario that the tissue inflammation is properly regulated by a factor from the macrophage during regeneration.

Z6262A Manipulating hair cell regeneration in zebrafish lateral line neuromast. *D. LIU*[1], Y. WU[1], X. MI[1], H. GUO[1], Z. ZHU[1], D. W. Raible[2]. 1) School of Life Sciences, Peking University, Beijing, CN; 2) Department of Biological Structure, University of Washington, Seattle, WA, USA.

Hearing or balance diseases, due to inner ear hair cell (HC) loss, are a global problem. While mammals including humans cannot regenerate hair cells, other vertebrates can restore lost HCs through mitotic division or by direct conversion of precursors. It remains elusive how these two modes of regeneration are regulated and whether both modes share precursors. In this study, we find that HC regeneration in zebrafish posterior lateral line (pLL) neuromasts uses two sequential modes: direct conversion (resulting in new HCs within 24 hours of damage) and mitotic regeneration (occurring 24-72 hours after damage). The relative proportion by which each mode regenerates HCs is amendable. In brief or persistent low Notch activity and high Wnt signaling, direct conversion becomes major regeneration mode. Mitotic HC regeneration is also regulated by low early Notch activity and late Wnt signaling. In homeostatic neuromasts, newly divided, *atoh1a*$^-$ support cells (SCs at G1 phase of mitosis) are competent to respond to direct conversion cues, while a few *atoh1a*$^-$ SCs in early cell cycle (S phase) are ready to proliferate upon damage. In conclusion, the cell cycle states of a few *atoh1a*$^-$ SCs in homeostatic neuromasts determine by which mode they become nascent HCs in damaged neuromasts, and both modes are differentially regulated by Notch and Wnt signaling.

Z6263B Role of Neuropilins in Zebrafish Heart Regeneration. *V. J. Lowe*, C. Pellet-Many, Ian Zachary. University College London, London, GB,.

Background Zebrafish are able to fully regenerate their hearts after injury by resolving the initial scar and replenishing the injury site with functional cardiomyocytes. Transforming growth factor β and platelet-derived growth factor BB are known to be important for zebrafish cardiac regeneration. They are also ligands that trigger intracellular responses *via* receptor complexes including neuropilins (NRPs). NRP1 and NRP2 are co-receptors for vascular endothelial growth factors and other cytokines, essential for developmental angiogenesis and implicated in diverse pathophysiological processes, but little is known of their role following myocardial injury.

Hypothesis Because several NRPs binding partners are involved in zebrafish heart repair, we hypothesised that neuropilins play a role in zebrafish heart regeneration. We used the zebrafish cryoinjury model of myocardial infarction to characterise neuropilin spatio-temporal expression in the regenerating heart.

Results Quantitative PCR shows n*rp1a, nrp1b* and *nrp2a* are significantly upregulated at 1 and 3 days post cryoinjury (dpci), whereas *nrp2b,* the mostly highly expressed isoform in the heart, does not change after cardiac damage. *In situ* hybridisation shows expression of *nrp1a* mRNA localised to the activated epicardium, proximal to the injury. Immunofluorescence imaging also indicated strong upregulation of NRP1 by epicardial cells overlaying the injured region, and expression by the endocardium. Furthermore, epicardial NRP1 expression was demonstrated in epicardial cells *in vitro.* NRP2 is expressed in leucocytes during the initial inflammatory phase following injury and by cardiomyocytes migrating into the injured zone during the regenerative phase.

Conclusions Neuropilin isoforms exhibit marked regional differences in expression following cryoinjury. Our results indicate a novel role for NRP1 in the activation of the epicardium, a region of the heart with an essential role in cardiac regeneration, whereas NRP2 may be more important for inflammation and cardiomyocyte replacement.

Z6264C Unravelling the molecular mechanisms of myocardial de-differentiation during zebrafish heart regeneration. *C. J. Onderisin*[1,2], I. C. Scott[1,2]. 1) The Hospital for Sick Children, Toronto, Ontario, CA; 2) Department of Molecular Genetics, Univ. of Toronto, Toronto, Canada.

Adult mammalian hearts are incapable of regenerating lost cardiomyocytes (CMs) after injury, replacing them instead with akinetic scar tissue that negatively impacts cardiac function. The adult human heart is notorious for its limited regenerative potential; evidence from multiple studies suggests that the CM turnover rate may be as little as 1% or less per year. For this reason, decades of research efforts have focused on stimulating CM proliferation following trauma. To date, delivery of stem and progenitor cells to the injured mammalian myocardium has had limited success in improving cardiac function. A promising alternative approach involves activating endogenous regeneration programs that are conserved through evolutionary history, present in vertebrates such as the zebrafish. The zebrafish heart can fully regenerate following partial resection of the adult cardiac ventricle, or genetic ablation of CMs in adult or embryonic hearts. Virtually all regenerated myocardium derives from pre-existing CMs that sequentially de-differentiate and proliferate. However, a mechanistic understanding of how this process occurs has yet to be described in detail, and specific molecular markers for CMs in the early stages of de-differentiation and cell-cycle re-entry are undefined. Following chemical-genetic ablation of ventricular CMs in embryonic zebrafish hearts, it has previously been demonstrated that atrial CMs de-differentiate and proliferate to re-populate ventricular myocardium (Zhang, R. et al, Nature, 2013). Importantly, a transient population of atrium-derived de-differentiated CMs was identified that had terminated expression of the atrium-specific marker *amhc*, but had not yet adopted a ventricular CM fate, as measured by expression of the ventricle-specific marker *vmhc*. Here I present the embryonic zebrafish heart as a model to study the process of CM de-differentiation in the context of myocardial regeneration. By combining cell lineage tracing techniques with a temporally-sensitive reporter for heart chamber-specific gene expression, I present a strategy for the isolation of de-differentiated CMs for further transcriptional analysis.

Z6265A Hair cell regeneration in the zebrafish lateral line is impared by crude root extracts of *Valeriana officinalis*. *R. E. Rodriguez Morales*, A. Santana, M. Behra. University of Puerto Rico, MSC, PR.

Hair cells (HCs) are sophisticated mechanoreceptors found in sensory tissues of all vertebrate inner ears that transduce sound waves into electrical signals. Mammals, unlike birds and fish cannot regenerate them, making HCs loss the leading cause for hearing impairment in humans. We are interested in finding new agents that can trigger or hamper HC regeneration, but sensory tissues are deeply buried in the skull and therefore hard to reach and manipulate. We took advantage of the fact that HCs are also found in a fish/amphibian mechanosensory organ which is called the lateral line (LL). It is composed of stereotypically and superficially distributed sensory patches, the neuromasts (NMs), which contain HCs surrounded by supporting cells (SCs). Cilia of HCs are directly exposed to and deflected by currents of surrounding waters. HCs of the LL are sensitive to a range of ototoxic drugs (antibiotics, metals…) which are present in the water and can be easily and quite specifically destroyed this way. It was shown that HC destruction will trigger proliferation and differentiation of SCs into new functional HCs in all NMs over the course of 3 days. To ablate HCs, we treated 5 day post fertilization (dpf) larvae with copper and observed HC regeneration during the following 3 day post treatment (dpt) in the presence of crude plant extracts. One of them, *Valeriana officinalis* (Val) crude root extracts did significantly delay HC regeneration. Moreover, several regenerating NMs seemed unstable and starting at 2 dpt they presented apoptotic-like features. This was never observed in animals which had not been copper treated, suggesting that the presence of the extract had no effect on LL development but was specifically affecting its regeneration. Val contains more than 150 active components. One of them is Valeric acid which led to the synthesis of an FDA approved drug, valproic acid (VPA). One of the postulated roles of VPA is to be a potent inhibitor of histone deacetylase (HDAC). VPA and Trichostatin A, another HDAC, were both shown to affect HC regeneration possibly by affecting SCs division and survival. We are currently exploring this tantalizing lead to understand the mode of action by which Val is hampering HC regeneration. Our work shows for the first time that a crude root extract of *Valeriana officinalis* is interfering with HC regeneration.

Z6266B Thyroid hormone coordinates zebrafish pigment cell lineages during post-embryonic development and homeostasis. *Lauren M. Saunders*, Cole Trapnell, David M. Parichy. University of Washington, Seattle, WA.

Global, circulating endocrine factors are important for coordinating differentiation and morphogenesis of numerous stem cell derived lineages during post-embryonic development and later adult homeostasis. One such factor, thyroid hormone (TH), plays a major role in the diversification and maintenance of neural-crest derived pigment cell lineages in zebrafish. Different classes of pigment cells—including black melanophores and yellow xanthophores—have markedly different responses to TH signaling. TH represses melanophore population expansion, and fish lacking TH have twice the normal number of melanophores. By contrast, TH promotes xanthophore differentiation and proliferation. We do not yet understand how this single factor, TH, differentially impacts the differentiation and morphogenesis of these cell lineages. Because TH has potentially hundreds of downstream effectors, we are taking whole-transcriptomic approaches to understand its different roles in these two cell types, including the extent to which TH specifies alternative fates of multipotent progenitors or has cell-type specific effects on morphogenesis and terminal differentiation after fates have been specified. We are also using epigenomic analyses to test whether TH differentially impacts chromatin organization in melanophore and xanthophore lineages. We anticipate that our unusually tractable system will provide novel insights into how a common endocrine signal is translated into alternative cellular outcomes across lineages during the development and maintenance of adult form.

Z6267C The induction of radial glial cell proliferation after stab injury in the optic tectum of adult zebrafish. *Y. Shimizu*, Y. Ueda, T. Ohshima. Dept. of Life Sci. and Med. Bio-Sci. Waseda University, Tokyo, JP.

Adult neurogenesis is a highly conserved phenomenon that neural stem cells (NSCs) produce new neurons, astrocytes or oligodendrocytes in the adult brain. In the adult mammalian brain, neurogenesis is restricted to the subventircular zone (SVZ) and the subgranular zone (SGZ). In contrast, zebrafish have 16 NSCs niches and can continue to produce new neurons through life. In the optic tectum where optic nerves project, radial glial cells (RGCs) located in the deeper layer express several stem cell markers as Sox2 and msi1, and are quiescent, while RGCs in the telencephalon are proliferative and work as NSCs. We confirmed that the number of proliferative RGCs in the optic tectum was fewer than that in telencephalon.

Zebrafish have also great ability to regenerate brain after the traumatic brain injury compared to mammalian. In this study, we established the stab injury of the optic tectum and analyzed the proliferation of RGCs after stab injury. We confirmed that the induction of RGC proliferation after stab injury. Then we analyze the differentiation of RGCs by BrdU labeling for 24 hours and confirmed that the number of HuC, neuronal marker, and BrdU-double positive cells was increased in the injured optic tectum at 1 week post injury compared with those in the intact side.

To analyze molecular mechanisms that control the proliferation of RGCs in response to stab injury, we injected zymsoan A into cerebrospinal fluid using cerebroventircular microinjection and confirmed that the proliferation of RGCs was also induced at 1day post injection. We treated zebrafish with dexamethasone (Dex), anti-inflammatory drug, 2 days before and after stab injury. The proliferation of RGCs in the Dex-treated groups was decreased at 2dpi. These results suggest that inflammatory responses have a key role in the induction of RGC proliferation after the tissue damage in the PGZ. Wnt signaling is well known to regulate stem cell proliferation and differentiation during development and also contributes to the regenerative response after traumatic brain injury. To elucidate contribution of Wnt signaling to the proliferation of RGCs, we analyzed the Wnt reporter zebrafish after the stab injury. We confirmed that the expression of GFP was detected in the BLBP-positive cells after the stab injury in optic tectum. Then we treated injured-zebrafish with the Wnt inhibitor and analyzed the proliferation of RGCs. The number of proliferative RGCs was significantly decreased compared with that of DMSO-treated zebrafish. These results suggested that the up-regulation of Wnt signaling may induce the proliferation of RGCs in response to stab injury.

Z6268A Systemic and local signaling interfaces of zebrafish bone regeneration. *Scott Stewart*[1,4], Benjamin Armstrong[1,2,4], Kryn Stankunas[1,3,4]. 1) Institute of Molecular Biology; 2) Department of Chemistry; 3) Department of Biology; 4) University of Oregon, Eugene, OR.

Zebrafish tissues and organs display exceptionally robust self-repair capabilities. For example, damaged fins are readily restored, which entails perfectly regenerating bony ray structures, each comprising two semi-cylindrical bones that encase mesenchymal cells, nerves, and blood vessels. Bone regeneration in fin rays is mediated by injury-induced progenitor osteoblasts (pObs) that later redifferentiate to produce replacement bone. Two opposing signaling pathways, Wnt/β-catenin and BMP, balance competing demands for pOb renewal and differentiation, respectively, until regeneration is complete. To identify additional factors that directly influence Obs, we performed an in vitro screen using a pOb-like cell line derived from regenerating fins. Unexpectedly, we found that insulin or insulin-like growth factor (IGF), combined with dexamethasone, is sufficient to stimulate Ob differentiation. mTOR signaling is required for insulin/IGF-driven differentiation both in vitro and in regenerating fins. Using a novel O-propargyl-puromycin and click chemistry-based approach, we determined that re-differentiating fin Obs dramatically and specifically upregulate mTOR-dependent protein anabolism. We suggest that during an initial “burst” phase of bone regeneration, locally produced IGF2b stimulates full Ob differentiation. Concomitant with re-vascularization, regenerating bone then enters a “steady-state” phase, when the restored blood supply delivers circulating insulin to sustain Ob maturation. At both phases, we propose bone maturation integrates Ob-autonomous BMP signaling, which maintains a specific differentiated Ob transcriptional program, with insulin/IGF environmental cues that promote sufficient mTOR-dependent protein synthesis to generate a robust bone matrix.

Z6269B The contribution of biliary epithelial cells to hepatocytes in the developing liver with *tomm22* knockdown. *J. Wu*[1,2], T. Choi[1], D. Shin[1]. 1) University of Pittsburgh, Pittsburgh, PA; 2) Tsinghua University School of Medicine, Beijing, China.

The liver has an elegant regenerative capacity. After mild liver injury, hepatocytes proliferate to restore the lost liver mass and

function. However, when hepatocyte proliferation is impaired, which occurs upon severe liver injury or in chronic liver diseases, biliary epithelial cells (BECs) activate and give rise to hepatocytes. The only effective therapy for patients with severe chronic liver diseases is liver transplantation, but the shortage of donor livers necessitates alternative therapies. Studying BEC-driven liver regeneration may provide insights into how to augment innate liver regeneration in the liver patients as the alternative therapy. Here, we presented a new liver regeneration model in which BECs contribute to regenerated hepatocytes upon hepatocyte damage and loss. The hepatocyte damage results from temporary knockdown of the mitochondrial import gene *tomm22* by morpholino antisense oligonucleotides (MO) as reported by Curado et al., 2010. We found that all hepatocytes in *tomm22* MO-injected larvae at 7 days post-fertilization (dpf) weakly expressed *Tp1:*H2B-mCherry, a BEC marker, suggesting BEC origin of these hepatocytes. To unequivocally determine the origin of the regenerated hepatocytes, we permanently labeled BECs with a BEC Cre line, *Tg(Tp1:CreER^{T2}),* and traced their lineage in the MO-injected larvae. Surprisingly, we found maximum 60% of the hepatocytes were derived from BECs, suggesting that both BECs and survived, pre-existing hepatocytes contribute to the regenerated hepatocytes in the MO-injected larvae. In addition, we found that in the MO-injected larvae, survived hepatocytes weakly induced *Tp1:*H2B-mCherry expression, suggesting hepatocyte dedifferentiation. Furthermore, we found that both macrophage ablation and the suppression of Wnt/β-catenin signaling in the MO-injected larvae increased the number of *Tp1:*H2B-mCherry-negative hepatocytes and concomitantly decreased the number of *Tp1:*H2B-mCherry-positive hepatocytes at 7 dpf. This new liver regeneration model will help one better understand the mechanisms of liver regeneration upon hepatocyte damage and loss.

Z6270C miRNAs function to limit vascular development flexibility. *S. Nicoli*. Yale Cardiovascular Research Center, New Haven, CT.

miRNAs confer genetic robustness by precisely regulating protein expression. Studies in invertebrate models support that miRNA regulation of developmental gene networks provides phenotypic reproducibility under genetic or environmental perturbations. Whether miRNAs ensure uniform phenotypes in vertebrate development is unclear, as most mammalian miRNA gene knockouts do not have embryonic defects. Using a multifaceted, single-cell resolution screen of zebrafish embryonic blood vessels, we found that TALEN and CRISPR/Cas9 mutagenesis of single and multi-gene endothelial-expressed miRNA families significantly altered natural phenotypic variation of vascular cells. Genome-wide analysis of endothelial miRNA target genes revealed that each miRNA functions in distinct specification and morphogenesis signaling networks. Upon pharmacological network perturbation, the vascular system becomes further sensitized to aberrant malformations with progressive loss of miRNA gene copies. Our data establish that miRNAs act individually or in concert with other members in the phylogenetic family to faithfully reproduce tissue architecture complexity and to stabilize specific phenotypes in the face of variable perturbations. These discoveries demystify the cryptic function of miRNA-gene regulation in vertebrate development, and establishes it as a pivotal mechanism in defining an individual's phenome and disease susceptibility.

Z6271A Syndecan4 facilitates FGF signaling in trailing cells and cell migration in the zebrafish lateral line primordium. *C. M. Fox*[1,2], A. B. Chitnis[1]. 1) NICHD, Bethesda, MD; 2) Johns Hopkins University, Baltimore, MD.

The posterior lateral line (PLL), a sensory system that zebrafish use to sense water movement, is an extraordinarily tractable system in which to study cell migration and pattern formation. The posterior lateral line primordium (PLLP) spearheads the early development of this system, migrating from the ear to the tail, depositing rosettes of cells that will develop into mechanosensory neuromasts. Two signaling systems work in concert to achieve this pattern in the PLLP: Wnt signaling maintains a population of mesenchymal cells in the leading domain and fibroblast growth factor (FGF) signaling organizes cells into protoneuromasts in the trailing domain. Heparan sulfate proteoglycans (HSPGs), found in the extracellular matrix and on the cell surface, are known to regulate both Wnt and FGF signaling in a variety of developmental processes. Several core proteins for HSPGs are expressed within the PLLP and have been shown to be generally important for FGF signaling during PLLP migration. We show that the HSPG syndecan4 (SDC4) is expressed in the most trailing cells of the PLLP, where FGF signaling depends on a diminishing supply of FGF ligand. Knockdown of *sdc4* interferes with protoneuromast formation, slows migration speed, and weakens FGF signaling output. Likewise, in *sdc4* mutants with compromised FGF signaling, we observe slower migration. Overexpression of *sdc4* induces dorsalization, a common effect of ectopic FGF signaling. Together, these results show that SDC4 maintains FGF signaling in the trailing cells of the PLLP, facilitating protoneuromast development and collective cell migration.

Z6272B The Sec14-like Phosphatidylinositol Transfer Proteins Act as GTPase Proteins to Mediate Wnt/Ca^{2+} Signaling. *S. Jia*, B. Gong, W. Shen, W. Xiao, Y. Meng, A. Meng. Tsinghua University, Beijing, CN.

The non-canonical Wnt/Ca^{2+} signaling pathway plays important roles in embryonic development, tissue formation and diseases. However, it is unclear how the Wnt ligand-stimulated, G protein-coupled receptor Frizzled activates Phospholipases for calcium release. We report that the zebrafish/human phosphatidylinositol transfer protein Sec14l3/SEC14L2 act as GTPase proteins to transduce Wnt signals from Frizzled to phospholipase C (PLC). Depletion of Sec14l3 attenuates Wnt/Ca^{2+} responsive activity and causes convergent and extension (CE) defects in zebrafish embryos. Mechanistically, Sec14l3-GDP forms complex with Frizzled and Dishevelled; Wnt ligand binding of Frizzled activates Sec14l3 on the plasma membrane and the resulted Sec14l3-GTP binds to and activates phospholipase Cδ4a (Plcδ4a); Subsequently, Plcδ4a tethers and cleaves phosphatidylinositol-4,5-bisphosphate (PIP_2) into diacylglycerol (DAG) and inositol 1,4,5-triphosphate ($InsP_3$), ultimately stimulating calcium release. Furthermore, Plcδ4a can act as a GTPase-activating protein to accelerate the hydrolysis of Sec14l3-bound GTP to GDP. Our data provide a new insight into GTPase protein coupled Wnt/Ca^{2+} signaling transduction.

Z6273C Atrazine Affects Cartilage and Heart Development in Zebrafish (*Danio rerio*). *C. S. Lassiter*, B. S. Walker. Roanoke College, Salem, VA.

Atrazine is a commonly used herbicide that has been implicated as an endocrine disrupting compound. Atrazine's role in cartilage and bone formation has yet to be established. Craniofacial cartilage and bone deformities account for a large number of birth defects in the United States. Zebrafish treated with 1 µM atrazine had gross morphological defects in their cartilage at 5 days post fertilization, while embryos treated with concentrations below 1 µM had cartilage elements with increasingly wide angles, resulting in a shorter, fatter face with increasing atrazine concentration. Further investigations into the heart rate and hatch rate of larvae revealed atrazine leads to increased heart rates and decreased hatch rates in embryonic zebrafish. Future experiments into the effects of atrazine on bone need to be performed in order to gain a better understanding of the overall effects of this chemical.

Z6274A Wdr68 modulates TGFβ interference with BMP signaling for lower jaw patterning. *A. J. Martinez*, T. Whitman, G. Alvarado, R. Shang, M. Yousefelahiye, Y. Yu, A. Pham, B. Wang, E. Alvarado, R. M. Nissen. California State University Los Angeles, Los Angeles, CA.

Birth defects are among the leading causes of infant mortality and contribute substantially to illness and long-term disability. Craniofacial anomalies, excluding cleft lip and palate, occur in 1 out of every 1600 births in the United States. Many craniofacial syndromes are caused by defects in signaling pathways that pattern the cranial neural crest cells (CNCCs) along the dorsal-ventral axis. For example, defects in Bone Morphogenetic Protein (BMP) signaling are associated with cleft lip/palate, auriculocondylar syndrome is caused by impaired Endothelin-1 (Edn1) signaling, and Alagille syndrome is caused by defects in Jagged-Notch signaling. The BMP, Edn1, and Jag1b pathways intersect because BMP signaling is required for ventral edn1 expression that, in turn, restricts jag1b to dorsal CNCC territory. In zebrafish, wdr68 is required for both the ventral Meckel's (M) cartilage and the dorsal Palatoquadrate (PQ). Previously, we identified the wdr68 gene as essential for edn1 expression in the zebrafish. Here we show that wdr68 activity is required between the 17-somites and prim-5 stages through experiments using an inducible Tg(hsp70l:GFP-Wdr68) zebrafish line. This identified developmental window overlaps with the known onset of edn1 expression at the 18-somites stage. Using an RNA rescue assay and in situ hybridization (ISH), we also found that ectopic edn1 mRNA can rescue the expression of the downstream target dlx6a in wdr68 mutants. We similarly examined the expression patterns of jag1b, hey1, and grem2 and found ventrally-expanded expression of these otherwise normally dorsally-restricted genes. Strikingly, we found that the BMP agonist ISL could partially rescue lower jaw formation and edn1 expression in wdr68 mutants. To elucidate the mechanism of action, we generated wdr68 deletions by CRISPR/Cas9 gene targeting in the BMP-responsive mouse C2C12 cell line. However, we found no defects in pSmad1/5 accumulation or BMP reporter induction in wdr68 mutant cells relative to non-target (NT1) controls. The Transforming Growth Factor Beta (TGFβ) signaling pathways are also important for several patterning events during early embryonic development, including proper craniofacial development. Notably, TGFβ can interfere with BMP signaling via Smad3 displacement of Smad4 from pSmad1/5 complexes. We examined this potential mechanism and found that TGFβ interference with BMP signaling was greater in wdr68 mutant cells relative to NT1 controls. To determine whether the interference mechanism might also act in vivo, we treated wdr68 mutant zebrafish embryos with the TGFβ signaling inhibitor SB431542 and found a partial rescue of craniofacial development. Together these data suggest an indirect role for Wdr68 in the BMP-Edn1-Jag1b signaling hierarchy through modulating TGFβ interference with BMP signaling.

E8001A *Tetrahymena* in the classroom: An example of the use of model organisms in K-12 education. *D. Cassidy-Hanley*, T. Clark. Cornell University, Ithaca, NY.

Model organisms can play an important role in K–12 science education. Engaging students in hands-on activities featuring real organisms adds a dimension of interest and excitement that cannot be obtained with other teaching methods, and encourages students to creatively explore scientific ideas and concepts. Here we present a successful educational outreach program that utilizes the resources of the national *Tetrahymena* Stock Center to foster the use of a safe, easy-to-grow protozoan for hands-on inquiry-based educational activities in K-12 classrooms. It is our hope that sharing our approach for supporting educational use of a model organism may provide useful insight and information to others interested in increasing the use of model organisms in K-12 classrooms. ASSET (Advancing Secondary Science Education through Tetrahymena), an NIH SEPA funded program at Cornell University, has worked with teachers and students to develop inquiry-based K-12 biology curricula that feature hands-on manipulation of live *Tetrahymena* cells, and that are ideal for demonstrating many of the basic principles of biology in novel and engaging ways. Teachers and student input during curriculum development insures that the self-contained modules are grade appropriate and user friendly, and rigorous testing and evaluation confirm that the educational content increases student understanding of fundamental biological concepts and knowledge of the scientific method. Grade appropriate cross-curricula activities engaging students in the inter-relatedness of science and society are used to make science more relevant to real life issues and to increase overall student interest in science. A unique independent high school research program is also being developed to provide students, especially at low-resource schools, with the means of carrying out a small independent research project in their classroom. All ASSET modules contain comprehensive teacher guides, detailed student protocols, unit-related questions, and answer keys. Guides to relevant literature are also provided, with links to additional source material available on the website. To support the use of ASSET modules at schools serving minority and low-income students, the basic materials needed to carry out the experimental protocols, including live cells and growth media, are available without charge using an on-line request system. In addition, an equipment lending library provides basic equipment for free short-term loan to under-resourced schools to insure equitable access to ASSET curricula. ASSET offers opportunities for collaborative educational outreach to interested *Tetrahymena* researchers around the country, and provides a model for the integration of model organism stock center resources with K – 12 educational outreach.

E8002B 'Moving' AP Biology forward: Using *Drosophila*-optimized wrMTrck to examine muscle mutants. *Nicole M. Green*[1], Rebecca Steiger[2], David Brooks[1], Erika R. Geisbrecht[1]. 1) Kansas State University, Manhattan, KS; 2) USD 475 Geary County Schools, Junction City, KS.

As scientific technology and techniques advance at an ever-increasing rate, researchers should be mindful to aid in the development of foundational concepts useful to the next generation of researchers. Current techniques are often underrepresented in pre-baccalaureate level programs due to lack of funding, equipment and expertise. However, technological advances in the lab and classroom have extended our ability for collaboration on topics of increasing complexity through guided experimental inquiry. The fusion of engineering solutions and scientific investigation forms the backbone of the Next Generation Science Standards (NGSS) that drives K-12 curriculum. This creates a need for more inventive and technology-inclusive laboratory modules and opens the door to broader impact projects to aid in recruitment of the next generation of researchers. Through our collaboration with the USD 475 Geary County school district, we have integrated our lab's research on muscle development into an inquiry-driven lab in which students use the model *Drosophila melanogaster* to examine the consequences of defective muscle proteins on overall organismal locomotion. Recently our lab has optimized a freely available ImageJ plugin for *C. elegans*, known as wrMTrck, to function as a tool for tracking the path and velocities of *Drosophila* L3 larvae. Biological structure-function relationships can easily be seen by using a genetic mutant for *thin/abba*, an E3 ubiquitin ligase found in muscle. Loss of proper protein turnover causes progressive degeneration of L3 somatic musculature and resulting locomotory handicaps. This laboratory module exposes students to the power of *Drosophila* for screening genes involved in muscle development and maintenance, as well as how to conduct and creatively analyze mutant phenotypes. We have adapted phases of experimental design to function in any normal high school lab via the use of iPhone/Android video capture and freely downloadable software installed on either PC or Mac computers. By providing accessible K-12 protocols modified from our own experimental procedures, we can motivate students to think critically, internalize scientific practices, and engage in authentic research experiences prior to their entry into institutes of higher education.

E8003C DNA barcoding: engaging students in molecular biology and bioinformatics through authentic biodiversity research. *E.Bruce. Nash*, David Micklos, Sharon Pepenella, Cristina Fernandez-Marco. Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

Just as the unique pattern of bars in a universal product code (UPC) identifies each consumer product, a "DNA barcode" is a unique pattern of DNA sequence that identifies each living thing. Using tools developed by Cold Spring Harbor Laboratory's DNA Learning Center (DNALC), educators can engage their students in the process of science, using molecular biology, ecology, and bioinformatics to design and answer questions about biodiversity.

The DNALC has a longstanding commitment to simplifying complex biochemical and bioinformatics workflows for use in biology education. Our mitochondrial DNA sequencing service and *BioServers* analysis workflow (http://www.bioservers.org) was the first distributed project to allow students to analyze their own DNA sequences. Over 110,000 student sequences have been uploaded since the program's inception in 1997, and the *BioServers* website has logged 1.6 million user sessions.

As educational lead for *CyVerse* (formerly iPlant Collaborative), NSF's major cyber-infrastructure for life sciences, the DNALC formally moved into the world of biological big data. Since 2010, DNALC staff have introduced *CyVerse* tools to 1,700 researchers and college educators at 2-day workshops conducted around the U.S. Under this project the DNALC also developed *DNA Subway*, an educational interface to bioinformatics workflows – including DNA barcode data analysis. Compementing these bioinformatics tools, the DNALC has also developed streamlined biochemistry and a sample database for student DNA barcoding research.

The letter preceding the number is the community. A, B, C after the number is presentation time.
W – *C. elegans*, C – Ciliates, D – Drosophila, M – Mouse, P – PEQG, Y – Yeast, Z – Zebrafish

Meeting the need for authentic research experiences, students can use the same tools and data as seasoned biologists to: 1) design their own research questions 2) sample organisms and collect metadata; 3) isolate DNA and amplify barcoding regions; 4) submit DNA for sequencing; 4) process and analyze sequences; and 5) use sequences to study phylogenetics, diversity, and evolution. Students use simple, affordable DNA isolation protocols and the DNALC's online analysis tools as they discover novel barcodes and track biodiversity - results that they can enter into the project database and publish. These scalable hands-on experiments and participation in a global biodiversity initiative immerse students in the process of science, providing relevance and ownership that enhance learning and attitudes towards science.

The poster will summarize the DNALC's efforts to introduce student DNA barcoding to diverse students, the results of these student efforts, and the effect on student learning and attitudes toward science and science careers.

E8004A SMART research collaborations to foster K-12 STEM development. *M. A. Pickart*[1], D. LaFlamme[2], X. Xing[1]. 1) Concordia University Wisconsin, Mequon, WI; 2) Saint Dominic Catholic School, Brookfield, WI.

Fostering STEM education and career paths remain a national priority. Despite the acknowledged importance of mentorship and support networks for student professional development, STEM enriching activities often do not foster lasting relationships with science professionals nor provide needed opportunities for youth to participate in professional science meetings, publications, and other activities. This is true for all educational levels, but is particularly challenging for elementary and middle schools where the complexity of language and concepts may hinder communication and learning when young students work together with science professionals. To meet these challenges, this work has centered on creating a continuum of STEM educational experiences through authentic, life science focused collaborative research for teams of students, teachers, and science professionals. The Milwaukee School of Engineering SMART (students modeling a research topic) Team Program that facilitates student abstraction of complex chemical concepts needed to understand structure function relationships of proteins by creating 3D printed models has been used for the basis of developing collaborative research teams. With an emphasis on building both relationships and models, the SMART Program provides the unique focus on scientific communication and process necessary for team development. Subsequently, teams have worked together to address specific research questions aimed at validating and extending scientific knowledge through experimentation in zebrafish. Over the past few years, proteins investigated include Collagen 8a1, T (Brachyury), and Factor X. Importantly, students have been welcomed into professional zebrafish conferences such as ZDM8, Boston, 2015 to present their findings and participate in a professional science meeting. In summary, this overall approach provides a unique way of addressing dual needs for both STEM education and scientific advancement in a fun, engaging, and meaningful way while fostering professional development for all involved.

E8005B Disruption of Sortilin-related receptor (sorl1) gene causes severe malformations, apoptosis and stunted structure in newly TALEN Knockout zebrafish *Danio rerio* model: Construction and molecular characterization. *T. Saleh*[1,2], J. Lee[1], S. Chang[1], H. Oh[1], K. Kim[1], T. Sakuma[3], T. Yamamoto[3], J. Park[1]. 1) Seoul National University, Seoul, Korea; 2) Suez Canal University, Egypt; 3) Hiroshima University, Japan.

Tamer Said Abdelkader[1,2], Ji-Min Lee[1], Seo-Na Chang[1], Hanseul Oh[1], Kyung-Sul Kim[1], Tetsushi Sakuma[3], Takashi Yamamoto[3], and Jae-Hak Park[1]*

Laboratory Animal Medicine, College of Veterinary Medicine, Seoul National University, Seoul, South Korea.

Department of aquatic organisms, College of Environmental Agricultural Sciences, Suez Canal University, Egypt.

Department of Mathematical and Life Sciences, Graduate School of Science, Hiroshima University, Japan

The sorl1 gene is a neuronal apolipoprotein E receptor predominantly expressed in the central nervous system. It is genetically associated with Alzheimer's disease (AD) as a switch in the Amyloid precursor protein (APP) processing pathway. Significant reduction in the gene expression has been found in brain tissue of AD patients. TALEN plasmids were constructed using the Platinum Gate TALEN Kit. Sets of plasmids designed to disrupt the first exon of zebrafish sorl1 gene. DSB-inducing activities of constructed TALEN plasmids were evaluated using a human cell-based reporter assay. Synthesized TALEN mRNAs were injected into cytoplasm of 1-cell stage embryos 1nl containing about 100-300 ng/ul mRNAs. Microinjected eggs were maintained in E3 medium at 28ºC for further analysis. Targeted genomic loci were amplified using primers designed to anneal approximately 150–200 base pairs upstream and downstream from the expected cut site. The test analysis showed high activity of generated TALEN plasmids than positive control ZFN. The fold change of sorl1_A TALENs with sorl1_A reporter recorded value was about 4 times. Analysis of genomic DNA extracted from TALEN microinjected embryos demonstrated three mutations in the spacer sequence; alteration of Cytosine nucleotide (C) to Guanine nucleotide (G) and addition of two thymine nucleotides (T) bases on different locations. Abnormalities like bent tail, stunted structure, cardiac edema, and apoptotic cells were found in defected individuals. We therefore conclude that disruption of first exon of sorl1 gene by TALENs mRNAs causes severe malformation suggesting after reduction of App function.

Keywords: TALEN, Sorl1, knock-out, zebrafish, *Danio rerio.*

E8006C *Drosophila* cancer model used to introduce research to freshman biology majors. *J. Ahlander*. Northeastern State University, Tahlequah, OK.

Model organisms are an excellent way to introduce students to research. The purpose of this work was to use a *Drosophila* cancer model in a freshman biology majors laboratory course as the experimental foundation for learning scientific thinking and research methodology. The *eyeful* cancer model exhibits an eye tumor phenotype caused by hyperactivation of the Notch and Akt signaling pathways. In a classroom laboratory, I used the *eyeful* cancer model to help students to study the relationship between genetics and the environment on the *eyeful* tumor phenotype. We discovered that altering the nutrient density of the fly food affected the proportion of flies exhibiting the tumor phenotype, where caloric density positively correlated with tumor formation. I modified this experiment for use in a freshman majors biology lab using a simple low versus high calorie food comparison. Within a 2-hour laboratory period, freshman students were asked to distinguish

between "normal" and "cancerous" phenotypes of flies raised on either low or high calorie media. Although they had never participated in such research beforehand, most students found a statistically significant difference between the experimental conditions. The students were then allowed to design and carry out their own experiements over subsequent weeks of the semester to determine whether other dietary changes could affect tumor formation in this experimental model. Using this approach, several benefits were gained by both faculty and students. Student motivation to participate in the class was high because of a general interest in diet and cancer, and they were able to test their own hypotheses regarding this relationship. In a short period of time a large number of students were trained in a classroom setting on some of the most critical aspects of biological science education - how to think about, design, and conduct research experiments. Finally, as several of these students continued to participate in independent laboratory research after the semester had finished, this approach can help students to discover early in their education whether research is something they may want to pursue.

E8007A Approaches and assessment of incorporating authentic research experiences into an undergraduate genetics course. *D. P. Aiello*. Austin College, Sherman, TX.

Mentoring of undergraduates by faculty in the research lab is a high impact teaching practice that improves a range of students' disciplinary skills, data acquisition and application skills, and writing and oral presentation skills, among others. These formative experiences can also provide a clarification of purpose for undergraduates with regard to career path. However, faculty are often limited in the number of students they can effectively mentor in a traditional research lab setting, thereby limiting the number of student participants. Incorporating authentic undergraduate research experiences into the teaching laboratory is a high-impact teaching practice that can achieve many similar outcomes as mentored research lab experiences, but provides for a broader engagement of students. Presented here is an approach taken over the last several years to incorporate authentic research experiences into a sophomore-level genetics class at a private liberal arts college. The laboratory combines two distinct, semester-long, research projects, one of student-design and one of instructor-design based on ongoing work in the research lab. The laboratory takes advantage of the relative ease of working with the model organism *Saccharomyces cerevisiae* (budding yeast) to introduce students to the foundational principles of transmission and molecular genetics. Three years of assessment using the Classroom Undergraduate Research Experience (CURE) Survey, developed by David Lapatto at Grinnell College, indicates significant learning gains by students participating in the course. The goals of this presentation are to engage and share ideas with colleagues from other institutions using this pedagogical approach, and to share ideas with others seeking to include authentic research into their own classrooms.

E8008B Promoting leadership development within undergraduate STEM curricula. *D. P. Aiello*, L. F. Barton, S. L. Gould, K. S. McCain, K. E. Reed, J. M. Richardson. Austin College, Sherman, TX.

All thoughtful, scientifically trained people are called to lead at some point in their lives and should be prepared to do so. The STAR Leadership Program is designed to intentionally develop five leadership behaviors (Collaborative Work, Interpersonal Communication, Problem Solving, Foresight and Planning, and Moral Consciousness) amount undergraduate STEM students. The curricular component of the program integrates intentional instruction on leadership theory and activities to promote the development of leadership skills in existing science courses. By having multiple opportunities to learn and practice these skills within different disciplinary contexts, and at different levels of instruction, students are given opportunities to develop their awareness, abilities, and commitment to leading others. Thus far, leadership instruction has been integrated into 25 courses from within biology, chemistry, environmental studies, and physics, ranging from introductory to advanced course levels. Behavior competencies are directly assessed using rubrics that were developed for all five leadership behaviors, derived from the AAC&U VALUE Rubrics, and modified to fit the needs of the STAR Leadership Program.

E8009C An undergraduate laboratory class using CRISPR/Cas9 technology to mutate Drosophila genes. *Richard Cripps*[1], TyAnna Lovato[1], Vanesa Adame[1], Holly Chapapas[1], Marilyn Cisneros[1], Carol Deaton[1], Sophia Diechmann[1], Chauncey Gadek[1], Maria Chechenova[1], Paul Guerin[2]. 1) Department of Biology, Univ New Mexico, Albuquerque, NM; 2) Institute for Social Research, University of New Mexico, Albuquerque, NM.

CRISPR/Cas9 genome editing technology is used in the manipulation of genome sequences and gene expression. Due to the ease and rapidity with which genes can be mutated using CRISPR/Cas9, we sought to determine if a single-semester undergraduate class could be successfully taught, wherein students isolate mutants for specific genes using CRISPR/Cas9. Six students were each assigned a single Drosophila gene, for which no mutants currently exist. Each student designed and created plasmids to encode single guide RNAs that target their selected gene; injected the plasmids into *Cas9*-expressing embryos, in order to delete the selected gene; carried out a two-generation cross to test for germline transmission of a mutated allele and generate a stable stock of the mutant; and characterized the mutant alleles by PCR and sequencing. Three genes out of six were successfully mutated. Pre- and post- survey evaluations of the students in the class revealed that student attitudes towards their research competencies increased, although the changes were not statistically significant. We conclude that it is feasible to develop a laboratory genome editing class, to provide effective laboratory training to undergraduate students, and to generate mutant lines for use by the broader scientific community.

E8010A *Drosophila* and zebrafish in undergraduate teaching laboratories and student-driven independent research projects. *M. Daggett*, H. Babcock. Missouri Western State University, St. Joseph, MO.

Drosophila and zebrafish have been incorporated into undergraduate teaching laboratories and independent research projects at Missouri Western State University. Both of these model organisms are accepted model organisms for the study of embryonic development, genetic based diseases and in toxicology. This poster outlines and presents specific protocols and practical information for how these two model

organisms are used at a predominately undergraduate institution with limited available resources. Examples of recent student projects will be presented, including the use of *Drosophila* in student-driven studies that test the effects of diet on the regulation of metabolism and physiological function.

E8011B Experiments in Inclusive Education. *E. A. De Stasio*, L. Stinson, B. T. De Stasio. Lawrence Univ, Appleton, WI.

We describe here concerted efforts to support and encourage persistence of members of marginalized groups in STEM education at our institution. These efforts include formation of a formal group jointly led by students and two science faculty members in which issues of inclusion, allyship, and instances of discrimination and micro-aggressions are discussed anonymously but openly in a safe space. Anecdotes revealed by students of color in particular were eye-opening for faculty members and have sparked change. For example, did you know that Think-Pair-Share pedagogy can lead to isolation in your classroom unless it is carefully choreographed? Attention to students' experiences led to experimentation with pedagogy and inclusion of topics that support the experiences of marginalized groups in an undergraduate genetics course that will be outlined. Lastly, we describe a version of supplementary instruction for introductory biology, the goals of which are community formation and practice with a variety of study skills, with content drilling as a tertiary goal. Though these experiments are being implemented in a small liberal arts college, the lessons learned should be transferable to other educational settings.

E8012C Teaching Experimental Design through Worm Picking. *N. C. Evans*. Purdue University Calumet, Hammond, IN.

At many primarily undergraduate institutions, research opportunities in biology can be difficult for students to obtain. Yet, due to the nature of science and the careers students will seek, research is an important part of their educational experience. The Experimental Design course at PUC is intended to allow undergraduate students to experience research projects from conception to completion within in the context of a semester long course. This course takes advantage of the short reproductive cycle of *C. elegans* to perform student led experiments focusing on genetic, molecular, and microscopy techniques - but could easily be modified based on the goals, skills, and equipment availability of any institution. The course is broken down into two projects. In the first project each student pair utilizes both forward and reverse genetics to analyze a unique mutant *C. elegans.* During the course of the genetic analysis additional skills are gained including animal husbandry, light and fluorescence microscopy, generation of recombinant DNAs, use of RNAi, DNA sequencing, and qRT-PCR. In the second project, students research, propose, and carry out experiments to test the effect of environmental factors on a physiological process (for example aging). This exposes students to the process of literature searches and design of well controlled experiments. Unlike, the traditional laboratory course, it is anticipated that students may not complete some portions of the project or may not obtain results. Efforts are then made to help students understand why and to design future experiments to address these issues. Furthermore, the layout of the class is ideal for teaching various forms of scientific communication including grant writing, journal article preparation, and oral/poster presentations. Due to the time limitations of this lab intensive course, digital tools can be integrated using a Learning Management System. For example, some course material is delivered via video tutorials, collaborative tools are used to edit and improve student writing, and discussion boards are utilized to promote student communication of ideas and results, and to encourage students to help each other with experimental difficulties.

E8013A Integrating professional development opportunities during graduate education. *Joyce Fernandes*. Miami Univ, Oxford, OH.

National dialogs such as Vision and Change, Future of the Research Enterprise, Engage to Excel, Achieving Systemic Change, have called for changes in instructional approaches that revitalize the learning environment at academic institutions. Supporting faculty development and leadership are key to sustaining pedagogical reform. This poster will present a case for including professional development opportunities for graduate students in a seminar format that allows the integration of research/teaching responsibilities. Such an approach, with a focus on improving educator skills can benefit graduate students irrespective of whether they enter academic or non-academic career paths. A Graduate seminar on "Trends in Undergraduate Biology Education" was offered for a 15-week period. The structure of this seminar and the outcomes will be presented. All studnets participatd in a survey at the end of the semester. With a focus on retention in Introductory Biology courses, students read and discussed at least 12 papers in the field. $1/5^{th}$ of the seminar time was used to engage students in an ongoing intervention to measure the impacts of a supplemental course on the success of undergraduates in an introductory biology class. The graduate students participated in data collection, which involved a quantitative analysis of assignments [concept maps and outlines], and a discussion of the rationale for the particular approach. 17/18 students enrolled in the seminar wished to teach at a 2- or 4-year primarily undergraduate institution; 18/18 indicated (1) the lack of adequate training to prepare them as TAs (2) the need for getting formative feedback about their output as TAs, and (3) to provide opportunities beyond the usual TA experiences to develop their skills not only in teaching but also in communicating the essence of the topic being taught. These and additional data from the survey will be presented such as preparation of TAs, how they develop thier teaching style, and what they found most useful by attemnding hte seminar.

E8014B Microscopic image analysis of zebrafish pigmentation in an undergraduate cell biology laboratory. *A. M. Henle*. Carthage College, Kenosha, WI.

I developed a new zebrafish laboratory module to introduce undergraduate cell biology students to animal handling, microscopic image acquisition, and analysis. This laboratory module addresses several of the core competencies outlined by the Partnership in Undergraduate Life Science Education *Vision and Change in Undergraduate Biology Education*, including integration of quantitative reasoning, the process of science, and modeling and simulation. Students work with two or more strains of zebrafish to compare pigmentation in the caudal fin. Adult zebrafish are anesthetized and the caudal fin is amputated. Melanophores, which are the melanin-containing pigmented skin cells, are then imaged in the caudal fin via microscopy. Students analyze their acquired images on the computer using the freeware FIJI (Fiji Is Just ImageJ,

NIH) to calculate the area of pigment dispersal (an estimate of cell size) and total pigmentation in the caudal fin. These measurements are compiled as class data and are compared across multiple lines of zebrafish to allow students the opportunity to work with authentic datasets. Students in this lab are excited to work with zebrafish and gain a deeper understanding of model organism research. This lab module is ideal for the undergraduate setting in that it provides students with an opportunity to design and perform a novel experiment, it uses limited resources, can be completed in as few as two lab sessions, and can be performed with many lines of zebrafish.

E8015C STEAM (Science Technology Engineering Arts and Math) approaches in the undergraduate classroom. *M. Kaplow*. New York Univesity, New York, NY.

New pedagogical approaches have recently emerged in higher education to make scientific learning more active and engaging in the classroom. While the curriculum of many colleges have started to use active learning techniques such as case study analysis, analysis of scientific literature, the emergence of STEAM, a method for integrating creativity and the arts with STEM fields is largely absent in the classrooms of undergraduate education. STEAM was initially developed at the Rhode Island School of Design as a way to foster collaboration between artists and engineers. The purpose of STEAM was to solve engineering problems through the creative approaches of design. While STEAM teaching practices have primarily flourished and have been utilized in elementary school education, STEAM remains to be explored in the undergraduate classroom. The following study investigates utilizing STEAM pedagogy in undergraduate upper elective science courses. Results show that students majoring in both biology and neuroscience are unfamiliar with combining creative arts with scientific ideas and concepts. While many students are familiar with reading and analyzing scientific papers most have never integrated art in STEM classrooms. Student assessments revealed students general reluctance to use “drawings” “schematics’’ during classroom assignments. Students were only willing to use creative arts approach to questions that were more challenging to answer. Results analyze the relationship between STEAM teaching techniques and student learning outcomes. The ongoing study proposes methods on improving student learning through STEAM techniques. The study also outlines approaches that make STEAM more accessible to undergraduate students in higher education.

E8016A Yeast orphan gene project: Finding a place for ORFans to GO. *J. B. Keeney*[1], E. Strome[2]. 1) Juniata College, Huntingdon, PA; 2) Northern Kentucky University, Highland Heights, KY.

When the genomic sequence of the model eukaryote *Saccharomyces cerevisiae* was completed in 1996, the expectation was that an understanding of the integrated functioning of the collection of genes in this single-celled eukaryote would shortly follow. Despite almost 20 years of intense collaborative effort among yeast researchers, nearly 10% of open reading frames (ORFs) are considered uncharacterized. Determining the function of these orphan genes (ORFans) will require mining the current yeast genomic data, compiled in the *Saccharomyces* genome database (SGD), to most effectively design ORF-specific experiments in cell and molecular biology, and comparative genomics. A network of yeast researchers/educators with a focus on teaching experimental design could help overcome the challenges and absorb the risks of researching individual ORFans. The goal of the proposed Yeast Orphan Gene Project is to organize a consortium of undergraduate researchers and faculty at primarily undergraduate institutions (PUIs) to coordinate resources and design strategies to assign molecular functions to *S. cerevisiae* ORFans. Ultimately, the yeast orphan gene project aims to use the process of determining orphan gene function as a tool to teach undergraduate students key concepts in bioinformatics, genomics, molecular biology, and genetics and impart valuable experience in scientific collaboration and leadership. Based on analysis of SGD information, students will design and execute ORF specific experiments for defining gene function. The network will facilitate collaboration between students at different institutions so that students can share strategies and technique solutions while developing experience in on-line collaborations. These skills, including the ability to (1) apply the process of science, (2) use modeling and simulation, and (3) communicate and collaborate, are core competencies in “Vision and Change”. The proposed network will prepare undergraduates for careers in STEM, provide tools for faculty at PUIs to expand research experience for undergraduates, and incorporate research experiences into undergraduate courses. It will also be a mechanism to distribute a tested model of an authentic course-based research experience to a diverse set of institutions by providing workshop and assessment support. The networking activities will expand the expertise of faculty, as well as provide undergraduates tools and resources for collaboration. Defining the function of yeast ORFans will advance the goal of the yeast community to determine the function of the entire set of annotated yeast ORFs.

E8017B The Genomics Education Partnership: Assessment of Key Elements of a Course-based Undergraduate Research Experience (CURE). *Judith Leatherman*[1], Anna Allen[2], Justin DiAngelo[3], M. Logan Johnson[4], Chris Jones[5], Lisa Kadlec[6], Hemlata Mistry[7], Alexis Nagengast[7], Don Paetkau[8], Susan Parrish[9], Laura Reed[10], Cleo Rolle[11], Jamie Sanford[12], Ken Saville[13], Chiyedza Small[14], Joyce Stamm[15], Matthew Wawersik[16], Leming Zhou[17], David Lopatto[18], Sarah Elgin[19], The Genomics Education Partnership. 1) University of Northern Colorado; 2) Howard University; 3) Penn State Berks; 4) Notre Dame College; 5) Moravian College; 6) Wilkes University; 7) Widener University; 8) St. Mary's College-IN; 9) McDaniel College; 10) University of Alabama Tuskegee; 11) Capital Community College; 12) Ohio Northern University; 13) Albion College; 14) Medgar Evers College-CUNY; 15) University of Evansville; 16) College of William & Mary; 17) University of Pittsburgh; 18) Grinnell College; 19) Washington University, St. Louis.

The Genomics Education Partnership (GEP) is a consortium of faculty members from over 100 colleges and universities who are involving students in classroom-based undergraduate research experiences (CUREs) in bioinformatics. Our project uses comparative genomics to study the unusual properties of the *Drosophila* Muller F element (dot chromosome). Students participate in two research areas: sequence improvement and gene annotation, working from recently sequenced *Drosophila* species. Student results are reconciled and pooled for final analysis; our recent paper in *G3* had 940 undergraduate co-authors (Leung *et al.* 2015 *G3* 5(5): 719-40). Our previous educational research

shows that students who participate in this project show attitude and knowledge assessment gains, irrespective of the type of institution or the implementation strategy used by the faculty member (ranging from short lab modules to stand-alone research courses and independent research projects). However, the level of student gains is strongly correlated with the amount of time spent on the project. GEP faculty members report that implementation of this research-based curriculum is strongly facilitated by core computational and pedagogical support from the Washington University team, and that a shared curriculum and organizational structure can mitigate issues caused by varying campus-level support. Our current educational research focuses on two questions: first, how active pedagogical strategies impact student learning gains, and second, how reminding students that they are performing original research impacts students' attitudes toward science. We are also developing new curriculum to make the GEP project more accessible to beginning students, including those at community colleges. Our consortium continues to recruit new faculty collaborators, particularly those interested in CUREs for first and second year undergraduate students. Supported by HHMI grant #52007051, NSF grant #1431407, and Washington University in St. Louis.

E8018C Open Genetics Lectures (OGL): An Open Source Introductory Genetics Textbook. *J. Locke*, L. Canham, M. K. Kang, M. Harrington, M. Deyholos. Univ Alberta, Edmonton, AB, CA.

Commercial introductory genetics textbooks are expensive for students and often don't cover topics or recent discoveries desired by instructors. At the University of Alberta we have written an open source college/university level introductory genetic textbook titled Open Genetics Lectures (OGL). This text contains ~128,000 words organized into 41 chapters that correspond to lecture sized topics typically covered in an introductory genetics course. Topics include "DNA is the Genetic Material" through to "CRISPR-Cas9 Technology". Each chapter includes many figures and tables that can be used in lectures, and ends with questions about its content. Sample answers are provided. Because it was written under the Creative Commons Copyright (open source), all text, figures, tables, and questions can be used without restrictive copyright concerns. The text chapters can be downloaded as Microsoft Word files or PDF format. Each chapter can be individually deleted or edited, or additional ones can be added to customize the text for any course.

All text, tables, images and questions can be accessed through an archive site:
https://dataverse.library.ualberta.ca/dvn/dv/OpenGeneticsLectures.

E8019A Zebrafish lateral line as an inquiry-based lab model for cell biology. *Jason Meyers*. Colgate University, Hamilton, NY.

As a bridge between a foundations-level survey of biology and upper level electives, we have recently developed a tier of courses that focus more on the process of doing biology rather than being content driven. As part of this tier, we are developing multi-week investigative labs that allow students to take an active role in experimental design, while introducing them to key methods within the field, and focus on iterative student-led exploration rather than obtaining specific expected results. For one of these courses focused at the cellular level, the majority of the laboratory portion utilized the zebrafish lateral line as a model. The zebrafish lateral line is a series of small sensory organs, called neuromasts, along the surface of the fish. These sensory organs are made up of clusters of sensory hair cells, homologous to those in in the inner ear, surrounded by supporting cells. These sensory organs are formed from a migratory primordium that travels along the embryonic fish's body depositing small clusters of cells, with zones of proliferation and differentiation coordinated by well-known signaling cascades including Wnt, FGF, and notch. As the development of the lateral line involves cell migration, cell cycle and proliferation, differentiation and cell cycle exit, cytoskeletal alterations, mesenchymal-to-epithelial transitions, and cell-cell signaling utilizing several different pathways, this system encapsulates many of the broad themes of cell biology. The rapid development, widely available transgenic lines that label key cell types or serve as reporters, and ease of genetic and pharmacological manipulation make it possible for young undergraduate students to easily explore many different aspects of these cells in an inquiry-based fashion. At the end of the term, students developed their own three-week research project building on aspects of their earlier investigations. The structure of the lab exercises and simple variations, examples of student data, and student outcomes will be discussed.

E8020B Using the Yeast Mating Response to Study Genetics and Cell Biology: From the Biology Lab to the Computer Lab and Back. *Michelle A. Mondoux*[1], Lara K. Goudsouzian[2], Patricia Riola[2], Karen Ruggles[2], Pranshu Gupta[2]. 1) College of the Holy Cross, Worcester, MA; 2) DeSales University, Center Valley, PA.

We have developed and implemented a laboratory exercise appropriate for a sophomore or junior-level Biology course. The laboratory reinforces and integrates several topics, including the cell cycle, the effects of checkpoint activation, signal transduction, and the cytoskeleton. Depending on the themes emphasized by the instructor, the laboratory can be adapted for either a Genetics or Cell Biology course.

Students evaluate the growth of *Saccharomyces cerevisiae* cultures of opposite mating types and observe the effects of adding mating pheromone on cell division and cell shape. Growth and morphology are assayed at regular intervals over the course of several hours. By the end of the laboratory, students have become adept at identifying the stages of the yeast cell cycle via their distinct morphologies by performing "bud counts". Students also become practiced in the use of a spectrophotometer to determine the concentration of cells in growth medium. Students can then analyze the data by generating growth curves and plotting changes in morphology over time. Both analyses lead to the demonstration that yeast cells will respond in characteristic ways to mating pheromone, but only in the presence of the opposite-sex mating factor.

This year, we have entered into a collaboration with a Computer Science seminar course on campus. The students in this course have been assigned the task of creating supporting materials for the yeast mating labs, with the Cell Biology professor as the group's formal "client". In accordance with the client's requests, the students are generating simulations of the laboratory, appropriate for use by those who take Cell

Biology lecture without enrolling in the laboratory. The Computer Science students have also been asked to generate games (both two-dimensional and three-dimensional) to accompany the laboratory, to reinforce the learning outcomes of the experiment as well as increase interest and engagement of the students.

Our preliminary assessment of this novel hybrid laboratory measures how the laboratory and the computer games and simulations, both individually and in conjunction, influence student learning outcomes and student attitudes and engagement in Cell Biology.

E8021C A Simple HPC Workflow for RNA-Seq in the Classroom. *E.Bruce. Nash*, Spector Mona, Williams Jason, Ghiban Cornel, Lauter Sue, Yang Chun-hua, Micklos David. Cold Spring Harbor Laboratory, Cold Spring Harbor, NY.

RNAseq – an entryway to Undergraduate Big Data Analysis:

A Simple HPC Workflow for RNA-Seq in the Classroom

Nash, E. Bruce, Spector M., Williams, J., Ghiban, C., Lauter, S., Yang, C., and Micklos, D.

In the last decade, "next-generation" sequencing (NGS) methods have decreased DNA sequencing costs by 10,000-fold. This means that undergraduate biology students could potential work with the same data and tools as high-level researchers. Surveys by the Cyverse (formerly *iPlant Collaborative*), an NSF-funded national cyberinfrastructure for biology, reveal that 95% of graduate students and researchers say they are currently, or soon will be, using large sequence datasets. However, two-thirds have little or no experience with bioinformatics and only a third have access to sufficient computational resources needed to analyze these data.

We have created an extensible infrastructure and training program that enables faculty to integrate NGS into undergraduate instruction. Free access to these tools democratizes NGS, allowing faculty at any undergraduate institution to engage their students in cutting-edge biological research.

Many biology faculty are also attempting to scale research projects into course-based undergraduate research experiences (CUREs). To allow NGS CURES, we developed the Green Line of *DNA Subway* (http://www.dnasubway.org) as a user-friendly graphical interface that allows access to compute resources of NSF's Extreme Scientific and Engineering Discovery Environment (XSEDE) to perform computationally intense RNA-Seq analysis through a web browser.

The project focuses on RNA-Seq as a tractable whole genome analysis for those new to NGS. The Green Line supports analysis of transcriptomes to measure gene expression or novel transcripts.. Collaborating with a faculty Working Group, we developed week-long workshops to introduce RNA-Seq to faculty. These workshops are now being adapted into online training materials.

Details of the program, online tools, and the results and effects of implementation in CURES and independant student research will be presented.

E8022A No lectures here: How an active and problem-based learning classroom in genomics transformed the confidence, creativity and communication skills of all students. *A. R. Skop*, S. Neumann, B. Minkoff. Univ Wisconsin-Madison, Madison, WI.

Effective use of active learning techniques remains a challenge in STEM disciplines. We will present our success with Genetics 564, a 100% active learning-based undergraduate capstone course on Genomics and Bioinformatics. Genetics 564 is devoid of 'traditional' lecture-based teaching. Students learn about bioinformatic techniques through the reading and presentation of primary literature, and apply this knowledge to their research project as they analyze a human disease gene. The culmination of students' research is the writing of a set of specific aims and the publication of a website detailing their results. Students also engage in an iterative process of peer review throughout the semester. This course uses active learning to provide students with presentation, research, and peer review experiences similar to those used by scientists. In Genetics 564, we have observed that, with direction, undergraduate students can utilize both primary literature and bioinformatic databases to design experiments and test hypotheses. Additionally, students constantly peer- and self-review their presentations and scientific writing, a second layer of active learning that challenges them to not only produce high-quality research but also to critique their work, an important aspect of a truly active classroom. Tasks such as these are usually reserved for graduate level students and higher. The success of the students in our course has demonstrated its utility for teaching students scientific presentation, writing, research, and review skills, and student responses to the course have been overwhelmingly positive. Altogether, this suggests that the active and project-based learning we have employed contributes to both students' success and motivation within our course setting. Given this, we propose that multiple courses across disciplines would benefit from incorporating aspects of the Genetics 564 structure into their undergraduate classroom. All course materials are freely available on the Genetics 564 website (http://genetics564.weebly.com), where one can also find an archive of past student final projects.

E8023B A Multi-Course Inquiry-based Science Laboratory Module Approach Integrates Research and Teaching through functional annotation of the *Tetrahymena thermophila* geneome. *J. J. Smith*. Missouri State University, Springfield, MO.

In 2006 the ciliated protozoan *Tetrahymena thermophila* genome was sequenced and predicted gene annotation has been completed. *Tetrahymena* is a unicellular model organism that has been used for molecular and cellular biological discoveries such as telomeres, histone modifications, and catalytic RNA. Now experimental research must be done to further functionally annotate the *Tetrahymena* genome, which will increase the usefulness of this model organism for many areas of study. In order to further annotate the genome of *Tetrahymena* and start functional and proteomic annotation of this organism we have taken on a multi-course inquiry-based approach to class laboratories in cell and molecular biology curriculum at Missouri State University. In this approach the predicted *Tetrahymena* genes are cloned into entry plasmids in an introductory level biomedical science lab (performed by Missouri Sate University honors students). The cloned genes can then be used in upper division molecular biology classroom labs in order to characterize the expression, localization, and protein interactions. Students in all classes conduct bioinformatics and gene expression experiments in order to

further characterize and confirm the annotation of the predicted genes. Through this multi-classroom inquiry-based laboratory approach students learn the basic techniques required for laboratory research in science as well as aid in the further genomic and proteomic annotation of the *Tetrahymena thermophila* genome. The students classroom laboratory experience culminates in the submission of their results for publication on the Student/UnPublished Results database (SUPRdb) website (http://ciliate.org/suprdb/; for student classroom research data). This allows any scientific researcher in the field to see what genes have been studied and the most current results and resources for each gene.

E8024C Research/education partnerships to develop course-based undergraduate research experiences. *R. M. Spell*[1], P. Hanson[2], M. E. Miller[3], C. W. Beck[1]. 1) Emory University, Atlanta, GA; 2) Birmingham-Southern College, Birmingham, AL; 3) Rhodes College, Memphis, TN.

Partnerships between research and education provide a powerful resource in the creation of course-based undergraduate research experiences (CUREs) for students. A national faculty survey about authentic research experiences in introductory laboratory courses found: 1) More than half of the intro courses incorporated **little or no** authentic research exposure; 2) **Lack of time** to develop new research experiences was the biggest barrier to implementation of authentic research in laboratory courses (4 out of 4 on the Likert scale); and 3) Faculty definitions of authentic research revealed non-overlapping constructions of course-based authentic research that emphasized either **the process of science** or **novel questions** (**Spell *et al*. 2014**). To bridge the divide between disciplinary researchers and education specialists and between separate emphases on the development of scientists (Process of Science) or the development of science (Novel Questions), our NSF-funded REIL–Biology RCN-UBE has recruited disciplinary researchers as part of institutional teams to develop curriculum for authentic research experiences in introductory laboratory courses. We have held workshops at both education and research-oriented conferences. Our first workshops generated applications from over 30 different institutions including faculty from diverse institutions including community colleges and minority-serving institutions and massive online college systems, in addition to liberal arts colleges and research universities. We discuss this effort in the context of a continuum of strategies to foster faculty and curriculum development and to provide examples for faculty creating their own CURE.

E8025A Research based learning in bioinformatics using yeast experimental evolution. *Laurie Stevison*[1], Molly Burke[2]. 1) Auburn University; 2) Oregon State University.

I recently taught an Introductory Bioinformatics course for advanced undergraduate and graduate students using the text 'Practical Computing for Biologists'. As a new course in an active learning classroom, I designed the course to follow a research study from start to finish to simulate real world challenges of data analysis and dissemination. I searched NCBI for a public dataset using yeast, due to their small genome size, and found an evolve and resequence experiment based on multiple genome sequences. Throughout the semester I corresponded with the first author, Dr. Burke, who provided advice and access to datasets. Early in the semester, students were each assigned an accession of a yeast genome. Then, in concert with teaching genomics and the GATK best practices workflow in class, the students analyzed datasets within research teams to understand the challenges of data analysis. I split the analysis into steps to scaffold the analysis to help the students hone their bioinformatics skills. In class, they learned several bioinformatic tools, and were required to use these tools to assess data quality and submit group reports. The reports reinforced their understanding of the tools and allowed them to see how the data quality improved at each step. While they were required to examine data in multiple ways, they were asked only to report findings relevant to their conclusions. After completing data analysis, I transitioned the class to statistical analysis. For this, I combined their samples into a larger class dataset moving forward. Each group performed a different statistical analysis done in the original paper. The students were introduced to Github earlier in the class, which has built-in educational assessment tools. Although this class is still ongoing, for their statistical analysis, they will make a 'readme' file and upload the associated scripts and graphs to a data repository to teach them that research should be repeatable. Dr. Burke will also be available to students in case they have any questions for the author. Then, they will read the manuscript to compare/contrast their findings to the original study. Since the class only analyzed 5 of 12 replicate populations, this comparison is meant to reinforce the large effort of one scientific paper. After a few lectures on effective science graphics and communication, they will present their work in an auditorium open to the biology department. The final step will be peer assessment where they evaluate each other's presentations and Github pages. While the students were not required to have prerequisites besides genetics, a statistics prerequisite was highly recommended. Future iterations may require some expertise in command line prior to taking the course as proficiency in this area is needed to handle the required workload.

E8026B F.I.R.E. lab: A full immersion research experience in an undergradate laboratory course. *C. L. Van Buskirk*, students of CSUN BIOL447/L. California State University Northridge, Northridge, CA.

CSUN biology majors are eager for opportunities to work closely with faculty members and gain research experience. However, there are not enough spaces in faculty labs to meet this need. The course BIOL447/L: Full Immersion Research Experience (F.I.R.E. lab)[1] helps to bridge that gap, allowing up to 18 students to participate in original, student-directed research. In contrast with many undergraduate lab courses that introduce students to a series of techniques, F.I.R.E. lab instead focuses on introducing students to the full process of scientific inquiry within the confines of a limited set of techniques.

During the first half of the course, students are introduced to a series of research articles that familiarize them with a specialized topic, in this case sleep behavior in *C. elegans*. During this phase of the course they also become familiar with nematode handling, behavioral assays, and RNAi. During the second half of the course, students perform a series of experiments that they have designed to address a unique question, and have the option of working individually or in groups. Prior to starting their projects, students apply for 'funding' by writing a grant proposal that undergoes rounds of peer review and instructor feedback. Student proposals must include an experimental strategy that is amenable to

the twice-per-week class schedule.

In the final weeks of the course, students analyze data, prepare figures, and assemble their work into a poster that they present at a mock conference on the final day of class. Several students go on to present their work at a campus-wide symposium the following semester. Some student projects contribute significantly to peer-reviewed publications[2]. Moreover, positive outcomes from the initial offering of this course contributed to a successful NSF:CAREER award application. This poster presentation is aimed at faculty seeking to better integrate their research and educational activities, and will include examples of student projects, challenges and successes, and assessment tools.

2. Hill, A.J., Mansfield, R., Lopez, J., Raizen, D.M., and C. Van Buskirk. (2014) Cellular Stress Induces a Protective Sleep-like State in *C. elegans*. Curr. Biol. 24; 2399-2405.

E8027C DNA Subway – An Educational Bioinformatics Platform for Genomics and Course-based Research. *J. J. Williams*[1,2], Sheldon McKay[3], Cornel Ghiban[1,2], Uwe Hilger[1,2,4], Mohammed Khalfan[5], Sue Lauter[1,2], David Micklos[1,2], CyVerse. 1) Cold Spring Harbor Laboratory, Cold Spring Harbor, NY; 2) CyVerse, T.W. Keating Bioresearch Building, University of Arizona, Tucson, AZ; 3) Ontario Institute for Cancer Research, MaRS Centre, Toronto, ON, Canada; 4) BIO5 Institute, T.W. Keating Bioresearch Building, University of Arizona, Tucson, AZ; 5) Center for Genomics and Systems Biology, New York University, New York, NY.

DNA Subway is an educational bioinformatics platform developed by CyVerse (formerly iPlant Collaborative - NSF #DBI–0735191). *Subway* bundles research-grade bioinformatics tools, high-performance computing, and databases into web-based, classroom-friendly workflows. "Riding" *DNA Subway* lines, students can predict and annotate genes in up to 150kb of DNA (Red Line), identify homologs in sequenced genomes (Yellow Line), identify species using DNA barcodes and phylogenetic trees (Blue Line), and examine RNA-Seq datasets for differential transcript abundance (Green Line).

The American Association for the Advancement of Science and other research and science policy groups have reached similar conclusions about reforming undergraduate Science, Technology and Engineering, and Math (STEM) education: 1) Focus on the first two years of college education is critical to recruiting and retaining STEM majors. 2) Foster conceptual understanding, higher level thinking, and practice of STEM rather than memorization of terms, facts, and techniques. 3) Adopt inquiry and student-centered approaches that begin with students' own questions. 4) Increase opportunities for interdisciplinary and collaborative work. *Subway* promotes these principles by combining bioinformatics with wet-lab 'hooks,' offering educators a paths to using student-generated data in course-based research experiences (CURES).

Since 2010, *Subway* has supported more than 90,000 student projects, and longitudinal data documents 19,418 student exposures collected from undergraduate faculty trained at CyVerse 'Genomics and Education' and NSF Advanced Technological Education workshops. Student using *Subway's* streamlined tools (e.g. 'Red Line' genome browsers) demonstrate increased confidence when using these tools in the same contexts as researchers (e.g. through online databases such as *UCSC Browser*). At the secondary level, high school students participating in research projects using *Subway* demonstrate comparable level of gains on attitudinal and behavioral measures to the aggregate results of undergraduate students assessed using the Survey of Undergraduate Research Experience (SURE).

Examples from The *Urban Barcode Project* (http://www.urbanbarcodeproject.org) and *RNA-Seq for the Next Generation* project (http://www.rnaseqforthenextgeneration.org) highlight how products of student research can be exported and utilized in follow-up experiments, including direct publication of sequence data to NCBI GenBank. *DNA Subway* is freely accessible at dnasubway.org.

E8028A *CourseSource*: a journal of evidence-based teaching resources for undergraduate biology education. *R. L. Wright*. University of Minnesota, Minneapolis, MN.

Colleges and universities nationwide are changing the ways they teach undergraduate biology courses. These changes reflect a growing understanding and application of evidence-based education practices, including active learning, aligned assessments, and inclusive teaching strategies. Implementation of these evidence-based practices will support recruitment and training the next generation of scientists, and also enable greater gains in scientific literacy among the non-scientists in our biology classes.

This educational transformation is slowed by the time and energy that an educator must devote to learn about evidence-based strategies and to develop teaching materials that implement those strategies. In response to this need, a national convocation (Vision and Change in Undergraduate Biology Education: A Call to Action) recommended creating a peer-reviewed, open access journal of student-centered, evidence-based biology education resources. *CourseSource,* now in its second year, is a response to that recommendation.

Built on collaborations with scientific societies, including the Genetics Society of America, *CourseSource* is an open-access journal of peer-reviewed college biological teaching materials that:

- Incorporate student-centered, evidence-based pedagogy.
- Focus on learning goals and objectives determined by scientific societies.
- Can be easily replicated or adapted for other classrooms.

CourseSource enables authors to publish teaching materials in a high-quality format that documents their scholarly teaching efforts, accomplishments, and innovations. A key feature of *CourseSource* is organization into "courses" with learning goals and objectives developed by the related scientific society. To see the genetics learning framework, go to http://coursesource.org/courses/genetics.

Just 12 months after the journal went live, each article had been downloaded an average of 25 times, suggesting that many readers are finding the articles to be useful. We will describe *CourseSource* publication standards, provide examples, and consult with colleagues about their ideas for *CourseSource* articles.

E8029B Course-Based Undergraduate Research in Molecular Biology. *D. Zies*. University of Mary Washington, Fredericksburg, VA.

The Biology Department at the University of Mary Washington recently revised our curriculum to focus on the research process. In addition to other requirements, Biology majors are now required to complete a two course sequence designed to improve their understanding of how scientific knowledge is acquired. First they take BIOL260, The Research Process, in which they are introduced to scientific method and the statistical analysis of data. Then they enroll in one of several upper level courses designated as research intensive. These courses require that small groups of students carry out a short research project and present their results in a research forum. I redesigned my molecular biology course to meet the new requirement and taught the course in the fall of 2014 and 2015. My course was designed around the use of yeast as a model organism. The lecture material was taken entirely from review articles and primary literature. In the laboratory portion of the course, student groups chose one gene from the lecture topics as the focus of their research project. Early on, students learned molecular techniques that they used later in the semester to characterize the mutant phenotype of their gene and to show normal gene expression under cellular conditions of their choice. Students had to research their gene of interest, write a proposal, design their own set of experiments, carry out the experiments and present their results to the rest of the class. In general, the course design was successful. Student comments from the first offering suggested that they enjoyed the topics and felt real ownership of their research projects. They did, however, struggle with designing and carrying out their projects. It was clear that our students were not well prepared for research and their comments confirmed the need for this type of course in our curriculum. In the second offering of the course, I administered the CURE pre-course and post-course surveys and received a more formal evaluation of the course. These results show that while students made significant gains in several areas of their appreciation for research, there is still room for improvement. In addition to evaluating my own course, my department has begun an evaluation of our two course sequence. We administered the CURE pre-course survey during the first two weeks of BIOL260 in fall 2015 and spring 2016. At the end of this semester, we will collect matched post-course surveys from students that enrolled in a research intensive course this spring. We will continue to collect these data over the next few semesters. Preliminary data from the first students that complete the survey in the two course sequence will be presented.

E8030C Learning how to teach: Using the PALM fellowship to design a student-centered instructional unit for a large-enrollment genetics classroom. *Christopher L. Baker*[1], Michelle K. Smith[2]. 1) The Jackson Laboratory, Bar Harbor, ME, USA; 2) The University of Maine, Orono, ME, USA.

The Promoting Active Learning & Mentoring (PALM) Network, a partnership between several communities including GSA, supports the incorporation of student-centered, evidence-based learning techniques into undergraduate education by partnering PALM fellows with experienced faculty. As founding members of this fellowship, we worked together to design an instructional unit on meiotic recombination and genetic linkage for a large-enrollment undergraduate genetics course. We selected meiotic recombination and linkage to capitalize on the research experience of the fellow in meiotic recombination and the faculty mentor's expertise in genetics education research and access to a large-enrollment class. Furthermore, previous work has shown that undergraduate genetics students struggle to integrate how linkage, recombination, and chromosome dynamics fit together in a unified model for heredity. In addition, the process of recombination is often introduced only as the mechanism for allowing gene mapping, rather than a fundamental biological process required for proper completion of meiosis and a critical driver of evolutionary diversity required for natural selection. Our instructional unit addresses these concepts through clicker questions with peer discussion, chromosome modeling, and in-class small group activities. To assess the impact of this instructional unit we: 1) examined student pre/post performance on the Genetics Concept Assessment, which contains questions about linkage and the arrangement of alleles on chromosomes, 2) used student responses to clicker questions to provide formative assessment feedback, and 3) measured student performance on summative assessments including homework and exams. We also examined instructional practices of the fellow using the Classroom Observation Protocol for Undergraduate STEM (COPUS), which records the behaviors of the instructor and students. Results of these assessments and plans to further improve the learning unit will be presented along with feedback on the effectiveness of the lesson from student surveys.

E8031A An Undergraduate RNAi-Based Genetic Screen Reveals a Novel Component of the Polyamine Transport System. *Michael Haney*[1], Corey Seavey[1], David Brown[1], Cole Washington[1,2], Adam Foley[1,2], Pascale Lubbe[1,2], Melissa Vega[1,2], Michael Dieffenbach[1,2], Connor Michalski[1,2], David Abad[1,2], Fiona Quigley[3], Laurence von Kalm[1]. 1) University of Central Florida, Orlando, FL; 2) Undergraduate Author; 3) High School Author.

Polyamines are small organic molecules required for multiple cellular functions including proliferation, growth, control of chromatin structure and transcription. Cancer cells require an abundance of polyamines through biosynthesis and transport to maintain their proliferative phenotype. An FDA approved drug (DFMO) that targets synthesis is often ineffective because malignant cells circumvent the therapy by up-regulating transport. Thus a combination therapy targeting both synthesis and transport simultaneously is highly desirable. Though synthesis is thoroughly explained, import through a polyamine transport system (PTS) remains undefined. Since polyamine transport is observed in all organisms this represents a major gap in our knowledge of a basic cellular process and hinders the development of effective drugs targeting the PTS.

Utilizing a team of undergraduate students supervised by graduate students, our lab conducted an RNAi-based genetic screen to identify components of the polyamine transport system. Starting with a previously identified gene encoding a family of P-type 5B ATPases we identified 29 genes with similar spatial and temporal expression profiles. These genes were then tested in a novel RNAi-based survival assay developed in our laboratory. As a result of the screen we identify RabX6, which is involved in endosomal transport as a novel component of the PTS.

E8032B Plumbing STEM education: Designing a "Pipeline" CURE for a small teaching-focused college. *K. L. Schmeichel*[1], T. W. Lee[2], C. May[1], D. J. Katz[2]. 1) Oglethorpe University, Atlanta, GA; 2) Emory University, Atlanta, GA.

Course-embedded undergraduate research experiences (CUREs) improve student learning, engagement, and retention in STEM disciplines. However, due to limited research support, undergraduate educators at primarily-teaching institutions are at a disadvantage when implementing such state-of-the-art practices. Nation-wide models provide accessible CURE options that address this disparity, but alternative models that benefit from the intimate faculty-student relationships that exist at teaching-focused colleges are also possible. A collaboration between an investigator at an R1 institution, Emory University, and a nearby teaching-focused college, Oglethorpe University, resulted in the design of a novel "Pipeline" CURE strategy that is a fusion of the apprentice- and cohort-style of undergraduate research and that can be implemented with basic laboratory infrastructure. Because Oglethorpe Biology majors take more than one course with an instructor, the faculty can build concept sophistication over time in a deliberately developmental manner. The "Pipeline" CURE applies the same sensibilities to laboratory work: over the course of four-years, students are incrementally trained through laboratory activities themed around the R1 investigator's laboratory focus: stem cell reprogramming in C. elegans. Students are introduced to nematode husbandry and behavior in Introductory Biology; as sophomores they use C. elegans in a linkage project in Genetics. In an upper-level class, students apply these skills in performing novel genetic screens germane to the R1 laboratory's research agenda. Under these circumstances, the R1 investigator can pilot high-risk inquiries that could spin-off into fruitful projects for graduate students/fellows. Although we have yet to produce a cohort that has completed a full pipeline, the foundations for this model are in place. In the fall of 2015, C. elegans modules were included in Introductory Biology and in Genetics with the idea that a fully-trained cohort will emerge from the pipeline in 2017. We have also incorporated class-wide RNAi screens for candidate enhancers/suppressors of a sterility defect, into the laboratory portions of two Developmental Biology offerings (2014 and 2016; 14 and 19 students, respectively). Anecdotal remarks indicated that students were engaged and enthusiastic about their involvement in authentic research. We also learned several logistical lessons for more fluid implementation in future iterations. The results of the 2016 cohort, including responses to indirect attitudinal surveys and direct performance evaluations are pending completion of the current academic term. If these trials prove effective at supporting students' interactions with the Biology curriculum, the "Pipeline" CURE approach may prove applicable to other teaching-focused/research-based academic alliances.

E8033C Fostering critical thinking skills via analysis of primary literature. *E. Tour*, C. Abdullah, R. Lie, J. Parris. Univ California, San Diego, La Jolla, CA.

Primary literature offers rich opportunities to teach students how to "think like a scientist." Calls for increased incorporation of original scientific literature into science education have been issued by a variety of educational organizations (e.g., "Vision and Change", AAAS, 2011). We describe a Master's-level course that offers a structured analysis of four recent papers from diverse fields of biology: one flawed paper, one exemplary paper, and a pair of conflicting papers. Students who took this course self-reported a significant increase in a variety of skills associated with critical engagement with primary literature (e.g., being able to critically analyze a paper's data, independently draw conclusions, propose a follow-up experiment). However, objective measures of the same students' skills detected only an improved ability to design experiments. We will also present the first analysis, to our knowledge, of what these recent biology undergraduates perceive as the most challenging aspects of engaging with the primary literature. We analyzed 69 pairs of pre- and post-course free responses to the question: "What aspects of reading and analyzing primary literature do you find most challenging?" Thematic analysis of these data was conducted by three raters who were blind to both the identity of the students and the pre-/post- status of the response. Before instruction, the challenges that students reported centered around unfamiliar experimental techniques, background, and jargon-rich scientific language. After instruction, drawing independent conclusions and evaluating authors' conclusions became the most frequently identified challenge. In addition, after taking this course, the frequency of challenges aligned with the Higher Order Cognitive Skills (Analysis, Synthesis, Evaluation) increased significantly. Together, these changes are consistent with a more competent, critical approach to reading scientific papers. We discuss the implications of our findings to instructional programs that utilize scientific primary literature.

E8034A Compatibility between learning and examination styles – analysis of the performance of students in advanced genetic courses. *Krassimir Yankulov*. University of Guelph, Guelph, ON, CA.

Learning styles and their effect on the efficacy of education is an important topic in educational research. Consequently, there have been numerous attempts to adjust lecture styles and course offerings in a fashion that is equally compatible with students who prefer the writing/reading style and students who prefer visual learning. However, the question on how to fit examination to the preferred learning styles of students has rarely been addressed.

Here I report the learning outcomes of students who prefer a presentation assignment versus students who prefer a writing assignment. Both groups have been students in a 4th year molecular genetics course. The performance of these two cohorts has been measured by their marks in the midterm and final exams and by their engagement in class discussions. Statistical analysis of the data indicates that the writers have slightly but consistently outperformed the presenters. Considerations of teaching style variations could not explain the higher marks of the writers. These observations suggest that strong writing skills can provide a sizeable gain to the overall success at university level. However, the possibility that the writers outperform the readers because of the predominant writing exams is not excluded.

Some recent data on this issue will be provided to initiate discussion on this intriguing topic.

E8035B Student peer review: an educational and assessment tool for upper year genetic courses. *Krassimir Yankulov*. University of Guelph, Guelph, ON, CA.

Peer reviews are the generally accepted mode of quality assessment in scholarly communities, however they are rarely used for evaluation at college levels. Over a period of seven years I have performed a peer review simulation at a senior level course in molecular genetics at the University of Guelph. Briefly, I have asked groups of two authors to write research proposals on one of four topics that are announced in the beginning of the semester. On average 10-12 proposals are written each year. Specific guidelines on how to compose the proposal are given ahead of time to the whole class. These proposals are submitted to a dedicated web tool available at our university (PEAR, Peer Evaluation, Assessment and Review) and anonymously directed to the class members for a peer review. This simulation of grant submissions and review has a significant educational value and is very well accepted by the students. The actual PEAR site is designed to fully protect the identity of the authors and the reviewers and meets the highest standards of double-blind review process.

I have used the data in PEAR to analyze the metrics of this simulation exercise. I show that student peer marks are highly variable and not suitable as a precise performance evaluation tool. Subsequent analyses have shown ways to improve precision of student evaluation, but their applicability is yet to be established. Interestingly, student peer reviews can clearly recognise substandard performance, but the peers struggle to distinguish between good and excellent performance. These finding provide provocative insight on the process of peer review in general.

E8036C ***Fungal infections Aspergillossis and Cryptococcal meningitis in C H U Oran .*** *Z. B. Benmansour*. Chu University of Medecine Oran, Algeria, oran, DZ.

Objective: The invasive fungal infections in hospital is a subject of concern both for the healthcare professionals .The infection at the hospital is a major risk for the patients the invasive acts, in first row of morbidity, mortality.

Materials and methods A retrospective study was conducted from september 2013 to Mars 2015, fungal infections immunocompromised patients and the occurrence of Cryptococcus neoformans admitted with Aspergillosis was diagnosed in 23 individuals. The median age of the patients under study was39.25 years With male preponderance .(27 cases/36), neck stiffness (16/36), altered consciousness (14/36), fever (12/36) and convulsions (9/36).Cryptococcal meningitis highly contributes to mortality in HIV-infected patients. A need exists to improve strategies for clinical management of AIDS patients and systhematique Aspergillosis 430 samples from different departments .Cryptococcal meningitis in HIV-infected patients is animportant fungal pathogen in immunocompromised patients. High mortality was related to delayed diagnosis.

Results: prevalence of the meningo-encephalitis cryptococcose at the patients infected by theHIV was 0,4 %. frequency practically decreased while it was 2,09 %**Discussion**: Theevolution of the symptomatologie before hospitalization represented 1 week. disease is progressive,fever, headache,immunosuppressed patient, with a rate of CD4 lower than200 / mm3,

Conclusion: the fungal infection relegated to the last rows neuromeningeal cryptococcose Aspergillosis in systematic study.

E8037A Fellowships in Research and Science Teaching (FIRST): An integrative postdoctoral experience that generates effective researchers and educators. *Joanna Wardwell-Ozgo*[1], Teresa Lee[1], Gandhy Pierre-Louis[1], Arri Eisen[1], J. K. Haynes[2], Doug Eaton[1]. 1) Emory University School of Medicine, Atlanta, GA; 2) Morehouse College, Atlanta, GA.

The Fellowship in Research and Science Teaching (FIRST) at Emory University is a three-year postdoctoral training program designed to provide a quality foundation for successful careers in academia. Supported for 16 years by an Institutional Research and Career Development Award (IRACDA) from the NIH, FIRST combines interdisciplinary research training with instruction in teaching pedagogies, classroom technology, course development, and undergraduate mentoring. As with traditional postdoctoral positions, fellows work under the direction of research mentors at Emory University, a nationally recognized research institute. As a crucial addition, however, fellows also receive training in innovative pedagogical methods like active learning and technology-based teaching. Fellows apply these skills by teaching and mentoring students at one of three Historically Black Colleges or Universities in Atlanta: Morehouse College, Spelman College, or Clark-Atlanta University. FIRST also aims to increase the overall representation of minority scientists within the biological/biomedical sciences by maintaining a diverse population of fellows, and thus inspiring minority undergraduates to pursue the same path. In 16 years, FIRST has trained ~170 fellows. In comparison to their peers in traditional postdoctoral positions or fellowships, FIRST fellows publish at the same rate, receive comparable external funding, and importantly, are more successful at obtaining academic positions after completion of postdoctoral training. Impressively of 145 alumni, 64% are faculty at research intensive, liberal arts, or minority serving institutions. By combining teaching and research training, FIRST produces scholars who are successful, independent researchers and effective educators that will inspire the next generation of scientists.

E8038B ***Developing Future Biologists*****: a dev-bio lab course for outreach, diversity recruitment, and professional development.** *S. Barolo*[1], B. Carpenter[1,2], A. Chin[1], E. Dulka[1], M. Echevarria-Andino[1], D. Lorberbaum[1], J. Martinez-Marques[1], L. Marty Santos[1], J. Pinskey[1], S. Raj[1], B. Allen[1], L. Bricker[1], L. Gruppen[1], D. Gumucio[1], D. Wellik[1], E. Suárez-Martínez[3], A. Ramos[1]. 1) University of Michigan Medical School, Ann Arbor, MI; 2) Emory University, Atlanta, GA; 3) University of Puerto Rico, Ponce, PR.

Future advances in human health will continue to depend on basic discovery research in developmental biology, and on the recruitment of a strong and diverse pool of talented researchers to that field. *Developing Future Biologists* is a one-week intensive laboratory course developed by doctoral and postdoctoral trainees at the University of Michigan (U-M), with the advice and assistance of faculty members. The DFB course

introduces modern concepts and techniques in developmental biology to undergraduate students in underserved populations. The course, which was created by a diverse group of graduate and postdoctoral trainees, aims to recruit talented students into the field, especially those who would not otherwise be aware of the excitement of developmental biology research; to increase diversity among trainees in the field; to develop professional skills in the trainees who develop, plan, and teach the course; and to improve the climate of diversity and cultural awareness among trainees and faculty at the University of Michigan. The *DFB* course was taught in 2015 and 2016 in Ponce, Puerto Rico. Assessment of the impact of *DFB* on the students who took the course, on the Michigan trainees and faculty who desgined and taught it, and on graduate recruitment at U-M, will be discussed.

E8039C The DNA Day Network: Integrating career training and outreach into trainee development. *S. Hall*[1], L. Villafuerte[2]. 1) University of Massachusetts Medical School, Worcester, MA; 2) University of Kansas, Lawrence, KS.

Careers in science require an important understanding of effective communication that can reach far from the bench, into the voting community, and to individuals that will be the future workforce. It is recognized that the ability to progress the scientific enterprise requires strong intellectual and financial support from the community. The Massachusetts and Kansas DNA Day programs work to develop early career scientists to strengthen their communication skills beyond the doors of the research institution and to integrate outreach into their research programs throughout their careers. Ambassador training provides tools to build an understanding of how to merge basic principles of science with the ambassadors' research interests. In addition to ambassador development, a major goal of the DNA Day programs is to link high school course content with real life research applications - building bridges between students, the textbook, and the bench. During DNA Day ambassador visits, students not only hear about the relevance of the work from the ambassadors, but also engage in an activity that allows them to experience simplified techniques that are used to explore and answer research questions. We put the tools in the hands of the students in hopes that this creates a sense of ability within the students, encouraging them to envision themselves pursing a career in STEM. Additionally, as part of the DNA Day experience, ambassadors discuss their research interests and the paths they have navigated to reach their current position. This opens the floor to questions from students that allow them to better visualize themselves as part of the future STEM workforce.

E8040A The Effects of Myrrh and Rosemary Extract on Cancer Cell Lines. *Areej Alanazi*. Tennessee State University, Nashville, TN.

The National Cancer Institute defines cancer as a collection of related diseases. We know that if there are any changes in our cells' function, such as how cells grow or divide, these changes include mutations in the deoxyribonucleic acid (DNA). From this point, a body's cell will divide without stopping, and it will be an abnormal cell that will produce a tumor. This study has tested the hypothesis that myrrh and rosemary have compounds that will inhibit the growth of cancer cells. In this experiment, four different types of cancer cells— which are lung cancer (A549), colon cancer (SW620), breast cancer (MCF7), and cervical cancer (HeLa)—were exposed to myrrh and rosemary extractions. The alamarBlue Cell Viability assay protocol and fluorescent analysis were used to evaluate the cytoxicity of the extracts. The findings indicate that the more we have a concentration of myrrh extraction, the more we get the inhibition of lung cancer cell growth. Also, rosemary appears to inhibit cervical cancer (HeLa).

E8041B The Effects of *Lepidium sativum* on Four Tumor Cell Lines. *Afnan Felimban*. Tennessee State University, Nashville, TN.

Cancer is considered as multiple diseases generally because there is not a single treatment for all disease forms. It is important to develop mechanisms to treat cancer that will not harm normal cells and possibly inhibit the reoccurrence of the disease. Natural compounds have been a valuable source for the treatment of human diseases. We are currently studying a medicinal plant to determine its effect on tumor cell lines. The plant is *Lepidium sativum*. Methanol extractions from the seeds of this plant produced the secondary compounds use to analyze cell growth. We used AlamarBlue® to measure cell viability. The cancer cell lines testing are breast cancer (BT549), lung cancer (A549), breast cancer (MCF7) and cervical cancer (HeLa). Our analysis shows a significant inhibition of the cancer cells growth after exposure for 24 hour. These results indicate that *Lepidium sativum* should be studied more to determine its effect on tumor cells.

E8042C Alterations induced in ovarian follicular kinetics of adult zebrafish on long term exposure to environmental estrogenic contaminants. *B. B. Goundadkar*, P. A. Katti. Karnatak University, Dharwad, Karnataka, IN.

The aquatic environment is the ultimate destiny for chemical contaminants of anthropogenic origin. Present study is an attempt to assess the alterations induced in the ovarian follicular composition of adult female zebrafish (*Danio rerio*) exposed to environmental estrogenic contaminants (EECs) at a concentration lower than environmental recorded levels for long-term (80 days) in the laboratory. Adult zebrafish (n=20) were maintained in a medium containing environmental estrogens such as, 17α-ethynil estradiol (EE2) (5 ng/L and 10ng/L) or diethylstilbestrol (DES) (5 ng/L and 10ng/L) or bisphenol (BPA) (5 ng/L and 10ng/L). Corresponding negative controls were maintained for comparison. On the 81st day the fish were sacrificed, body and ovarian weights were recorded and ovaries were processed for histology, sections of 3 µm thick were cut and stained with hematoxylin and eosin. All the follicles were counted and quantified from alternative serial sections. Growing follicles were classified into 6 stages based on their functional status and size. Atretic follicles were counted separately. The results reveal that exposure of female fish to estrogenic compounds even at a very low dose for long-term leads to increased body weights and size, with an increase ($P<0.05$) in the gonadosomatic index (GSI). There was a significant decrease in the number of previtellogenic follicles in all EEC exposed groups. Vitellogenic follicle number was greater in EE2 group compared to other EEC exposed groups, while atretic follicles were relatively greater in DES and BPA groups. It is suggested that long-term exposure to EEC even at lower concentrations alters follicular composition of adult zebrafish ovary.

The letter preceding the number is the community. A, B, C after the number is presentation time.

E8043A Genetic modifiers compensating for loss of epidermal growth factor receptor. *S. Howe*, D. Threadgill. Texas A&M Health Science Center, College Station, TX.

Genetic compensation usually occurs when polymorphic modifier genes provide robust compensation for the loss of a gene of interest. The epidermal growth factor receptor (EGFR) is a critical gene for early development. Its disruption can cause abnormal embryonic and placental development, and it is implicated in tumorigenesis. Mouse embryos lacking *Egfr* have reduced proliferation in trophoblast stem cell lineages that form the spongiotrophoblast layer of the placenta. Depending on severity, this can impact the labyrinth layer, the size of the placenta, and the timing and frequency of embryonic lethality. These placental phenotypes are strongly dependent on genetic background, indicating the presence of *Egfr* modifier genes. We crossed the ALR/LtJ mouse strain, a robust survivor with *Egfr* loss, to the 129S1/SvImJ, which have a mid-gestation lethality phenotype due to placental dysfunction, to show that hybrid ALR.129 *Egfr*-null embryos survive into late gestation. Using a phenotypic congenic approach, we generated evidence suggesting the presence of three dominant loci. We are using a reverse genetics approach to identify the *Egfr* modifiers by investigating dysfunction of known trophoblast stem (TS) cell lineage pathways. We utilized 129S1 and ALR mice that are homozygous for a conditional *Egfr* allele ($Egfr^{tm1.1Dwt}$) to generate TS cells. The introduction of Cre recombinase into TS cells by electroporation induces recombination at the loxP sites deleting *Egfr*, which provides genetically matched TS cell lines with and without EGFR. We are using these cell lines to elucidate candidate *Egfr* modifier genes capable of compensating for loss of EGFR. The findings will aid in the identification of modifier genes of *Egfr* that may influence the severity of conditions related to malformed placentas, such as intrauterine growth restriction, and may impact the effectiveness of EGFR-targeted cancer chemotherapies.

E8044B Nutritional Regulation of Oogonial Proliferation and Differentiation into Primary Oocytes in the Adult Ovary of Zebrafish (*Danio rerio*). *P. A. Katti*, P. A. Deshpande, S. S. Narvekar, M. S. Kanetkar. Karnatak University, Dharwad, Karnataka, IN.

Nutritional stress is known to block stem cell multiplication and cause delay germ cell divisions. In the present study nutritional regulation of oogonial proliferation and differentiation into primary oocytes was studied in zebrafish (*Danio rerio*) by subjecting adult fish to different feeding regimes. Adult female zebrafish (wild) after acclimatization to the laboratory (temperature: 26 ± 1°C and photoperiod: 11.30L: 12.30D) for one week, were divided into five groups and maintained under different feeding regimes. Group-I daily four times fed; Group-II daily twice fed; Group-III daily once fed; Group-IV every alternate day fed and Group-V every fourth day fed. The experiment lasted for two months; all experimental fish were fed on commercial pellets and *Artemia nauplii ad libitum*. At the end of experiment, body mass and body size of each fish were recorded, ovaries were excised, weighed and processed for histology. Serial sections (3µm thick) were cut and stained with hematoxylin and eosin. Oogonia, primary oocytes, vitellogenic oocytes and atretic follicles were quantified from serial histological sections. Our observations reveal that there was an increase in body mass, ovary mass, number of oogonia and primary oocytes in daily four times, daily twice and daily once fed fish over initial controls. While they remained comparable to initial controls in alternate day fed fish, and were significantly lower in every fourth day fed fish. These results indirectly suggest that overfeeding increased body mass of fish without causing a corresponding increase in body size, oogonial population and their rate of proliferation while, underfeeding depleted oogonial number. It is concluded that nutrition regulates germ cell mitosis optimally in zebrafish ovary, overfeeding may not increase rate of proliferation linear but under feeding curtails it.

E8045C Effect of heat stress on condesin II levels and localization. *V. Rana*, H. Nguyen, G. Bosco. Dartmouth College, Hanover, NH.

In interphase, the genome is known to organize into topologically associated domains (TADs) of transcriptionally active and inactive gene clusters. Gene expression during this phase is dynamic and chromatin must reflect structural organization but maintain a level of plasticity in order to respond to different stimuli through gene expression changes. Stimuli like stressors can globally change the chromatin landscape in very short time scales. One such stressor is heat stress which can lead to reorganization of topologically associated domains in cultured insect cells. Interestingly, heat shock results in an increase of chromatin bound structural proteins and changes in TAD arrangements. However CAP-H2, a subunit of condensin II and regulator of genomic topology, levels are reduced on chromatin after heat shock. This contradictory result presents many questions such as what the role of CAP-H2 and therefore condensin II is during heat shock and what the fate of CAP-H2 is during this time. Investigation into the turnover of CAP-H2 using cell fractionation and western blots revealed that CAP-H2 is degraded after release from chromatin due to heat stress. Recovery after heat stress does not require CAP-H2 as knockdown with RNAi does not indicate significant levels of cell death compared to the control. Despite these results many questions still remain such as what the role CAP-H2 in re-establishing or restructuring of chromatin is during recovery? We hypothesize that condensin II may prevent long range interactions necessary during heat shock and facilitate short range interactions as cells recover.

E8046A Effect of genetic variations on various post translational modifications (PTMs) and its role in protein regulation. *M. Saleem*[1], Rabia Arif[1], Siu Lee[2]. 1) University of the Punjab, New Campus, Lahore, Punjab, PK; 2) University of Melbourne, Australia.

High resolution melting analysis together with Real time PCR was tested for quick identifications of cellobiohydrolase I (cbhI), Ketosynthase, beta tubulin and two ribosomal proteins (RpS29 and RpS26) in eight strains of *Sordaria fimicola* (S1, S2, S3, N5, N6, N7, SW17.2 and SW92.1). HRM analysis successfully reported these (RpS29 and RpS26) genes in *Sordaria fimicola first time*. All strains of *Sordaria fimicola* were authenticated by targeting ITS2 region. Above mentioned proteins were targeted to predict three dimensional structures based on various post translational modifications (PTMs). Post translational modifications are very important to understand the regulatory mechanisms of cytoplasmic and nuclear proteins. Different post translational modifications (PTMs) such as phosphorylation, glycosylation, acetylation, and methylation control the structure, function regulation of proteins. In this work the role of different modifications and their interplay, is investigated by using various bio-informatics tools.

E8047B Acute heat shock leads to loss of polarity in *C. elegans* embryos. *D. Singh*, C. Pohl. Institute of Biochemistry II, Goethe University, Frankfurt am Main, DE.

Cortical flows are indispensable for *C. elegans* development. Anterioposterior (A/P)[1], dorsoventral (D/V)[2] and left-right[3] asymmetries rely on differential regulation of cortical actomyosin. Our work has shown how a previously un-described rotational cortical flow polarized orthogonal to the A/P axis repositions the cytokinesis midbody remnant (MB^r) onto the future ventral side of an otherwise D/V symmetric embryo. The MB^r acts as a polarizing cue by serving as a cortical landmark for F-actin accumulation. Upon subjecting the embryos to a transient heat shock we found that the cortical flows are severely diminished[4]. Acute heat shock abolishes cortical flows leading to loss of all other discernable signs of A/P and D/V polarity. Hallmarks of cell polarity in *C. elegans* include mutually exclusive polarity domains and asymmetric cell division; both these processes fail in heat stressed embryos. We observed mass internalization of cortical domains loaded with polarity markers (PAR-2/6), indicating that lack of cortical domain recycling leads to polarity loss. Taken together, our work reveals heat-labile aspects of actomyosin regulation, asymmetric cell division and polarity.
